FOREWORD

Agriculture production increased significantly in the second half of the past century as a result of intensification through increasing external inputs first of all energy and agrochemicals per unit of land. To meet the challenges of increasing food demand, ways should be found to improve the productivity, profitability and sustainability of the agricultural and forestry systems.

Industrial agricultural system has led to irretrievably changes in the landscape diversity, soil quality, environment integrity, and natural resource base. This has resulted in major questions world-wide in relation to the sustainability of agricultural production systems. At the field level, the optimization of resource use efficiency is a key to issue to achive the different goals with respect to food supply, income and protection of the environment.

The most significant damage to natural ecosystems and the environment as a whole is caused by habitat conversion and corresponding climate change, loss of biodiversity and ecosystem functions, soil erosion and degradation, and pollution from fertilizers and pesticides.

Concepts in plant protection have changed in past decades from exclusion or destruction of pest to pest management. Serious problems with pesticides, rapid development of pest resistance, environmental effects of pesticides, and high costs led to the development of new approaches and techniques in pest management based on improved knowledge of pest dynamics and their natural enemies, and the interaction between the pest and the crop.

Many of the papers included in the present Proceedings identify a number of approaches and market-based inventives that would encourage producers to achieve entirely new levels of performance, and as a result raise the awareness of governments, and other stakeholders in the agro-food system. Some governments, too are experimenting very innovative approaches to support or encourage sustainable agriculture. One of the goals of the sustainable agriculture movement is to create farming systems that mitigate or eliminate environmental harms associated with industrial agriculture. That aim can be realized only with adapted agricultural practices to the different agro-ecological conditions (cf. different regional characteristics, soil types, adapted cultivars for low-input or organic production). For our conditions it is important for the conservation of the ecological environment to develop organic production.

The result reported here will be also significant in the dissemination of knowledge to the wider audience about the importance of agriculture and food science, one of the most important strategic scientific areas of the European and many national research strategies.

The 6th International Scientific Agriculture Symposium “Agrosym 2015” made an important contribution to the agriculture practice in different areas. During the four-day symposium (15-18 October 2015), approximately 750 papers were presented to more than 800 participants representing more than 70 countries.

The symposium was made possible through the commitment and contributions of a wide range of partners and cosponsors. We were encouraged by symposium success.

This publication comprises an edited selection of the many papers submitted to the symposium.

It remains only for me to thank all those who have helped to make this Symposium such a great success.

Much appreciation is due to the authors and reviewers of all papers submitted and presented at the symposium, as well as to all symposium participants whose ideas and contributions ensured rich and lively discussion during the various sessions.

East Sarajevo, 03. October 2014.

TOWARDS A NEW PARADIGM OF INNOVATION IN THE BIOECONOMY

John M. BRYDEN

Research Professor, NIBIO Grounded Innovation Group, Norway
Emeritus Professor, University of Aberdeen, Scotland
*Corresponding author: john.bryden@nilf.no

Introduction and outline

We live in troubled times. Inequalities in income and wealth are growing nearly everywhere nationally and transnationally (Picketty, 2014; Varoufakis *et al*, 2014), as are migration and refugee streams resulting from failures of political, social and economic systems and the collapse of the climate regulation system. The neoliberal hegemony has so far triumphed, and private capital is penetrating formerly public spheres, and generating further inequalities. However, the system is 'broke', and it is up to the intellectual community to join with civil and political society in the search for alternatives. If both the extremes of soviet communism and neo-liberal finance capitalism are dead, we must search for a range of 'third way' solutions in which the Nordic model has something to offer (Bryden *et al*, 2015). Without important changes, the world will become less, and not more, sustainable. We, as social and indeed natural, scientists can no longer afford to adopt the fiction of objectivity and avoid normative questions, as Weber famously advised us to do; we need to address the norms and values that underpin our work (Bryden and Gezelius, 2014).

An increasing number of scholars believe that innovation, innovations systems, and innovation policies and practices are adding to these problems rather than solving them (STEPS, 2010). This is a huge challenge for the innovation community in general, and to innovation scholars in particular.

In this paper I suggest that a new paradigm of innovation is needed if these concerns are to be addressed, especially perhaps in relation to the bioeconomy, but also in other fields. I further suggest that the new paradigm is reflected in some key examples of locally generated and initiated innovation systems in rural regions. The order of the discussion, and questions raised, are as follows:-

- What is the bioeconomy and what are its special characteristics
- What is innovation?
- Who is innovation for?
  - The '3 Ds' – Direction, Distribution and Diversity
  - The TBL – Economic, Social and Environmental
  - The HRB-TBL – Human Rights governed TBL
- Why we need a new paradigm?
- Can we see signs of the new paradigm in the 'real world'?
- How can we stimulate and shape the new paradigm through praxis and policy?
- Concluding remarks

The Bioeconomy

Our focus here is on the bioeconomy because the wider bioeconomy has a number of important particularities, notably

- It is a source of basic needs for all humanity – especially food, water, shelter;
- It is associated with many public and quasi public goods, notably climate regulation, landscapes, biodiversity;

- It is closely linked to a number of important human rights, notably the rights to an adequate diet, clean water, and perhaps in future energy;
- Bioeconomy is part of the transition to a low carbon economy, involving the replacement of fossil-based fuels, plastics, building materials, pharmaceuticals etc.
- One of the key natural resources on which it is based – land – is limited in supply (cannot be easily added to) and variable in quality, as well as being closely linked to important social systems of ownership and use rights.

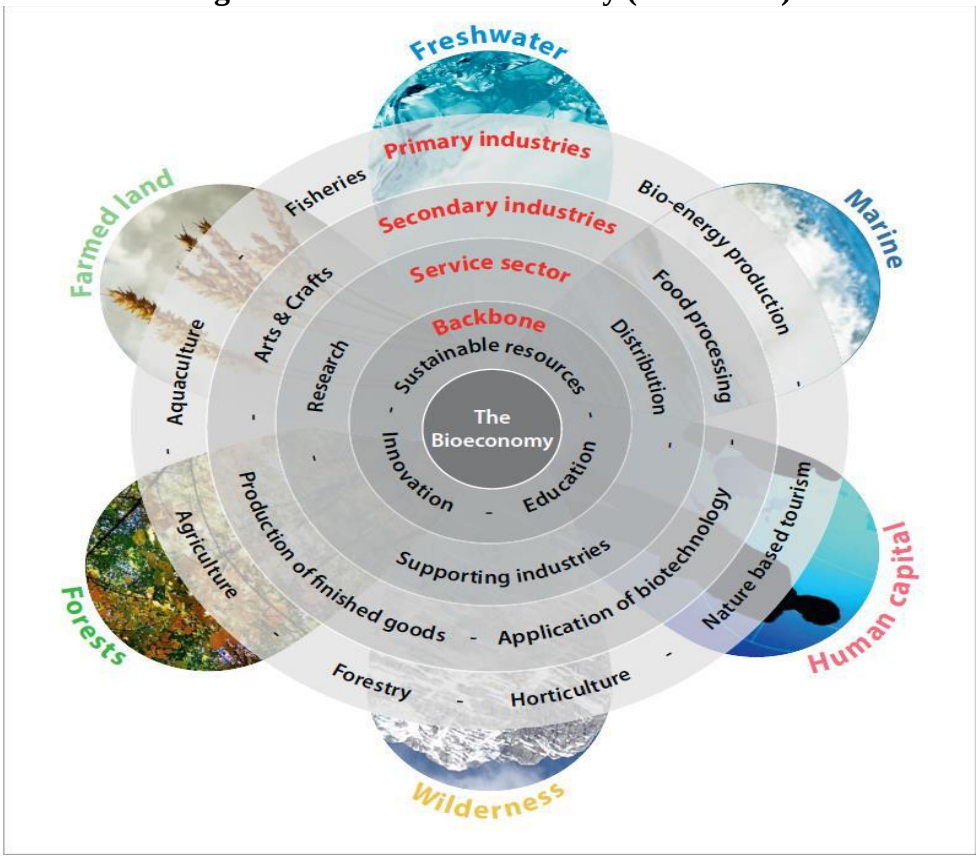
In NIBIOs grounded and inclusive innovation research group[1], we define the bio-economy widely, to include, in principle, all the living natural resources of land, air and sea that are transformed into useful commodities or public goods and services (including 'ecosystem services'), together with their related upstream and downstream industries. Agriculture and its related upstream and downstream sectors, the main focus of this conference, all lies within the bioeconomy. As social scientists, out key interest lies in human behaviour and decisions relating to this bioeconomy, and especially concerning changes defined as 'innovation', and related institutions, policies and governance, and in conflicts of use. These conflicts are important, since the biomass has alternative uses with different social and market values. One way to deal with such conflicts – for example between energy and food – is to adopt what is called the 'cascading' principle, which means taking the highest value uses first and using waste or residues for the lowest value uses. Here social scientists must help decision-makers and citizens penetrate the term 'value', and the determinants of value when market price is taken as a surrogate for 'value'.
The broad definition of the bioeconomy we adopt is reflected in the mostly recent bioeconomy strategies of a range of countries, the EU, and also recent documents of the OECD. The following diagrams illustrate the cases of Finland (mainly forest-based bioeconomy) and Iceland (mainly marine-based bioeconomy).

Figure 1: The Finnish Bioeconomy Strategy

"Bioeconomy refers to an economy that relies on renewable natural resources to produce food, energy, products and services. The bioeconomy will reduce our dependence on fossil natural resources, prevent biodiversity loss and create new economic growth and jobs in line with the principles of sustainable development."

[1] At one time called NILFs 'Green Innovation' Group. See http://www.nilf.no/green_innovation_research/
NILF joined Bioforsk and Skog og Landskapp Institutes to form the Norwegian Institute for Bioeconomy Research (NIBIO) in July 2015. The websites are not yet harmonized.

Figure 2: Icelandic Bioeconomy (Matis Ltd.)



Our main focus in this paper is the land-based bioeconomy, but in our view the new paradigm for innovation is probably one that is universally desirable in all fields.

Innovation

We must think of *innovation* broadly – not only *technological* innovation, and also not as equivalent to *invention*. Of course invention and technology are important, but if indeed the system is ‘broke’, then we desperately need institutional and policy innovations. It is not innovation or invention *per se* that produce unsustainable outcomes, but human behaviour and the institutional and governance systems that guide it (Bryden, 1994). Moreover, the problems of complexity, implicit in the goals of sustainable development, which cut across disciplinary boundaries, also demand multiple solutions and adaptations to different needs and contexts[2]. This is especially so in the bioeconomy based on natural resources, where multiple natural conditions determine the production possibilities, productivities, and interactions with society and environment. One size does not – and cannot – fit all needs and circumstances.

Innovation is different from *invention*. In particular, Innovation typically involves *adaptation* of existing techniques or institutions to local (economic, social, cultural, geographical, physical, ecological) conditions, needs, etc. While we generally, but not always correctly, think of *invention* as the solitary work of a scientist , craftsman or entrepreneur, innovation is commonly a collective process involving a range of actors in ‘doing using and interacting’ (‘DUI’). Interaction typically takes place between public institutions, universities or research instituted, raw material suppliers, craftsmen and enterprises transforming raw materials, and final users of the goods and services produced. Research has demonstrated that innovations typically involve two key modes working together, namely science, technology and

[2] Delvalle(2015) cites Ashby’s (1956) Law of Requisite Variety in his discussion of the governance problems around complex issues.

innovation ('STI') and DUI (Jensen et al, 2007). Here the growing focus of research has been on 'innovation systems', first at national level (Lundvall, Freeman, Nelson, Fagerborg among others), but later at regional and local levels (Edquist, Cooke et al, and others). The innovation systems research focused on the nature and process of *collective learning* and *forms of knowledge*. Within that, the regional and local innovation systems research focuses on the *embedding* of innovation systems within specific regional and local contexts. Our main focus in this paper is on *local* innovation systems, and especially 'grass roots', 'inclusive' and 'participatory' innovation in its various forms.

We further argue that such local innovation systems are 'social' in the sense that they are collective learning systems. Later we add the further notion that they are also 'social' in at least some of their key objectives. They are also dynamic, in the sense of all learning systems – the various conditions under which they are functioning alter through time, and they in turn have new issues and questions to solve; feedbacks from initial changes also cause internal adjustments and innovations. Innovation thus needs to be seen as an on-going process, rather than a one-off occurrence.

Innovation and sustainability

The STEPs[3] manifesto (STEP 2010), the work of the collaboration of scholars from many countries, argued that radical changes in the policy and institutional framework were needed if the problems of sustainable development were to be tackled. Specifically we needed to address the problems of the Direction and Diversity of Innovation, and the Distribution of the benefits arising from it – the so-called Three D's. This is closely related to the notion of the '3 Ps' – People Planet and Profit – and to that of the 'Triple Bottom Line' or TBL (Elkington, 1997). However, as Bryden & Gezelius (2014) argue, the 3D's contain an ethical imperative, whilst the TBL is based on consequentialist ethics. Ethical issues are very important in the bioeconomy, for several reasons, but especially because many basic needs are goods and services from the bioeconomy, or closely linked to it, notably food, water, housing and energy. Moreover, food and water are codified in Human Rights legislation. This issue is further discussed below.

The growing concern about the link between innovation and processes of social inequality and all levels is indicated by the international network of scholars within the Globelics group, who study innovation systems. Globelics recently held an international conference on Innovation and Inclusion in Cuba (September 2015). The high level of submissions from all parts of the world indicates the strong degree of interest in the issue of whether innovation policies and institutions, as well as innovation systems, can help to address the problems of social inequalities, whatever their source.

There has also been a growing interest in innovation and innovation systems within the EU. The SCAR committee report (2012) emphasised the role of innovation platforms[4], as did the discussion of European Innovation Partnerships in Innovation Europe. This was followed by the current R&D programme H2020, which has a large focus on innovation including social innovation, and which was certainly influenced by the SCAR report. In one sense innovation platforms can be seen as social innovations, because they explicitly recognise the importance of social processes of collaboration and learning in creating (product and process) innovation.

[3] STEPS Centre at Sussex University, a collaboration between SPRU (Science Policy Research Unit) and IDS (Institute of Development Studies) supported by the UK Economic and Social Research Council.

[4] Innovation platforms are not a new idea – Roling and Jiggins (1994) worked on them, drawing on the soft systems work of Checkland (1981) and Checkland & Scholes (1991), discussed in Bryden 1994. However, what is new is the debate on the impacts and objectives of innovation stimulated by the STEPS *New Manifesto* in 2010 and subsequent work in this area.

However, since social innovation is most usually treated as a sub-category of innovation, and one that is mainly concerned with the delivery of social services[5], we prefer to address the general innovation discourse in this paper.
Given this background, there are three further questions we want to address in this paper. Firstly, why do we need a new paradigm? Secondly, what would the new paradigm look like in practice, given our revised norms? Thirdly, can we observe instances of innovation systems that illustrate the new paradigm in practice?

Why we need a new paradigm?
A set of more or less tacit normative value premises underpins most of today's innovation discourse, and is taken for granted by policy makers (Bryden & Gezelius, 2013, 2014, 2015; Bryden et al, 2015). It is also, for the most part, silently and uncritically adopted by scholars. In particular, a widely adopted premise is that a key purpose of innovation is to *promote economic growth and to increase the international competitiveness of national industries*. Founding on this premise, it is the ability to promote growth and competitiveness that makes innovation a 'good thing' and that justifies public funding of innovation related research and development. The evidence base is thus influenced, even determined, by these tacit norms and values: this consists, mainly, of numbers on public and private expenditure on research & development, and the numbers of patents filed, as measures of input and output respectively. This is what represents the 'old paradigm' because it focuses on only one of several sources of knowledge needed for the processes of co-learning that are implicit in most innovation systems.
But suppose we challenge and replace these norms with others? In particular, norms based on premises about sustainable development and human rights?
STEPs' *New Manifesto* emphasises that development and innovation should pursue poverty reduction, social justice, and environmental sustainability.
To achieve this, innovation should be driven by those in the greatest need of it. Consequently, innovation should be driven from the bottom-up, rather than by politicians and scientists who promote ready-made solutions that disregard local needs and contexts. Innovation processes should thus include, especially, poor and underprivileged groups. Their guiding '3 Ds' are about the *Direction* of Innovation and its link to the *Distribution* of income and wealth, and to *Diversity* of solutions to practical problems.

- **Direction** – what direction will this or that type of innovation take us? Some pathways – like highly specialised, capital-intensive, centralised, large-scale and long lead-time nuclear infrastructures – can 'crowd out' alternatives. Where should innovation resources be focused?
- **Distribution** – what will be the impacts on distribution of income and wealth? Will the innovation help the poor? How? Many scholars of development do not accept the hypothesis that this question does 'not matter' because wealth will 'trickle down' no matter where it is created, since the hypothesis is contradicted by the evidence and has no robust theoretical underpinning in any case.
- **Diversity** – diversity is a strength (not to put 'all eggs in the same basket'; letting 'a thousand flowers bloom').

Triple bottom line (TBL) accounting is a principle for business ethics developed largely within a rich country context (Elkington, 1997). Its basic idea is that business results should

[5] Much of the discourse relates to the so-called 'social economy', in which much of the activity concerns delivery of social services that were formerly delivered by public – often local – authorities within the framework of the welfare state. This focus is however too narrow for our purposes.

be measured not only in terms of profit, but also in terms of social consequences and environmental effects. It is very similar – even analagous - to the idea of PPP, or 'people, planet, and profit', widely adopted by environmental interests, for example.
Despite obvious similarities, the New Manifesto and the Triple Bottom Line build on different ethical foundations. The STEPS manifesto brings in a strong element of duty ethics, focusing on social justice and addressing human rights such as the poverty issue. Triple bottom line thinking is fundamentally consequentialistic because of its focus on the measurement of outcomes. Social justice is by nature an *obligatory* normative standard. Human rights are even more so; *they are not something that can be traded off against other benefits.*

To conclude this section, we need a new paradigm of innovation to

- change the *objectives of innovation*
  - three Ds + TBL = HRB-TBL
  - "innovation as if people mattered"
  - "inclusive innovation"
- change *innovation praxis*
  - from STI to STI plus DUI
  - from top-down to bottom-up
  - from exclusion to inclusion
- change *innovation policies*
  - from science-led to actor-led
  - from property rights to common property
  - from private interest to public interest

What should the New Paradigm look like?
At this stage we can briefly contrast the 'old' and the 'new' paradigms. The 'old paradigm' of innovation is primarily characterised as innovation serving the private sector in its quest for international competitiveness through improvements in the productivity of labour and capital. State support for innovation has become almost wholly captured by this normative and largely tacit objective, which is nowadays barely discussed. In contrast with Polanyi's notion of the market being 'within' the State, the State is now within the market, a very powerful belief in western market economies, especially the 'anglo-saxon' and lately neo-liberal countries of the UK, the US, Canada and Australia. The State is seen as 'subservient' to capital, serving its needs, rather than protecting citizens from the impacts of capitalism, for example on inequalities and the environment. Capital is in fact directing the focus of R&D through its close relationship with national and transnational policies, and firms and individual entrepreneurs and 'innovators' are seen as the main actors and policy targets. The main and often the only indicators used to measure the 'strength' of innovation, or the rank order of states, are the number of patents registered and the expenditure on research and development. The outcomes may be evaluated by growth in productivity or GDP.
The 'new paradigm' stands in stark contrast to this. Based on the previous, normative, analysis, we argue that innovation should serve citizens, and the State's activities and policies in relation to innovation should be based on the needs and priorities of citizens as expressed through civil and political society. The market, and market actors, are of course part of that civil and political society, but we follow Polanyi (1944) in arguing that the market is within the State, rather than *vice-versa*. Innovation is thus driven by societal problems and priorities – especially 'sustainable development'. To summarise, the New Innovation Paradigm involves:

1. the state serving citizens; the market is within and not above the state;

2. the objectives are first and foremost *social; they are concerned with human wellbeing and the natural environment that sustains it; where these are codified in human rights they give priority to these;*
3. research and innovation as a *multi-actor collective learning process* which is *inclusive* in the sense that it includes all those with an interest in the outcomes, including those normally excluded from such processes. This is wider than the notion of 'including users' where 'users' are considered as 'customers';
4. innovation policies target and encourage multi-actor innovation platforms that are inclusive, we call these 'Grounded Innovation Platforms' or 'GRIPs' (Bryden et al, 2013; Bryden and Gezelius, 2014; Bryden et al 2015)
5. the outcomes of innovation are assessed by TBL and Human Rights impacts.

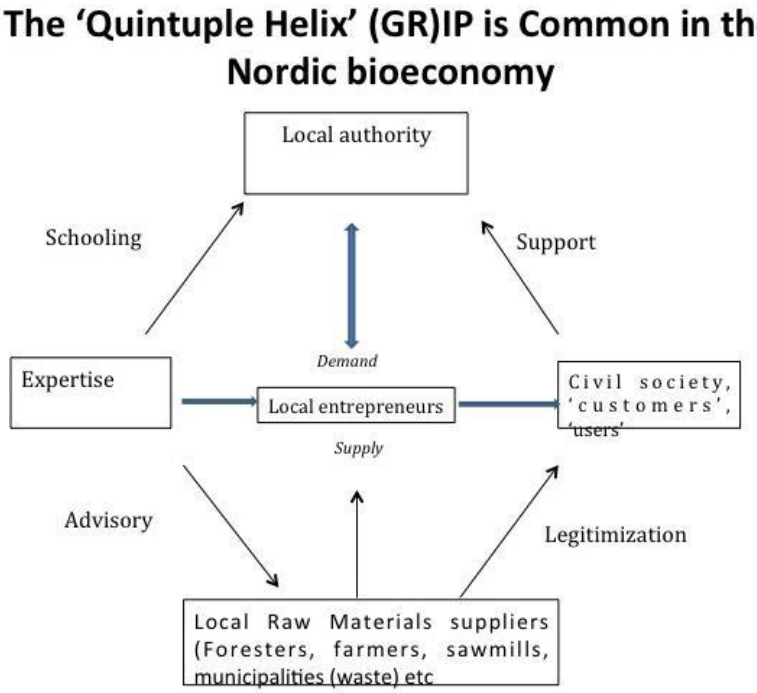
Can we see signs of the 'new paradigm' in the 'real world'?

Sheik (2015) discusses 'grass roots' innovation in Indian 'informal' sector. He cites Gupta's (1999) attempt to conceptualise grassroots innovations in India, in which he "maintains that technological solutions at the grassroots level seem to be more environmentally sustainable, local in nature, developed through bottom up approach and suited to the local communities". In his paper, Sheik focuses on two Indian institutions focused on the poor, and on action research at the grass roots level involving the 'blending' of formal and informal knowledge systems. These are the National Innovation Foundation (NIF) and Barefoot College (BC). NIF, in collaboration with Shodyatras and its volunteers at Honey Bee Network "claims to have build up a database of more than 200,000 ideas, innovations and traditional knowledge practices from over 555 districts of India

To us the GRIP is one concrete expression of the New Paradigm in action in the Nordic context, but there are many terms for the same kind of structure. A GRIP is firstly an innovation platform in the sense that it is a grouping of actors who come together because they have a shared goal of changing something together. The object can be technology, but it can also be a policy or a practice going beyond technology. It is a means of collective learning by those whose lives are most directly affected by the outcomes, and so it is a 'participatory' or 'bottom up' process. It also builds on the existing experience, knowledge and evaluations of the actors. It may or may not be inclusive, and it may or may not have HR-TBL outcomes – neither can be assumed, and both are empirical questions[6]. But we follow Gupta in hypothesising that such new paradigm institutional forms are likely to be more inclusive and more likely to have HR-TBL outcomes than those of the old paradigm.

Our own research in the TRIBORN project can be used to illustrate GRIP like structures. In it we have identified a form of 'quintuple helix' structure active in the bioeconomy at local levels in Norway, Sweden and Finland. That is to say there are five distinct types of actor involved, notably the suppliers of raw materials (typically foresters or farmers, but also sawmills, food processors and other sources of 'waste' biomass materials); the firms that transform those materials into energy (district heating, electricity, biofuels, biogas, pharmaceuticals, bioplastics and chemicals etc); the local authorities that create local regulations and so engage in 'market-making' as well as being 'responsible' to their electorate and therefore concerned with legitimacy, fairness and other ethical and moral questions as well as local development and employment issues; one or more sources of formal knowledge, in some cases universities and research institutes, in others knowledge intermediaries such as extension agents, consultants, etc. ; and finally, the citizens either as 'customers' or through their civil society organisations. The following diagram illustrates such structures:-

[6] Research has shown that such 'bottom up' structures can be 'captured' by elites, for example.



There are also many examples of similar structures from around the world. Some are documented in the background work for the New Manifesto. Others are discussed by Fressoli *et al* (2014), and Sheik (2015) mentioned earlier. Alfredo del Valle from Valparaiso in Chile recently discussed a paper called : "Building a rural future in Valporaiso, Chile via Participatory Innovation. Methodical governance of complexity as a seed for post-neoliberal policy" in which he discusses the structure of this new governance system. Since the local governance system he describes incorporates government, the productive sector, business-associations, the knowledge sector and NGOs, we can think of it as a form of GRIP. The local action groups of the EU LEADER programme had similarities to a GRIP in its earlier manifestations prior to 'mainstreaming' (Bryden, 2011). In more general terms, the move to more 'inclusive' innovation in terms both of its objectives and its institutions is an on-going topic of discussion and research within the GLOBELICS group, thanks to the work of young scholars like Judith Sutz, Gaby Bortz, Mariano Fressoli, and Susan Cozzens, to name but a few.

To some extent at least, the European Innovation Partnerships (2010), elaborated for agriculture in the EU report of the Standing Committee on Agricultural Research (SCAR) 2012, opened a door to the new paradigm, even if the arguments were somewhat different (if also relevant). The EIPs and the SCAR report undoubtedly influenced the thinking behind Horizon 2020. However, the focus of the EU has mainly been in EU competitiveness and technology development, and our arguments and proposals go far beyond these issues.

Conclusions

1. *The world needs a New Paradigm of Innovation (NPI)*
    a. To address growing global problems of inequalities and exclusion, climate change and its impacts
    b. To shift the normative goals of innovation and innovation policy
2. *There are many examples of institutions from different parts of the world that appear to illustrate the New Paradigm, and policies moving towards their support*. At the moment, though, they are a form of experiment

   a. We need to study them carefully, and learn from processes and outcomes
      i. How do GRIPs form, how do they learn and adapt, are they temporary or long-lasting?
      ii. What kind of formal or informal governance and/ or organizational structures do they have, and how do these influence things like learning processes, longevity, and outcomes?
      iii. What are their objectives and are these concerned with HR-TBL outcomes?
      iv. Do innovations through GRIPs produce HR-TBL outcomes?
3. *Such experiments give us grounds for hope in the quest for more sustainable human development.*

We will be continuing to work on these issues in future both in relation to the bioeconomy, and beyond it, and hope that others will join in this endeavour in their own fields. We will also work with policy makers at all levels to find new ideas about how GRIP-like structures can be fostered without becoming controlled and inhibited by the bureaucracy and technocracy that kills so many creative ideas and structures. What is sure is that public policies towards the stimulation of innovation need to change if innovation is to contribute fully and adequately to social, environmental and economic goals of sustainability and to human rights.

Abstract

In 2015 world is commemorating 150 years since Gregor Mendel presented his lectures Experiments in Plant Hybridization (*Versuche über Plflanzen-hybriden*), on the 8th of February and March 1865. He presented, for the first time, the results of his research into breeding peas and other plants that he had been performing for a number of years in the gardens of the Augustinian monastery in Old Brno at a meeting of the Natural Science Society in Brno (*Verhandlungen des naturforschenden Vereines in Brünn*).

Using the garden as a genetics laboratory, Gregor Mendel could manipulate and select for certain traits to formulate and test out his hypotheses about mechanisms of inheritance and distribution of traits in offspring. In order to trace the transmission of traits, he chose seven pea traits that were expressed in a distinctive manner, such as plant height (short or tall), seed color (green or yellow), etc. The F_1 of crossing varieties that differed in one trait- for instance tall x short, displayed the trait of one variety but not that of the other. He observed that the plant height was a trait that was passed on to progeny independently from other traits. In Mendel's terms, one character was dominant and the other recessive. The recessive character reappeared in F_2, and the proportion of offspring bearing the dominant to offspring bearing the recessive was very close to a 3 to 1 ratio.

After seven years of research and analyses of thousands pea plants, Mendel′s observational talent and mathematics knowledge were base for the defining of three principles, often known as Mendel's principles of heredity- Law of dominance, Law of segregation and Law of independent assortment, which are the essential for the Mendelian genetics and heredity. Remarkably, Mendel described elements of DNA-based inheritance in the absence of any knowledge of the molecular biology behind it. His important contributions to the field of genetics continue to influence modern scientists and every geneticist or genetics student has heard his name.

Although initially well-received, Mendel's work was not given proper appreciation during his lifetime, even after it was published in 1866. In fact, over the next 35 years, this paper was only cited three times. The genetics became more important at the beginning of the 20th century when three different research groups (Dutch botanist and geneticist Hugo de Vries, German botanist and geneticist Carl Erich Correns, and Austrian botanist Erich von Tschermak with their co-workers) independently re-discovered Mendel's Laws. Biologist William Bateson became the strong supporter of Mendel's theory and later zoologist and geneticist Thomas Hunt Morgan located the genes on the chromosomes. As the architect of genetic experimental and statistical analysis, Mendel remains the acknowledged father of genetics.

Key words: *Gregor Mendel, genetics, inheritance, dominant, recessive.*

Introduction

Since the beginning of human history, people have wondered how traits are inherited from one generation to the next. The fact that living things inherit traits from their parents has been used since prehistoric times to improve crop plants and animals through selective breeding. Although children often look more like one parent than the other, most offspring seem to be a blend of the characteristics of both parents. Centuries of breeding of domestic plants and animals had shown that useful traits - yield of wheat, speed in horses, larger fruits in crops, protein content in milk - can be improved by controlled mating. However, there was no scientific way to predict the outcome of a cross between two particular parents.

A number of hypotheses were suggested to explain heredity. During the 19th century, prior to the discovery of genetics, many biologists support to the idea of blending inheritance (Jenkin, 1867). Blending inheritance was merely a widespread hypothetical model, rather than a formalized scientific theory since it was never formally presented to a scientific community nor published in any scientific journals. By this theory inherited traits were determined randomly, from a range bound by the homologous traits found in the parents. For example the height of a person, with one short parent and one tall parent, was thought to always be of some intermediate value between its two parents' heights. The shortcoming to this idea was in how it required the person of intermediate height, in turn, to then become one of the limiting bounds (either upper or lower) for future offspring, and so on down the entire lineage. Thus, in each family, the potential for variation would tend to narrow, quite dramatically, with each generation, and it would go for the entire population with every trait. If blending inheritance were true, in this example, all members of a species would eventually converge upon a single value for height for all members, variation disappeared, every generation should be more uniform than the previous one. By now, all individuals should be as indistinguishable as clones. Blending inheritance failed to explain how traits that seemingly disappeared for several generations often reasserted themselves down the line, unaltered. Blue eyes and blond hair, for example, often could disappear from a family's lineage for several generations, only to have two brown-haired, brown-eyed parents give birth to a blond, blue-eyed child. If blending inheritance were fact, this could not be possible.

In 1868 in England, Charles Darwin proposed his pangenesis theory (pan- whole, genesis-origin) to describe the units of inheritance between parents and offspring and the processes by which those units control development in off spring (Darwin, 1868). Indeed, pangenesis theory originated from the claim that characteristics acquired during an organism's life were heritable. A theory of inheritance of acquired characteristics (IAC) had persistent for almost two thousand years, since Greek antiquity. Hippocrates, who lived during the fifth to fourth centuries BC in Greece used this theory to explain why some people had longer than normal heads. Many scientists and philosophers in the eighteenth and nineteenth century favored some form of IAC theory, including Jean-Baptiste Lamarck in Paris, France. Lamarck stated that all the characters acquired during an individual's life transmitted to their offspring.

Darwin propose the concept of gemmules, which he said referred to hypothesized small particles of inheritance inside cells. Darwin argued that, in what he called higher animals or plants, every cell in their bodies emitted small particles, which were units of heredity, that he called gemmules. The gemmules could either circulate and disperse in the body system, or they could aggregate in the sexual cells located in reproductive organs. As hereditary units, the gemmules transmitted from parents to offspring, where they developed into cells that resembled the parents' cells. It was not sexual cells alone that generated a new organism, but rather all cells in the body as a whole. The theory suggested that an organism's environment could modify the gemmules in any parts of the body, and that these modified gemmules would congregate in the reproductive organs of parents to be passed on to their offspring. In sexual reproduction, gemmules from both parents blended in the sexual organs to be passed to

the offspring With the term pangenesis, Darwin suggested that all parts of the parents could contribute to the evolution and development of the offspring. Darwin's theory of pangenesis gradually lost popularity in the 1890s when biologists increasingly rejected the theory of inheritance of acquired characteristics (IAC), on which the pangenesis theory partially relied.

Around the turn of the twentieth century, biologists replaced the theory of pangenesis with germ plasm theory and then with chromosomal theories of inheritance, and they replaced the concept of gemmules with that of genes. Weismann stated that small units of materials in the cells of organisms pass from parents to their offspring (Winther, 2001). Nonetheless, Weismann argued that only the hereditary material in the sexual cells, or germ cells, could transmit to offspring. Weismann called his theory germ-plasm theory. Principles of the germ-plasm theory gradually replaced Darwin's pangenesis theory, but biologists adopted little of Weismann's terminology.

The particulate hypothesis states that parents pass on to their offspring distinct factors that retain their offspring while the blending hypothesis states that parents′ hereditary material blends in their offspring.

In the 1860s in Brno, Austrian Empire, which later became the Czech Republic, Mendel had studied how heritable factors in sexually reproducing plants behaved across generations, and he had inferred laws to describe those behaviors. Mendel did not study the actual units of inheritance, but only the phenotypes or traits hypothesized to develop in organisms that had those factors. With his laws, Mendel could predict phenotypes among the offspring from data about the phenotypes of parents. Mendel's laws, unstudied for decades, were rediscovered in 1900, and Walter Sutton in the US and Theodor Boveri in Europe soon paired those laws to the mechanistic descriptions of how chromosomes behaved in replicating cells, creating a chromosomal theory of inheritance (Satzinger, 2008). Mendel's hypothesis states that parents pass on to their offspring separate and distinct factors (today called genes) that are responsible for inherited traits. Mendel stressed that these heritable factors retain their identity during next generations.

Following Bateson in England and Johannsen in Denmark, most biologists eventually rejected theories of the inheritance of acquired characteristics and Darwin's pangenesis theory, and they used the term gene to refer to those things that Mendel had called factors (Bateson, 1900; Johannsen, 1909). Scientists in the early and middle decades of the twentieth century worked to fit the chromosomal and genetic theories of inheritance with Darwin's theory of the evolution of species by natural selection.

Education and early career of Johann Mendel

Johann Mendel was born 1822 in a farmer′s family in Hynčice about 120 km north of Brno. He was the son of Anton and Rosine Mendel, and had two sisters; older Veronika and younger Theresia. From his mother Johann Gregor inherited some of his character traits, for he seems to have been good-natured, quiet, and modest. Probably his talent came also from the mother's side of the family. Anton Mendel had a great fondness for fruit-growing. They lived and worked on a farm which had been owned by the Mendel family for at least 130 years. During his childhood Johann helped his father farm their land working as a gardener and studding beekeeping, but he was not destined to be farmer. On the farm Johann developed his love for the science.

Johan began attending the village school as soon as he was old enough and his teachers noticed that he was an exceptionally intelligent boy. Johann′s teachers recommended him to an upper elementary school in Leipnik. This was a school where exceptional students were sent to prepare them for the gymnasium. The gymnasium (grammar school) was a school that provided an education for the best students, which were selected to go on to study

an university. Later, when Johann was 11 years old, he attended Gymnasium in Opava in 1834. Johann's parents had to deal with the fact that Johann would not be taking over the family farm when his father grew older. In 1938 Johann's father was seriously injured while working and that situation places a lot of stress on Johann, because his parents were no longer able to pay for any of his schooling, leaving him to support himself entirely. Due to that Johann become quite sick and stayed in bed for four months. To provide money for studying Johann decided to study to become a teacher for tutoring his classmates. He graduated from the gymnasium in 1840.

Johann wanted to continue his education at a university and prerequisite for that was two year philosophical study. From 1840 to 1843, he studied religion, philosophy, ethic, pedagogy mathematics and physics at the University of Olomouc Faculty of Philosophy, taking another year off because of illness. When Mendel entered the Faculty of Philosophy, the Department of Natural History and Agriculture was headed by Johann Karl Nestler who conducted extensive research of hereditary traits of plants and animals, especially sheep. Johann had the problems with his health whenever he was faced with difficult circumstances. He also struggled financially to pay for his studies, and Theresia gave him her dowry. Later he helped support her three sons, two of whom became doctors. He was excelled in physics and mathematics. Johann Mendel no longer wanted to have to struggle.

Indeed, Friedrich Franz, his professor of physics who was a priest, urged Johann to become a monk. For Mendel that was the only way for obtaining education since monasteries were known to be centers of learning. Johann Mendel in late 1843, at the age of twenty one, joined the Augustinian monastery of St. Thomas and began his training as a priest; born Johann Mendel took the name Gregor. Gregor Mendel was ordained into the priesthood in August 1947. As a priest Mendel found his parish duty to visit the sick in hospital. It quickly become clear that he was not fit for these duties because whenever he visited the patients he became very upset. Mendel wanted to teach. Head of the monastery Abbot Napp found him a substitute-teaching position at Znojno, where he proved very successful in teaching mathematics and literature at the high school. Mendel began teaching in 1849, even he did not yet have a formal document from a university approving him to do so. In 1850 he failed the oral part, the last of three parts, of his exams to become a certified high school teacher. From point of Mendel it was debacle, but from point of genetics it was good that he did not pass the exam. If he passed Mendel probably would be happy teaching at the Znojno high school for the rest of his life and probably would never work with pea.

In 1851 Mendel was sent to the University of Vienna to study under the sponsorship of Abbot Napp so that he could get more formal education. As at Olomouc, Mendel devoted his time at Vienna to physics and mathematics, working under Austrian physicist Christian Doppler and mathematical physicist Andreas von Ettinghausen. He also studied the anatomy and physiology of plants and the use of the microscope under botanist Franz Unger, an enthusiast for the cell theory. In the summer of 1853, Mendel returned to the monastery in Brno, and in the following year he was again given a teaching position, principally of physics, this time at the Brno high school, where he remained until elected abbot 14 years later. In 1856 he took the exam to become a certified teacher and again failed the oral part. In 1867 he replaced Napp as abbot of the monastery.

After he was elevated as abbot in 1868, his scientific work largely ended, as Mendel became occupied with his increased administrative responsibilities. The increased responsibilities prevented him from conducting any further scientific experiments. Mendel died on 6 January 1884, at the age of 61, in Brno, from chronic nephritis. After his death, the succeeding abbot burned all papers in Mendel's collection, to mark an end to the disputes over taxation.

Mendel's Genetics

In 1854 in the garden of monastery Gregor Mendel established the experimental program in hybridization . Between 1856 and 1863, he cultivated and tested some 5,000 pea plants. The aim of this program was to trace the transmission of hereditary characters in successive generations of hybrid progeny. Mendel found that garden pea (*Pisum sativum*) has many distinct varieties and he selected it to conduct his studies. Pea is suitable due to ease of growing and control of pollination and the high proportion of successful seed germinations. In period from 1854 to 1856 Mendel tested 34 pea varieties for stability of their traits. In order to understand the transmission of characters, Mendel observed seven traits that are easily recognized and apparently only occur in one of two forms: flower color is purple or white, flower position is axil or terminal, plant is tall or short, seed shape is round or wrinkled, seed color is yellow or green, pod shape is inflated or constricted and pod color is yellow or green. This observation that these traits do not show up in offspring plants with intermediate forms was critically important because the leading theory in biology at the time was that inherited traits blend from generation to generation.

He crossed varieties that differed in one trait- for instance, varieties with purple flower crossed with varieties with white flowers. The first generation of hybrid (F_1) displayed the character of one variety but not that of the other. In Mendel’s terms, one character was dominant and the other recessive. He grown numerous plants from this hybrid and obtained the second generation (F_2), in which the recessive character reappeared, and the proportion of offspring bearing the dominant to offspring bearing the recessive was very close to a 3 to 1 ratio. Study of the descendants (F_3) of the dominant group showed that one-third of them were pure line and two-thirds were of hybrid constitution. The 3:1 ratio could hence be rewritten as 1:2:1, meaning that 50% of the F_2 generation were pure line and 50% were still hybrid.

This was Mendel’s major discovery, and it was unlikely to have been made by his predecessors, since they did not grow statistically significant populations, nor did they follow the individual characters separately to establish their statistical relations.

Mendel′s knowledge in physics and mathematics, especially combinatorial mathematics served him to represent obtained results. If dominant form of a trait denote by *A* and the recessive by *a*, then the 1:2:1 ratio recalls the terms in the expansion of the binomial equation: $(A+a)^2 = A^2+2Aa+a^2$.

From these experiments, Mendel induced two generalizations which later became known as Mendel's Principles of Heredity or Mendelian inheritance. He described these principles in a two-part paper, Versuche über Pflanzen-Hybriden (Experiments on Plant Hybridization), that he read to the Natural History Society of Brno on February 8 and March 8, 1865, and which was published in 1866. Mendel's Laws of heredity are usually stated as:

1) The Law of segregation: Each inherited trait is defined by a gene pair. Parental genes are randomly separated to the sex cells so that sex cells contain only one gene of the pair. Although Mendel did not know the physical basis for heredity, he observed that organisms inherit traits via discrete units of inheritance, which are now called genes. Offspring therefore inherit one genetic allele from each parent when sex cells unite in fertilization.

2) The Law of Independent Assortment: Mendel realized that he could test his expectation that the seven traits are transmitted independently of one another. Crosses involving first two and then three of his seven traits yielded categories of offspring in proportions following the terms produced from combining two binomial equations, indicating that their transmission was independent of one another. So, genes for different traits are sorted separately from one another so that the inheritance of one trait is not dependent on the inheritance of another.

3) The Law of dominance: Therefore, a cross between a homozygous dominant and a homozygous recessive will always express the dominant phenotype, while still having a

heterozygous genotype. Recessive alleles will always be masked by dominant alleles. In a cross between two organisms pure for any pair of contrasting characters, the character that appears in the F1 generation is called dominant and the one which is not expressed is called recessive.

Mendelism - important and controversial theory

It is obviously that Mendel did not make effort to publicize his work. Today it is not known how many reprints of his paper he distributed. He had ordered 40 reprints, the where of only eight of which are known. Other than the journal that published his paper, in 19th century 15 sources are known in which Mendel′s plant hybridization work is mentioned. Few of these provide a clear picture of his achievement.

Indeed, Mendel's results were largely ignored. Although Mendel's laws were not completely unknown to biologists of that time, they were not seen as generally applicable. A major barrier to understanding their significance there was in the apparent blending of inherited traits in the overall appearance of the progeny, now known to be due to multigene interactions, while Mendel studied the organ-specific binary characters. In 1900, however, his work was "re-discovered" by three European scientists, Hugo de Vries, Carl Correns, and Erich von Tschermak but they partially still ignored Mendel's findings.

Bateson was the strongest promoter of Mendel's theory (Bateson, 1909). By 1902, he had translated Mendel's works into English and was a strong supporter of the Mendelian laws of inheritance. Bateson is credited with coining the terms "genetics," "allele", "zygote," "heterozygote" and "homozygote". Bateson first used the term "genetics" publicly at the Third International Conference on Plant Hybridization in London in 1906 (Bateson, 1906), and Johannsen first used the word "gene" in 1909 to describe the units of hereditary information. Many other biologists were against Mendel's model of heredity because it implied that heredity was discontinuous, in opposition to the apparently continuous variation observable for many traits. However, later Fisher (1936) showed that if multiple Mendelian factors were involved in the expression of an individual trait, they could produce the diverse results observed. After the rediscovery of Mendel's work, scientists tried to determine which molecules in the cell were responsible for inheritance. In 1911, Thomas Hunt Morgan argued that genes are on chromosomes and the chromosomes of cells were thought to hold the actual hereditary material, and created what is now known as classical genetics. This finally strengthen Mendel's place in history of genetics.

Discussion

The fundamental laws of inheritance are now known as Mendel's laws, and the science on which they are based is called Mendelian genetics. However, because Mendel's importance was unrecognized during his lifetime, little original information about his scientific work was preserved. Most unfortunately, his scientific records were apparently burned around the time of his death (Orel, 1996). Classical study of seven genes by Gregor Mendel was basis for modern genetics development, although relatively recently little was known about their function. Progress in molecular genetics in last few decades dramatically changed this situation and identity of Mendel′s genes in pea has been discovered. The gene Mendel studied that governs seed shape trait is *r* on chromosome 7, the gene that governs cotyledon color is *i* on chromosome 1, the gene that governs seed coat color is *a* on chromosome 1, the gene that governs pod shape is either *v* on chromosome 4 or *p* on chromosome 6, the gene that governs pod color is *gp* on chromosome 5, the gene that governs flower position is *fa* on chromosome 4 and the gene that governs stem length is *le* on chromosome 4.

Although Mendel's paper is considered a classic in the history of biology, it generated much controversy throughout the century that elapsed since the rediscovery of Mendelian laws in

1900. Some authors glorify Mendel as a brilliant scientist whose work was ahead of its time, others are critical of his methods, and a few claim he was a deception (Monaghan and Corcos, 1993; Weldon, 1902; Hartl and Fairbanks, 2007). There is substantial disagreement about his objectives, the accuracy of his presentation, the statistical validity of his data, and the relationship of his work to evolutionary theories of his day. Fairbanks and Rytting (2001) apostrophize five of the most contentiously debated issues by looking at the historical record through the view of current science: (1) Are Mendel's data too good to be true? (2) Is Mendel's description of his experiments fictitious? (3) Did Mendel articulate the laws of inheritance attributed to him? (4) Did Mendel detect but not mention linkage? (5) Did Mendel support or oppose Darwin? Some scholars disagree about Mendel's integrity in his presentation, his articulation of the fundamental laws of inheritance, his experimental design, his motives for conducting his experiments, and his conclusions. However, given the lack of suitable terminology at the time, this seems a very unpleasant judgment. Fisher (1936) certainly saw the significance of Mendel’s contribution to the field even though he was the one who raised several concerns about the data. Some of these concerns still exist, and the controversy has not been resolved, despite recent implications to the contrary (Franklin, 2008; Stigler, 2008).

Fairbanks and Rytting (2001) concluded that Mendel did not fabricate his data, his description of his experiments is literal, he articulated the laws of inheritance attributed to him insofar as was possible given the information he had, he did not detect linkage, and he neither strongly supported nor opposed Darwin.

FEEDING THE WORLD IN 2050: FOOD AVAILABILITY VS FOOD ACCESS

William H. MEYERS*, Kateryna G. SCHROEDER

Abstract

This paper assesses the projected growth of food supply relative to population growth and estimated food demand growth over the next four decades. World population projections are analyzed for the main developed and developing regions. Implied food demand growth is then compared to grain and oilseed supply projections from a few of the most reliable sources. Three of these are ten-year projections and two extend to 2030 and 2050. To the extent possible, comparisons are made among the alternative projections. Conclusions about food availability and prices are finally drawn. Meeting the growth in demand for food, feed, and biofuels to 2050 will not be a steep hill to climb, but there will need to be continued private and public investment in technology to induce increased production growth rates through productivity enhancements and increased purchased inputs. The main food security challenge of the future, as in the present, is not insufficient production but rather increasing access and reducing vulnerability for food insecure households. The dominance of future population growth in the food insecure regions of Africa make this challenge even more critical between now and 2050 and even more so in the years beyond 2050 when climate change effects on resource constraints will be more severe.

Keywords: food supply, population growth, price projection, production growth

Introduction

In 2009, FAO issued a report (Bruinsma, 2009) that contained estimates of how much agricultural production needed to increase between 2006 and 2050 to meet the projected growing consumption from increasing population and changing diets. It was the basis for what became a widely used figure that production needed to double by 2050, even though that was only the FAO estimate for production in developing countries. The actual estimate in the 2009 report was that global agricultural production would need to increase by 70 percent. Moreover, that “double by 2050” continues to be repeated even though agricultural production has already increased substantially since 2006. More recently, FAO (Alexandratos & Bruinsma, 2012) updated these estimates and projected a 60 percent increase in agricultural production needed to provide an adequate food supply from 2006 to 2050. These figures are used later in this paper but we will first take a look at the broader context for this and other estimates of future needs.

Since the end of World War II, rapid technological change combined with inelastic demand for food has been generating declining real agricultural prices. Consumers have been the ultimate beneficiaries of agricultural innovation, while farmers have had to expand their operations and become more efficient to offset price declines. Governments in high-income countries have adopted various support and protective trade policies to shelter their farmers from price declines which often contribute to even lower market prices. This long-term decline in real prices has periodically been interrupted by price spikes caused by crop failures or other factors.

From the beginning of 2006 to the end of 2008, the world witnessed the largest surge of commodity and food prices since the early 1970s. After a short and deep price decline, they rose again between 2011 and 2014, and then began another decline in 2015 (Figure 1) The

2007/08 price surge raised the age-old Malthusian question of whether food production can keep pace with growing demand. Numerous studies have found complex factors related to this issue. Historically, the main driver of production has been technological progress. Meanwhile, the drivers of consumption have been population growth (which increases the number of mouths to feed) and income growth (which increases the quality and quantity of food consumed per person). Changing diets that accompany both increased incomes and increased urbanization generally lead to more meat consumption and thus more grain consumption per person. Aging of the population which is occurring at a faster pace in higher-income countries, may have the opposite effect on diet and quantity of grain consumed.

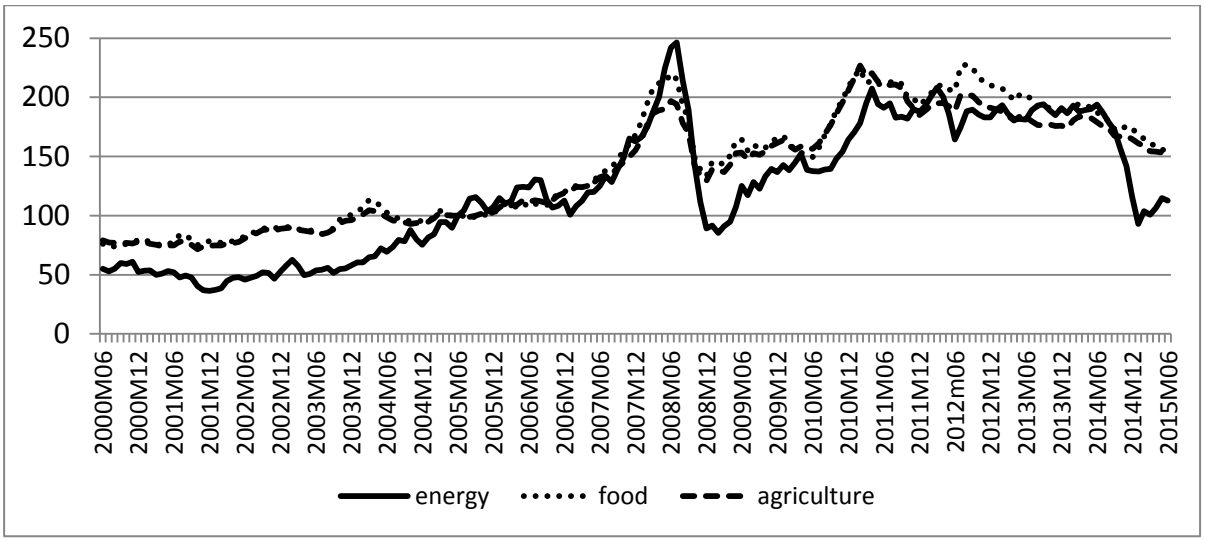

Figure 1. World Bank food, agriculture, and energy price indices, 01/00 to 6/15, 2005=100
Source: World Bank monthly commodity prices (Pink Sheet), accessed July 11, 2015.

A number of factors have contributed to the rising and more volatile prices since 2007, including declining grain and oilseed stocks, depreciation of the US dollar, poor weather (leading to yield shocks), governmental policy reaction to rising prices, changing diets, and rising demand. It has been in many ways a ‘perfect storm’ of factors (Abbott, Hurt, & Tyner, 2009; Meyers & Meyer, 2008). In a number of countries, the implementation of policies stimulating biofuel production in pursuit of environmental and farm support objectives has formed a much stronger link between fuel and food markets, a link that can contribute both to the level and the volatility of food prices (Food and Agriculture Organization of the United Nations [FAO] 2008a; Food and Agricultural Policy Research Institute [FAPRI-MU], 2008; Organisation for Economic Co-operation and Development [OECD], 2008). These policy changes have increased the profitability of investments in biofuel capacity and the increased use of existing capacity, resulting in more grains and oilseeds being used as feedstock for biofuel production. Biofuels component of grain and oilseed demand rose strongly from 2005 to 2011, but it is not expected to be a major factor in future demand (FAPRI-MU, 2015).
Examination of grain and oilseed world markets indicates that the rate of production growth was decelerating since the 1970s. This has contributed to declining stock positions in global markets (Table 1), although the new millennium saw a rebound partly in response to higher commodity prices. This rebound has continued into the second decade of the twenty-first century, but the growth rate has decelerated again. While a significant share of the decline in the 1990s was due to the restructuring and reform in the Former Soviet Union (FSU-12), even without that, grain production growth would have been slower than in earlier decades. In comparing growth rates in yield over each decade from 1960 to 2013, there has been a steady

deceleration in yield growth rates since the 1970s. Added to this problem is the finding by the Intergovernmental Panel on Climate Change (IPCC, 2007) that natural disasters may become more frequent and extreme in the future due to climate change, thus contributing to decelerating average growth in yield. Grain area which also declined between 1980 and 2000 to less than 1% per annum in production growth has rebounded, but not to previous levels.

Table 1. Average annual percent change in area, yield, and production, grains and oilseeds

Production and consumption tend to run parallel over time. Production may temporarily outpace consumption and build buffer stocks in years of bumper crops or fast land expansion. Conversely, shrinking land use or bad weather may lead to lagging production and falling buffer stocks. Not surprisingly then, since the 1980s, consumption growth rates for both grains and total grains and oilseeds have declined, dropping below the 1% per year level in the 1990s. These, too, have since rebounded, although not to the levels seen in the 1970s and not to the same degree as growth rates in production. This suggests that decelerating population growth rates have not been completely offset by the consumption boosting effects of income growth (Alexandratos, 2008). A major factor in the consumption deceleration of the 1990s was what happened in the FSU-12, when excessive and wasteful feed use was drastically cut by market forces that rationalized grain use. Consumption growth in the rest of the world did not decline substantially in this period.

Over the past several decades, food security as an economic and political objective has grown increasingly important in all the nations across the globe. During this time the concept of food security has been changing as well - from concern for global levels of food supply, to national food self-sufficiency objectives, and more recently to a more balanced view that not only adequate national and local supplies of foods must be available but also that effective demand must be assured for the people most at risk.

We first look at population growth projections and the implications for food demand growth, and then looking at grain and oilseed supply projections from several sources. Supply and demand growth are analyzed relative to whether or not supply-demand pressures will sustain an upward pressure on prices and relative to which supply-side developments may be needed to keep pace with possible demand growth. Finally, we discuss the factors that can improve access to adequate food by those at risk of being food insecure.

Materials and Methods

First the population dynamics are taken from the US Census Bureau 2015 estimates and analyzed by region of the world. Second, the simple projection of demand is conducted with population growth, income growth projections and the income elasticity of demand for food. Then, supply projections from various alternative sources are compared to check for similarities or differences. Analysis of price projections is discussed relative to recent past price dynamics. Finally, we discuss the main factors that can improve access to food for vulnerable populations.

Population Growth Dynamics and Projections to 2050

The United States Census Bureau (2015) projects the world population to reach 9.38 billion persons by 2050, an approximate 36.5% increase over the population in 2010, while the United Nations (2012) projects 9.55 billion persons by 2050. While world population continues to increase, rates of population growth have been decreasing where incomes and education levels increase (Table 2). It is known that higher income and education levels increase the marriage age of women and reduce the number of children per family. This more than offsets increased life expectancy at birth and reduces population growth rates (Table 2). In the projected aggregate of developed countries, population begins to decline beyond 2040, and for the European continent this decline is projected to commence in 2020. Europe's birth rate has been below the replacement level for many years; only immigration has kept Europe's population increasing. In China, with its one-child policy, the population growth rate is projected to go negative in 2033 and be below the developed country level by 2050.

Table 2. Population growth rates, historical and projections in 10-year increments, 1960–2050

Source: International database, US Census Bureau (2015).

Another important aspect of global population growth is the evolution of regional distribution. From 1970 to 2010, 63% of the world population growth was in Asia and 21% in Africa (Figure 3). These numbers change dramatically between 2010 and 2050, when the total share of population growth will be about 42% in Asia and 48.5% in Africa. More than 1.2 billion people are projected to be added in Africa, which well exceeds the 1.0 billion projected for Asia. This dramatic shift in shares of population in Asia and Africa may have a significant impact on global food consumption patterns and food security because the most
food insecure regions are growing the fastest. Meanwhile, Europe's population, which has been at essentially zero growth since 1990, is expected to decrease from 11% of the world population in 2010 to 7.5% in 2050. The shares of total population in North America and South America are projected to be around 7% each in 2050. With the expected 2.67 billion

additional people between 2010 and 2050 and nearly half of these in Africa, there will be future food security challenges.

Potential Income and Demand Growth

As an approximation of the growth in demand for food, if there were no change in per capita consumption in each country, food demand would grow at a slower rate than population simply because the populations with lower per capita consumption levels also tend to have higher population growth rates (Alexandratos, 1999). In addition, per capita consumption tends to grow with income in low-income populations, where the diet is often inadequate. At higher income levels, where there is an adequate diet, the income effect is insignificant. The percent growth in demand for food for 1% growth in income is called income elasticity of demand. We can illustrate this by comparing the calculated growth in demand for food with no change in per capita consumption (or no income effect) compared to scenarios where the income elasticity of demand for food is 0.2 or 0.4, meaning that food consumption would grow by 2% or 4% for every 10% growth in income, assuming that nothing else changes (this means there is no change in prices or other factors that may influence food demand).

Food demand growth is calculated as

Food demand growth = population growth + (income elasticity * per capita income growth)

This calculation requires a projection of the growth in income per capita for which we use the projected growth in real gross domestic product (GDP) per capita. GDP figures reflect an average growth rate of 2% or slightly higher on a per capita basis and between 3% and 3.5% per annum, including population growth. Applying the different income elasticities and using the world population growth rates from the previous section, we obtain food demand growth rates that range from about 2% per annum for the higher-income elasticity to about 1% per annum when there is no income effect or no change in per capita consumption (Figure 4). To check which of these may be closest to a recent long-term projection of food demand growth, we use the FAO (Alexandratos & Bruinsma, 2012) projection for growth rate of demand for all commodities and all uses. For the period 2000 to 2030, the estimated average growth rate is 1.4% per annum which is virtually identical to the middle calculation from 2015 onward

(Figure 4). Since population growth rates are declining, it is likely that future food demand growth will be lower.[7]

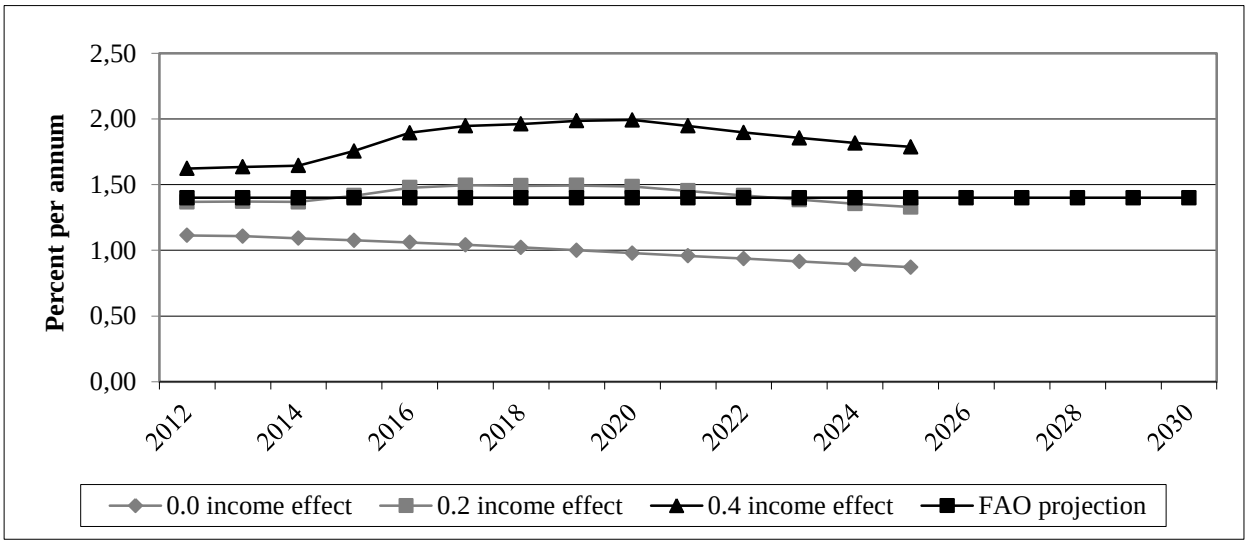

Figure 4. Calculated food demand growth rate compared with FAO long-term projections
Source: GDP growth rates are IHS Global Insight projections used in the FAPRI January 2015 baseline.

Results and Discussion

We do not want to dwell too much on food demand growth without speaking of supply and price conditions, but it is useful to have a reference point when speaking of potential growth in supply. When looking at supply growth, we focus on grains and oilseeds since they are the basic commodities from which most foods are derived. When incomes grow, people tend to shift from direct consumption of grains to indirect consumption of grain through meat (animals eat grain as a feedstuff). This is reflected in the income effect represented by the income elasticity; that is, more grain per capita is used when meat constitutes an increasing percentage of the national diet.

Supply Projections for Cereals from Different Sources

As discussed earlier, several factors have contributed to slow production growth in cereals. A key market factor was the extended period of declining real prices that reduced market incentives to invest and produce. The result was a decline in grain area (Table 1) at the same time that yield growth rates were decelerating.

Another important factor in slowing yield growth rates was the diminishing national and international public investment in agricultural research and development (R&D) that began in the 1990s. The international research investments of the 1960s were deliberate policies to enhance agricultural productivity in developing countries which resulted in the high yielding Green Revolution wheat and rice varieties that spurred yield growth and enhanced multiple cropping opportunities with shorter growing seasons. Along with continuing public and private agricultural R&D in industrial countries, improved technologies supported grain yield growth of nearly 2.5% and production growth of 3% annually from 1960 to 1970. While yield growth remained relatively high in the 1970s and 1980s, grain area declined and finally plateaued in the 1990s.

[7] This global illustration greatly oversimplifies the process used in conducting such projections. Generally, projections of demand growth must be conducted in more disaggregated ways and preferably country by country (Alexandratos, 1997).

Numerous World Bank, FAO and International Food Policy Research Institute (IFPRI) documents have established that investment in agricultural development has been lagging, especially in developing countries. Developing countries have underinvested in agriculture since the 1990s (World Bank, 2007a). Only 4% of total public R&D goes to agriculture in developing countries where 75% of the world's poor live in rural areas. Pardey, Beintema, Dehmer, and Wood (2006) find that growth in public agricultural R&D spending (which was critical to the Green Revolution) declined by more than 50% in most developing countries from 1980 onward and turned negative in high-income countries from 1991 onward. While there have been important exceptions in China and India (World Bank, 2007b), national governments and international organizations have mainly neglected these investments despite the high rates of return demonstrated in past R&D projects.

Grain and oilseed area and production have been increasing in response to a commodity price surge and increasing biofuels feedstock demand since 2006. Another contributing factor has been the steady recovery and growth of the crop sectors in the FSU-12 since 2000. It is in this context that the most recent ten-year projections of future supply have been conducted. These projections are also conducted in the context of public R&D deficiency because, even if urgent action were taken to reverse the investment path for agriculture, such action would constitute the beginning of a long-term endeavor.

The first comparison of grain and oilseed production projections comes from three well-known annual global market assessments. The first is by FAPRI-MU with assistance from the University of Arkansas on global rice market analysis (FAPRI-MU, 2015). The second is by the United States Department of Agriculture (USDA, 2015). The third is conducted jointly by the OECD and FAO (OECD/FAO, 2014). The implications of all three projections are quite similar.

Grains (except for rice) and oilseeds have had significant growth in production, primarily in response to rapidly rising prices and agricultural recovery in the FSU-12 from 2000 to 2014 (Table 3). Projected production growth rates for 2014 to 2023 are lowered, with only wheat production growth rates remaining higher than in the 1990s. Wheat is a special case in the United States because the decoupling of payments from base acres in the mid-1990s led to a large shift of land from wheat to soybeans in the 1990 to 2000 period. The comparison of FAPRI with USDA and OECD/FAO projections serves to show a considerable agreement on production growth rates.

Finally, we compare these ten-year projections to long-term projections conducted by FAO (Alexandratos & Bruinsma, 2012) and by IFPRI (Rosegrant et al., 2013). The long-term projections use different kinds of modeling systems than the ten-year projections. FAO essentially assumes constant real prices and projects that the use of grains and oilseeds for biofuels feedstock will not grow beyond 2020. IFPRI's projections also estimate prices and incorporate models of biofuel feedstock demands. The long-term estimates also take account of water and land resource constraints in the analysis. We use the FAPRI results for comparison and find a rather consistent outlook (Table 4).

Table 3. Comparison of growth rates for grains and oilseeds production, % per annum

Crop	1990–2000	2000–2014	FAPRI 2014–2023	USDA 2014–2023	OECD/FAO* 2014–2023
Rice	1.48	1.28	1.03	0.89	1.06
Wheat	0.38	1.38	0.90	0.63	0.91
Corn/Coarse grains*	1.98	3.57	1.40	1.31	1.08
Total Grains Above	1.24	2.25	1.14	1.00	1.03
Soybeans/Oilseeds*	5.25	3.98	2.24	2.38	1.57

*OECD aggregates coarse grains and oilseeds.

Sources: FAPRI (2015), OECD (2014), and USDA (2015). Historical figures use three-year average of production.

Table 4 Comparison of growth rates for grains and oilseeds production, % per annum

Crop	FAPRI 2014–2023	FAO* 2006–2030	FAO* 2006–2050	IFPRI 2010–2050
Rice	1.03	—	—	
Wheat	0.90	—	—	
Corn	1.40	—	—	
Total above/Cereals*	1.14	1.20	0.90	0.84
Soybeans	2.24	1.0	1.3	N/A
Population	1.00	1.04	0.87	0.87

*FAO and IFPRI do report aggregate cereals

Sources: FAPRI (2015), Alexandratos and Bruinsma (2012), and (Rosegrant et al., 2013).

Comparing FAO and IFPRI analyses, it is sufficient to look only at the 2010 to 2050 summary, or 2006 to 2050 for FAO, to see that they are very similar in terms of total cereals. However, the IFPRI analysis has slightly lower growth rates in grain production despite the fact that they include the growth of biofuel feedstock demand through 2050, which FAO does only through 2020. Another factor to consider when looking at these figures is that they project about a 50 percent increase in cereal production over the next 30 years, compared to a 12.5 percent actual increase over the last 4 years and 22 percent over the last 10 years.

Commodity and Food Price Projections

Projections of commodity and food prices are also important. The FAPRI, OECD/FAO, and USDA projection models include a wide range of production, consumption, trade, and price information for crops and livestock/dairy products. Price spikes in 2007/08 and shortly thereafter have opened a dialog on whether the downward path of real commodity prices has come to an end. The FAPRI price projections that accompany the most recent outlook do not answer this question. It is a price path that is neither increasing nor returning to the lowest levels seen at the beginning of the twenty-first century (Figure 4). Price projections of FAPRI include a stochastic price band that makes it clear prices will continue to be volatile whether the long-term path is increasing or decreasing. The demand for grains and oilseeds as feedstock for biofuels adds to the traditional demands for food grains and animal feeds but this growth is expected to be relatively small in the future. Declining petroleum prices have diminished these price pressures in the near term.

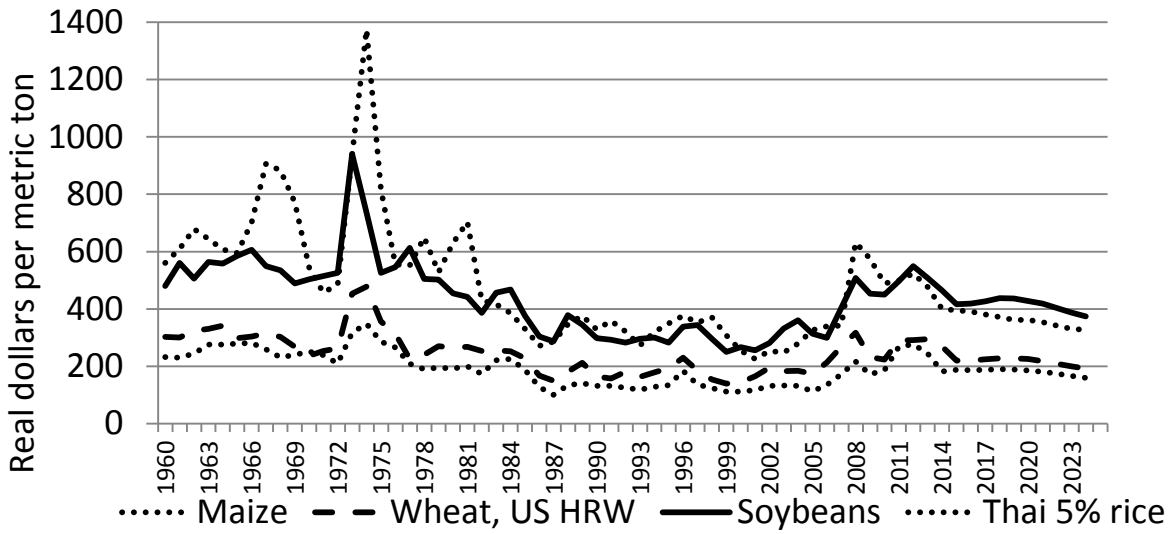

Figure 4. World grain price projections consistent with supply and demand projections
Source: History from World Bank Pink Sheet, projections calculated from FAPRI 2015 Baseline

A thoughtful recent study of alternative analyses and modeling approaches to projecting future food needs points to much research that remains to be done and alternative modeling approaches to be considered (Wise, 2013). He also highlights the post-2050 timeframe as being a much more challenging issue to analyze, especially because climate change impacts will be more pronounced. Likewise, the dominance of population growth in Africa beyond 2050 will also continue, so increasing challenges in the world's most food insecure region will be difficult. The projections cited in this paper also do not attempt to estimate the possible impacts of reducing food loss and waste, which in some locations could be a substitute for increasing production at the farm level. This is a relatively new and growing concern, and increasing information is emerging on its effects and the potential for action to reducing waste in ways that would improve food security. The questions of cost effectiveness of policies and how such actions could improve food security still need careful assessment.

Improving Access to Adequate Food

A central policy question for food-insecure regions around the world is to understand what drives changes in food security and how to incorporate this understanding into agricultural and food policy. When it comes to dealing with poverty and malnutrition, overall economic growth seems to be one of the most efficient remedies. Income redistribution and social safety net programs that target vulnerable populations are also efficient ways to address malnutrition.

A strong science and technology system contributes to innovation for equitable agricultural development and food security. Along the human history, public agricultural research and technology adoption have enabled a growing populace to avoid mass starvation. If properly focused, agricultural innovations can also enhance nutritional value of our food. Therefore, policy options boosting research and innovations in agriculture should be an intrinsic part of the national or regional food security strategies. However, the impact that public research can have on food and nutrition security is still limited since very often the scientific outputs, developed either in their own countries or elsewhere, are not easily or widely accessible to farmers. The performance of research and innovation systems can be enhanced with the help of information and communication technologies (ICTs) to improve access to knowledge in a cost-effective way, improve the demand- and technologies uptake, more effective interface

with international and national institutional partnerships and finally contribute to food and nutrition security.

Conclusions and Implications

Prior to the beginning of the twenty-first century, production and consumption growth rates have decelerated. Parallel declines in real food prices over a long period suggest that, until recently, demand pressure was not driving up prices in the food system in response to decelerating production. However, since 2000, declining stocks and a series of market shocks have led to markedly higher prices that have induced increased land use and a more rapid growth of yields and production. Limits on future agricultural land-use expansion and water resources are constraints on both production growth and consumption growth. Prices are not likely to return to the low levels seen in the early part of this millennium and will surely continue to be more volatile than in those years of stagnation. It does appear that meeting the growth in demand for food, feed, and biofuels to 2050 will not be a steep hill to climb, but there will need to be continued private and public investment in technology to induce increased production growth rates through productivity enhancements and increased purchased inputs. There will be greater land-use and water-use pressures, as well as greater pressure on food import costs, to meet food demand and provide greater food security among low-income households, especially in developing food-importing countries.

Most of these baseline projections assume a continuation of technology growth patterns of the recent past, which has seen a deceleration of yield growth rates. An alternative future would see an increased rate of technological advancement through higher private and public R&D investment which would generate a higher yield growth path, permit substitution of technology for cropland, and benefit farmers through higher productivity and consumers through lower food prices. Such an alternative higher technological future would improve the well-being of consumers, especially in developing countries, and contribute to long-term sustainability of agricultural resources by substituting technology for land, thereby reducing pressure on cropland.

The main food security challenge of the future, as in the present, is not insufficient production but rather increasing access and reducing vulnerability for food insecure households. The dominance of future population growth in the food insecure regions of Africa make this a significant challenge between now and 2050 and even more so in the years beyond 2050 when climate change effects on resource constraints will be more severe. These are also the regions where waste reduction could be a cost-effective alternative to increased production, but ideally both of these means to increase availability should be pursued simultaneously.

HOW TO REDUCE SOIL EROSION – REQUESTS OF LEGISLATION AND EXPERIENCES WITH CONSERVATION TILLAGE IN THE CZECH REPUBLIC

Vladimir SMUTNY, Lubomir NEUDERT, Vojtech LUKAS, Tamara DRYSLOVA, Blanka PROCHAZKOVA

Mendel university in Brno, Zemedelska 1, 613 00, Brno, Czech Republic
*Corresponding author: smutny@mendelu.cz

Abstract

In the Czech Republic there is more than 50% of agricultural land exposed to water erosion. It is a very urgent problem at present and mainly for the future. The goal of legislation is to protect soil against soil erosion especially on slope areas. The payment of direct support for farmers and other selected subsidies depends on fulfilment of the Statutory Management Requirements (SMR) and Good Agricultural and Environmental Conditions (DZES), which are standards of the cross compliance system. The restrictions are concerned to cultivation of wide-row crops in seriously and slightly endangered areas by erosion. In seriously endangered areas, wide-row crops (maize, sugar beet, potatoes, sunflower, bean, soybean and sorghum) are not allowed to grow. In slightly endangered areas, growing of wide-row crops is allowed, but using conservation tillage, where limits for minimum crop residue coverage were defined. Conservation tillage systems with their modification are increasingly being introduced under the economic pressure on the fields of the Czech Republic. Reducing tillage operations improves soil surface properties, including improved soil aggregation accounting for increased infiltration and percolation; less compaction due to less usage and more biological activity due to an increase in organic matter. Adding soil surface cover increases water infiltration, reducing soil drying and maintains available water for crops. Apart from above mentioned approaches in soil tillage, new crop management practices are tested with potential effect against erosion. In maize, systems based on narrower spacing and higher stand density, are evaluated in different locations of the Czech Republic.

Keywords*: soil erosion, conservation tillage, legislation rules*

Introduction

Soil erosion is a major environmental threat to the sustainability and productive capacity of agriculture. During the last 40 years, nearly one-third of the world's arable land has been lost. (Pimentel et al., 1995). Soil erosion as a physical process has been consistently studied for the last two centuries (Dotterweich, 2013) by scientists from backgrounds as diverse as geography, agronomy and engineering (Boardman et al., 2003). The use of large amounts of fertilizers, pesticides, and irrigation help offset deleterious effects of erosion but have the potential to create pollution and health problems, destroy natural habitats, and contribute to high energy consumption and unsustainable agricultural systems. It is well known, that water erosion increases on slope areas. Living and dead plant biomass left on fields reduce soil erosion and water runoff by intercepting and dissipating raindrop. Both texture and structure of soil influence its susceptibility to erosion. Soils with medium to fine structure, low organic matter content, and weak structural development have low infiltration rates and experience increased water runoff.

Soil tillage in a sustainable land management harmonises the soil protection with demands of the crop to be grown on the given land and aims soil conservation, without increasing the production risks even in the long term (Birkás et al., 2002). It can be stressed, that the demand of the crops is independent of the tillage methods. The sustainability in a soil tillage viewpoint

can evolve toward greater efficiency of resource use, and can develop and maintain a harmony between crop production technologies and soil environment (Birkás, 2013).
From above mentioned facts is visible, that crop yields on severely eroded soil are lower than those on protected soils because soil erosion reduces soil fertility and water availability.
Reliable and proven soil conservation technologies include ridge-planting, no-till cultivation, crop rotations, strip cropping, grass strips, mulches, living mulches, agroforestry, terracing, contour planting and cover crops. Although the specific processes vary, all conservation methods reduce soil erosion rates by maintaining a protective vegetative cover over the soil, which is often accompanied by a reduction in the frequency of ploughing. Each conservation method may be used separately or in combination with other erosion-control techniques (Pimentel et al, 1995). By substantially decreasing soil and nutrient loss, conservation technologies preserve the soil's fertility and enable the land to sustain higher crop yields. In many instances, the use of conservation technologies may actually increase yields.
Voluntary incentive-based measures often form parts of regional development policies. These policies have formed a basis for many cases of conservation success in Europe, including a substantial reduction in soil erosion due to a change from autumn to spring ploughing in Norway (Lundekvam et al., 2003), mitigation of harmful sheep grazing practices in Iceland (Arnalds and Barkarson, 2003), and greater farmer involvement in soil conservation schemes in Belgium (Verstraeten et al., 2003) and the Netherlands (Spaan et al., 2010).

In the Czech conditions according to the database of Research Institute for Soil and Water Conservation (2008), individual types of degradation differ with the area, the most notable being water erosion which threatens more than 50% of agricultural areas. This is followed by wind erosion (11%), extreme soils – clay soils (4.5%), and soils affected by dryness (1.5%).
In this paper we describe and analyse weak points of current Czech agriculture in relation with soil protection, introduce valid legislation principles against water erosion and present approaches of suitable soil management practices based on results from research.

Materials and methods

In paper there are presented results from different topics focused on the impact of soil tillage on soil parameters and profitable and environmentally friendly management practice for maize in conditions of South Moravia (Czech Republic).

Soil tillage and soil parameters

Grain and silage maize are crops, where acreage increased in last years. Successful soil management system is based on improving soil properties. In lowlands, especially in dry areas, water saving soil tillage technologies can be enough efficient against a lack of suitable water for maize plants during vegetation. On the other hand, the systems, which are preserving soil erosion, could be used on slope areas. The effect of different soil tillage for grain maize on chosen soil parameters was assessed in two field trials established in different soil-climatic conditions in South Moravian region. Both localities are in maize-production region. Locality Visnove is characterized with brown loamy soil, in comparison with clay-loamy fluvisol, which is in Zabcice. Average annual temperature is similar in both localities (approx. 9.0 °C), annual sum of precipitations differed (480 mm in Zabcice and 557 mm in Visnove). Different variants of soil tillage were used: CT – conventional tillage - ploughing to the depth of 0.22 m; MT – minimum tillage included soil loosening (disking) to the depth of 0.15 m and NT – no tillage (direct drilling without any tillage). In Zabcice, grain maize was grown after winter wheat and two variants of soil tillage were used (CT and MT). In Visnove, there is grain maize monoculture, all three variants were assessed (CT, MT and NT). The

grain yield was evaluated in both trials, in Visnove physical soil properties (bulk density, soil porosity, soil moisture, minimum air capacity and water infiltration into soil) were assessed as well. Kopecky's physical cylinders were taken from soil depth (0–0.10 m; 0.10–0.20 m; 0.20–0.30 m) in five replications, each year in June (2005 – 2010). A double ring infiltrometers with diameter of 0.28 m and 0.54 m in soil depth of 0.1 m were used for soil infiltrability measurement.

Effect of row spacing and stand density on silage maize yield

Maize grown in a standard row spacing (0.75 m) is connected with high risk of soil degradation by water erosion mainly on sloping plots. Except of conservation tillage technologies, growing of maize in narrow rows is approach aimed on faster canopy closure and water runoff reduction when keeping sufficient yield level. Influence of different row spacing and stand density on silage maize yield was evaluated in a field experiment in the Czech Republic. In years 2013 and 2014, a field experiment, where influence of different row spacing and stand density on silage maize yields, was established on a field experimental station in locality Zabcice (description is mentioned above). Three different row spacing were compared in both years - standard spacing 0.75 m, twin rows (rows on standard 0.75 m spacing, where each row is further divided into adjacent sub-rows spaced approximately 0.20 m) and sowing to narrow rows, which width is half of standard spacing – 0.375 m (Tab. 1). Stand density of maize was another observed factor - standard sowing rate 80.000 – 90.000 seeds per ha and end sowing rate increased about 10.000 – 20.000 seeds per ha. In 2013 these two densities were observed and in 2014 was a third sowing rate added (109.000 seeds per ha). Precise numbers of sown seeds differ in case of every technology because of different setting of drilling machine for precision sowing (KINZE 3500). Maize was sowed on 23. 4. 2013 (hybrid Silotop) and 14. 4. 2014 (Beautiful), the depth of sowing was 0.07 m. Fertilizing dose of nitrogen was 180 kg, fertilizer urea was used. Post emergent application of herbicides and insect treatment against European corn borer was made. Harvest was made in the phase of milk-wax maturity by one-row cutter in four replications.

Table 1. Overview of experimental variants in 2013 and 2014

Row spacing (m)	Technology name	Stand density (seeds per ha) – variants in 2013	Stand density (seeds per ha) – variants in 2014
0.375	narrow	1 – 85.000	1 – 87.000
		2 – 99.000	2 – 97.000
		x	3 – 109.000
0.75	standard	1 – 76.000	1 – 89.000
		2 – 80.000	2 – 97.000
		x	3 – 108.000
	twin	1 – 91.000	1 – 87.000
		2 – 102.000	2 – 97.000
		x	3 – 109.000

Results and discussion

The main characteristic of agriculture in the Czech Republic (Křen and Dušková, 2013)

Agriculture belongs to strategic branches of national economy of the Czech Republic as summarized by its production and off-production functions. Agricultural land resources occupy 54 % of the country's acreage. Production potential of the Czech agriculture represents the area of 4.25 mil. ha of farm land with more than 70 % of its plough-up. The level of arable land is higher compared to EU states with similar soil-climatic conditions. Approximately 50 % of farm land is located in less favoured areas (LFA) because of lower soil quality and adverse climatic conditions.
From a production viewpoint, basic restructuring of the sector occurred as early as the 1990's (that is prior to entry into the EU on 1.5.2004). It was accompanied by a significant decrease in production, higher unemployment and a deepening imbalance of agrarian foreign trade. After "Velvet Revolution" in 1989, in the Czech Republic, there was a period of agriculture transformation, when state farms and cooperatives were privatised. Consequently, this process had a significant impact on agronomic standards, and a lack of financial resources also negatively affected the level of inputs into the crop production.

Since entry into the EU and during gradual integration of the Czech Republic to common market and implementation of the Common Agricultural Policy, deepening of structural disequilibrium has occurred.
The efforts of enterprises are, more than to market, oriented to the subsidy obtaining which results in the following:

- Changes in crop structure, i.e. total decrease of animal husbandry, especially of pigs, decrease of acreage of crops which are too demanding on quality labour including management and marketing (fruits and vegetables), and also acreage of forage crops (clovers and alfalfa) on arable land with significant positive impacts on the environment. These structural changes cause at the same time the decrease of total agricultural production. Typical Czech farm is without animal husbandry, where "three-crops" are grown (winter wheat, winter oilseed rape and maize or spring barley).
- Although the current regulatory measures (cross compliance) and stimulation agro-environmental measures within the rural area development strive for better relationships between agriculture and the environment, further soil quality degradation, water regime deterioration and biodiversity loss continuously occur. Soil quality and water regime are predominantly affected by inappropriate large-area utilization of farm land together with reduction or even giving-up of animal husbandry accompanied with shortage of organic fertilizers. Reduction of desirable diversity of soil use e.g. by growing forage crops is also one of the courses.
- Maize (*Zea mays L.)* is a crop which has an important place in a structure of crops grown in the Czech Republic. Maize areas have been increasing all over the world. In the Czech Republic the same trend is, in spite of the fact, that during the last twenty years number of livestock, which was an important consumer of silage maize, rapidly reduced. In recent years became silage maize the main source of biomass used in biogas stations. The Czech agriculture has a free market in biomass production for energetic utilization. For this purpose, up to 900-1100 thousand ha (about 25 % of farm land) can potentially be used while maintaining food self-sufficiency. The volume of energy produced from biomass occupies within the renewable energy sources (RES) increasingly important position in the Czech mixture of energy sources.

Future development in the use of RES will be formed according to the obligations of the Czech Republic which delimitate the national goal of RES proportion of gross energetic consumption to 13.5 % till 2020 or 10 % proportion of bio-fuels in transportation. Currently, this goal is being re-evaluated at the EU level. A considerable decrease of subsidies or more strict conditions of their granting can be expected in the field of RES. Goal fulfilments will be connected with orientation to energetic utilization of agricultural commodities (including energy crops and fast-growing species) and agro-wastes and crop residues for heat production or a combine production of power and heat.

- Inappropriate use of predominantly rented farmland contributes to the increase of internal and external negative impacts of climate change on soil quality, water regime and risk to conduct a business in agriculture under more and more frequent periods of drought and floods. Climate change causes the transformation of some regions into new ones, often with adverse climatic conditions (e.g. constant increase of temperature and water shortage in the South Moravian region) together with higher importance of agriculture in less favoured areas (LFA).

Soil degradation causes annual damages estimated to be 4 to 10 billion of Czech crowns (loss of arable land and soil quality, decreased yields, clogging of watercourses, property damage etc.) and poses a significant threat for long-term competitive strength of the branch. A considerable part of waters is constantly contaminated; 82 % do not reach a suitable ecological status, and 25 % of waters do not comply with a good chemical status even though nearly no watercourses flow into the Czech Republic.
On the contrary, our country is an important European water divide and the status of ground- and surface-waters is entirely dependent on precipitations and the landscape status. Water flows very fast from the Czech area due to degradable changes in agricultural land, and thus the landscape losses its retention capacity. Great part of the present cultural landscape lost its natural characters owing to unsuitable farming. This results in lower ability of the landscape to cope with fluctuations in climate change.

National legislation rules linked with soil care, especially measures for soil protection against water erosion

Handling the negative impact of agriculture on the landscape and the environment is one of the main topics of the contemporary agricultural policy. The system of cross compliance was initiated in 2003 as part of the Common Agricultural Policy reform, and became a key element in negotiations on maintenance/evolvement of EU subsidies in agriculture in the future. The compliance with standards and requirements is ensured by monitoring the performance of so-called “control” requirements. EU member states determine their own methods of inspection on the national level. Since 1 January 2009, the system of cross-compliance is applied in the Czech Republic. The direct payments and other selected subsidies can be granted only on the condition that a beneficiary meets the statutory management requirements addressing environment, public health, the health of animals and plants, and animal welfare; the standards of good agricultural and environmental conditions (GAEC, now is used abbreviation in Czech language - DZES); and minimum requirements for fertilizer and plant protection product use as part of agro-environmental measures. In case that the potential beneficiary does not meet above-mentioned conditions, the financial support may be reduced or not provided at all.

The issue of water soil erosion is addressed mainly by the Good Agricultural and Environmental Conditions standards – DZES 4 and 5, applied to agricultural parcels listed in the Land Parcel Identification System as arable land.

DZES 4 defines soil conservation measures on arable parcels with a slope greater than 5◦. Applicants for farming subsidies on this type of land are required to sow a inter-crop after harvest, latest at September, 20th and staying till sowing of chosen spring crop or to apply one of the following measures: (1) The stubble of the harvested crop is left on the block of land or part thereof until some spring crop establishment. (2) stubble breaking and leaving the soil without ploughing till crop establishment in spring.

The main aids of DZES 5 are to protect soil against water erosion and to reduce both direct impacts of erosion and indirect impacts caused by flooding and muddy floods. There are two categories of soils classified: strongly and slightly endangered soils.
Applicants for farming subsidies (direct payments) on land classified as strongly endangered by erosion are required through cross-compliance not to grow wide-row crops on this land, i. e. maize, potatoes, beetroot, broad beans, soybean, sunflower and sorghum. Cereals and rapeseed crops are to be planted using soil conservation technologies, when crop residues cover on soil surface is at least 30 % till emergence of crop. For cereals, these measures are not required where the crop is sown into protective clover or grass-clover.
On slightly endangered soils, the applicant is required to grow wide-row crops only with soil conservation technologies. Limit for minimum crop residue cover is changing with developing of crop stand: 20% is requested during sowing, 10 % till June, 30 and visual provability of usage of conservation tillage system after July, 1.

Results from agricultural research in South Moravia

Table 2 includes the results from impact of soil tillage on soil properties. Values of bulk density increased with lower intensity of soil tillage and with soil depth. Values around 1.50 g cm^{-3} were found out in variant MT and NT (except surface layer). The highest values of soil porosity were in CT (50.24 % in average of 0-0.30 m), the lowest in NT (44.18 %). Smaller differences in soil porosity were between layers 0.10 – 0.20 m and 0.10 – 0.20 m in all variants of soil tillage. Minimum air capacity decreased with intensity of soil tillage, in MT and CT. The values in deeper layers were lower than 10 %. Soil moisture was the highest in NT, where surface and the deepest layers had the highest values. CT and MT variants had the driest layer close to the surface. Smutný et al. (2013) found out non-significant differences among variant of soil tillage.

Table 2. Physical soil properties (Visnove, 2005 – 2010)

soil layer	bulk density (g cm^{-3})			soil porosity (%)			minimum air capacity (%)			soil moisture (%)		
soil tillage	CT	MT	NT	CT	MT	NT	CT	MT	NT	CT	MT	NT
0 - 0.10 m	1.19	1.22	1.36	54.92	53.64	48.37	20.01	17.25	11.97	17.41	21.99	27.37
0.10 - 0.20 m	1.35	1.53	1.52	48.71	41.68	42.07	12.39	7.94	8.44	25.10	25.66	23.70
0.20 - 0.30 m	1.39	1.49	1.52	47.09	43.35	42.15	10.87	10.13	9.10	25.12	25.67	27.23
average 0 - 0.30 m	**1.31**	**1.41**	**1.47**	**50.24**	**46.22**	**44.18**	**14.42**	**11.77**	**9.84**	**22.54**	**24.44**	**26.10**

Above mentioned results are in relation with results of other authors. According to Birkás (2013), soil quality is focused on dynamic soil processes and properties influencing plant production risks even in the long term. Any method of tillage may be considered as beneficial

if the soil is not damaged while fulfilling plant demands or if the soil physical and biological quality is improved.

Soil tillage and water infiltration rate

The results from location Visnove shown, that the highest infiltration rate in first minutes was for conventional variant (CT) and the lowest for no tillage variant (NT). But this order was changing through time intervals (1, 10, 30 and 60 min) and the infiltration rate of NT was increasing to the level of CT variant. This corresponds to the review of Strudley et al. (2008), which describes the tendency of NT to increase macropore connectivity and deeper movement of water. Lipiec et al. (2006) noted that the differences in initial infiltration and reduction of infiltration rate with time among tillage treatments imply higher capability of conventional tillage pore system to increase amount of water infiltrating before filling macro-pores and reaching steady state. Kroulík et al. (2007) compared the differences between tillage practices at same locality in 2006. The results were similar – the highest infiltration rate was observed for CT and lowest for minimum tillage (MT) variant. Coloured water infiltration was used as well, and it showed a water saturation of CT in the top layer, while the variants with reduced tillage (MT, NT) were saturated deeper.
Results of influence of different row spacing and stand density on silage maize yields and statistical comparison of variants in both observed years 2013 and 2014 are in Fig. 1. In 2013 were statistically significant higher yields in case of narrow rows and twin rows compared to standard spacing 0.75 m. Standard technology also had lower dry matter at harvesting time. In relative values it is a difference 37 – 42 %. Only in case of twin rows stand yields increased due to an increased sowing rate (+ 28% compared to the standard sowing rate).

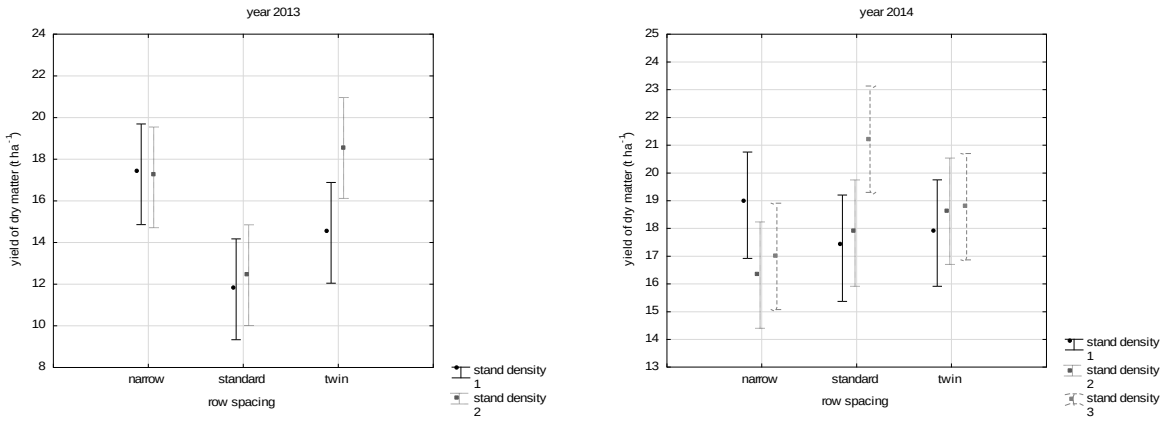

Figure 1. Yields of aboveground dry matter of maize grown under different row spacing and stand density in 2013 and 2014

Different results were reached in 2014. There were not found statistically significant differences among variants with different row spacing as in case of sowing densities. The highest yield of aboveground biomass was from variant with standard row spacing (0.75 m; 18.76 t ha^{-1}), lower from twin rows (18.39 t ha^{-1}) and the lowest from narrow rows variant (17.87 t ha^{-1}). In case of twin rows and standard technology the yields increased as sowing rate increased but the difference was not statistically significant. Twin rows proved the highest yield in case of the variant with the lowest seed rate. Explanation for different results in 2013 and 2014 can be given by different rain precipitation distribution during vegetation season. In 2013 was the first part of vegetation season humid and the summer part of vegetation season was significantly dry. Distribution of rain precipitation in the vegetation

season 2014 was in comparison to year 2013 reversed. Smutný et al. (2015) published more detailed results from this field trial, included the effect of different technologies on soil moisture, temperature and relative air humidity.

Two years results showed an advantage of maize growing in narrow rows proved by higher yields in a season with longer dry period during the first part of vegetation season. Under these conditions stand cover was involved earlier, which gave preconditions for better water management. In the wet year with sufficient amount of precipitation during vegetation season was maize yield in case of narrow rows the lowest but without statistically significance compared with others row spacing technologies. Nowadays, suitability of "narrow maize cropping system" is evaluated in the field conditions in different locations in the Czech Republic.

According to Czech legislation linked with protection of soil against erosion, different types of conservation tillage methods are applied by farmers. Conservation tillage technologies, where ploughing is replaced by tillers and shallow soil loosening, are increasingly used as soil treatments. It is typical for shallow soil tillage that all crop residues are left on the soil surface, or in the treated (tilled) upper soil layer. Crop residues can play a very important role by the next crop cultivation. Leaving crop residues on the soil surface year around, before and after planting provides soil surface protection at critical times to protect the soil against wind and water erosion. Reducing tillage operations improves soil surface properties, including improved soil aggregation accounting for increased infiltration and percolation; less compaction due to less usage of field implements; and more biological activity due to an increase in organic matter. Adding soil surface cover increases water infiltration, reducing soil drying and maintains more moisture for crop utilization. Especially conservation tillage systems with their modification are increasingly being introduced under the economic pressure on the fields of the Czech Republic (Mašek et al., 2012).

The inter crops have an important role in cropping systems. Integration of crop into crop rotation in short grow period between the two main crops protects the soil against erosion, supplies the soil with easily decomposable organic matter (Thorup-Kristensen, 1994), enhances the physical and chemical properties of soil (Eichler-Löbermann et al., 2008) and soil biological activity (Piotrowska and Wilczewski, 2012). The effect of catch crops on the reduction of erosion risk depends on the crop stand establishment, height of plants, leaf area index (LAI) and duration of soil coverage (Janeček, 2007). The highest values of coverage were found for variants with white mustard, phacelia and crambe, the lowest for buckwheat and common millet in field experiment in period 2007-2012 in Žabčice (Lukas et al., 2013). However, the results were strongly influenced by the year.

Conclusion

The results have shown that conventional and also minimum soil tillage can be suitable for maize growing, especially in lowlands. For areas endangered by water erosion, different modifications of conservation tillage are used. Suitable soil tillage management has to create good conditions for germination, emergence a development of maize stands. Conditions for high yield productivity could be in relation with improvement of soil fertility and protection soil against erosion.

AGROECONOMIC KNOWLEDGE IN THE FUNCTION OF AGRICULTURAL EXTENSION SERVICES

Snežana JANKOVIĆ[1], Nebojša NOVKOVIĆ[2], Zorica VASILJEVIĆ[3]

Abstract

The role of agricultural advisory services in the second half of the 20th century both in the Republic of Serbia and in other countries of former Yugoslavia consisted primarily of collecting information, innovations and knowledge from agricultural research and educational institutions and transferring them to the farmers, in order to increase production and labour productivity, and to introduce innovations and technological progress into farming practices. Advisory services mainly comprised activities related to biological, technical and technological knowledge in agriculture. The structure of employed advisers confirms this fact (only 6.6% of advisers in Serbia are agricultural economists). Development of market economy has put a focus on economic aspects of production, so agricultural advisory was faced with the need to expand its scope of work, switching to the "market-oriented" mission, which requires the introduction of an increasingly wider range of agro-economic knowledge in the activities' programme of advisory services. The European integration processes have confirmed and strengthened this tendency.

The paper analyses the state of agricultural advisory services in the Republic of Serbia and its development perspectives concerning agro-economic knowledge and activities imposed as an imperative for the current agricultural and rural development stage, as well as the preparation processes for European integration. In addition to the methodological procedures commonly used for this type of research (desk research, the method of deduction, descriptive statistics), the authors also used the results of the survey conducted in April and June 2015 on the sample of about 30% of advisers who work in Central Serbia.

The results show that most of the advisers think their scope of work has been increased in the last few years by agro-economic activities, and therefore they need some additional training on agro-economics. Since 2010 the Institute for Science Application in Agriculture (IPN), as an appointed training institution, has been constantly incorporating agro-economic courses for advisers into annual training plans. It is necessary for the Agricultural Advisory Service of Serbia to strengthen its capacities – to employ more agricultural economists and continue to organise regular training courses for the existing staff, especially in domain of agricultural economics.

Key words: *agricultural advisory, agro-economic knowledge, European integration, Serbia*

Introduction

The first written records of the agricultural advisory beginnings can be traced back to 1800 BC, to ancient Mesopotamia (modern-day Iraq), where clay tablets were found with advice on irrigation and pest management. In Egypt, data on flood advice were found. Onwards, such written records with agricultural advice can be traced from Ancient Greece and the Phoenician civilization all along to Ancient Rome (Radišić, 2015).

The beginnings of modern advisory are related to founding the first farmers' association in 1723 in Scotland, while the first practical advisory activities started in 1743. Soon after that, such associations started to emerge in other leading agricultural countries in Europe (France,

Denmark, England, Germany) as well as in the USA. In the 19th century there were eight of them, 33 more were founded by the Second World War and 49 in the post-war period (Ceranić et al., 2011).

The work of Philipp Emanuel von Fellenberg is important for advisory development in Europe. A decade after purchasing an estate in Switzerland in 1799, he started founding agricultural schools. These schools, albeit not being the first of such kind, led to spreading ideas of advisory work in Denmark, Germany, France and Great Britain. On the Universities of Cambridge and Oxford the idea of agricultural advisory gained ground in 1890s, spreading to the USA, where agricultural advisory (extension) services were established within land-grant universities. In the USA, the Morill Act at the end of 19th century allowed establishing of land-grant universities, and within them, agricultural advisory services. The Smith-Lever Act of 1914 formalised advisory tasks and defined funding models.

Further development and modernisation of the society and economy have inevitably led to emergence and growth of professional consulting services and advisory work. While agricultural advisory in developed European countries started in the mid-18th century, its beginnings in Serbia could not be traced before the mid-19th century. In the 20th century, advisory developed significantly in Europe and the USA, as well as in other parts of the world. Today it is hard to find a country without some kind of a formally organised agricultural advisory service.

The role of agricultural advisory, its form of organisation, operation and growth in Serbia and in the world have been subject-matter for numerous Serbian authors, among which: Novković (Novković et al., 1993; Somođi, Novković, 1992; Šnjegota, Novković, 1997, Novković et al., 2013), Janković S. (Janković et al., 2013; Berjan et al., 2015; Janković et al., 2015; El Bilali et al., 2015), Janković. D. (Petrović, Janković, 2010; Hoffmann et al., 2008.1; Hoffmann et al., 2008.2;), Ceranić (Ceranić et al., 2011) and others.

Agricultural Advisory Service of the Republic of Serbia

The work of the Agricultural Advisory Service of the Republic of Serbia (PSSS) is defined by the Law on Advisory and Expert Services in Agriculture, adopted in 2010 (Law on Advisory and Expert Services in Agriculture, 2010 / *Zakon o obavljanju savetodavnih i stručnih poslova u oblasti poljoprivrede, 2010*).

PSSS operates as:

- Agricultural Advisory Service in the Autonomous Province of Vojvodina and
- Agricultural Advisory Service in Central Serbia.

PSSS comprises 34 centres, covering the whole territory of Serbia and employing 259 advisers trained to provide agricultural advice. The work of 22 centres (agricultural stations and institutes) in Central Serbia is coordinated by the Institute for Science Application in Agriculture (IPN), whereas the work of 12 centres and the Oenological station – Vrsac in the AP Vojvodina is coordinated by the Provincial Secretariat for Agriculture, Water Management and Forestry. Advisory services in animal husbandry are also provided by the veterinary stations. The advisory stakeholders are also agricultural input companies, private advisers, as well as the local NGOs.

The Serbian Ministry of Agriculture and Environmental Protection together with the Provincial Secretariat for Agriculture, Water Management and Forestry provide the institutional framework for work and development of agricultural advisory services, ensuring legislation and finances. The government ensures farmers receive advice free of charge.

During the second half of the 20th century, the role of agricultural advisory services in the Republic of Serbia, as well as in other countries of former Yugoslavia, consisted primarily of collecting information, innovations and knowledge from agricultural research and educational

institutions and transferring them to farmers, in order to increase production and labour productivity, and to introduce innovations and technological progress into farming practices.
The “production-oriented“ mission also determined the content of advisory activities and services that were offered to farmers at the time. Advisory services mainly comprised activities related to the biological, technical and technological knowledge in agriculture. The structure of advisers employed in PSSS today confirms this fact (only 6.6% of advisers in Serbia are agricultural economists).
The current Law on Advisory and Expert Services in Agriculture defines advisory services in agriculture as activities performed to: “increase general knowledge and awareness of farmers; increase competitiveness and modernise agricultural production; increase profitability; enhance the quality of products; introduce the production of safe food; encourage farmers to associate; protect natural resources and the environment; improve living conditions and the culture of life in rural areas and, consequently, improve rural development“ (Law on Advisory and Expert Services in Agriculture, 2010 / *Zakon o obavljanju savetodavnih i stručnih poslova u oblasti poljoprivrede, 2010*).
Agricultural knowledge is transferred along all levels of formal education (from secondary education to PhD studies) through different types of training organised by various educational and research institution and organisations, PSSS, private enterprises, project units, media, etc. (Agriculture and Rural Development Strategy for the period 2014-2024, 2014 / *Strategija poljoprivrede i ruralnog razvoja Republike Srbije za period 2014-2024. godine, 2014*). Since 2010, advisors’ training has been organised by an authorised institution – the Institute for Science Application in Agriculture.
According to the Strategy, the general objectives of agricultural advisory services are, as follows: production of safe food, profitable production, increased competitiveness and higher quality of agricultural products, encouraging farmers to associate in interest groups, improving farmers’ knowledge, enabling farmers to run the farm successfully, protection of natural resources and the environment, and rural development. In addition to these general objectives, the Strategy also defines the following advisory activities within the scope of work of PSSS: increasing the competitiveness of agricultural production; upgrading the existing knowledge of farmers and raising their awareness; training of farmers on how to make their production and run farms more successfully; assisting farmers in production and with economic and organisational issues related to farm development; improving economic position of farms; increasing farmers’ income; adjusting production to match natural resources and market demands; encouraging entrepreneurship in agriculture and in rural areas; protecting and improving natural resources; encouraging farmers to associate in interest groups; helping farmers to plan how to improve future production and develop their farm; and rural development (Development Strategy of Agricultural Advisory in Serbia, 2009 / *Strategija razvoja poljoprivrednog savetodavstva u Srbiji, 2009*).
From the above mentioned one can see that the mission of agricultural advisory has been shifting over the last ten years from the “production-oriented“ one to the “market-oriented“ mission, so agricultural advisory was faced with the need to expand its scope of work, switching to a “market and development-oriented“ mission, which requires the introduction of an increasingly wider range of agro-economic knowledge in the work programme of advisory services. (Janković et al., 2013; Berjan et al., 2015; Janković et al., 2015). The process of European integration has confirmed and strengthen this tendency (El Bilali et al., 2015).
The authors of this paper tried to investigate whether advisers in the Republic of Serbia are ready to adjust their activities to the present requirements. In other words, whether they are ready for a new “market and development-oriented“ mission of advisory that implies a wide range of agro-economic knowledge.

Materials and Methods

In addition to the methodological procedures commonly used for this type of research (desk research, the method of deduction, descriptive statistics), the authors used the results of the survey conducted in April and June 2015 on advisors employed in the Agricultural Advisory Service of Serbia who work on the territory of Central Serbia. The survey comprised 49 advisers, which makes 18.9% of the total number of advisers employed in the Agricultural Advisory Service of Serbia (259), i.e. 29.3% advisers who work on the territory of Central Serbia (167). The survey used a questionnaire with both open-ended and close-ended questions.

Results and Discussion

The goal of the questionnaire was to show the advisers' level of agro-economic knowledge, to indicate whether there had been some changes in the structure and character of their activities in the last few years, or whether they dealt with agro-economic issues more than before. Moreover, the questionnaire also asked for advisers' opinions on whether they need some more advanced training on agro-economics. At this point, the goal of survey was not to introduce the farmers, their opinions and level of agri-economic knowledge, but there is a plan for such survey in the future.

Most of the surveyed advisers had formal education in the field of agro-economics and fruit and wine production.

Table 1. Educational profile of the surveyed advisers

Educational profile	Number of advisers	Structure (%)
Agro-economics	10	20.4
Fruit and wine production	10	20.4
Animal husbandry	8	16.3
Plant protection (Phytopharmacy)	8	16.3
Field and vegetable crop production	6	12.2
General course	4	8.1
Soil amelioration	1	2.1
Technology	1	2.1
Organic production	1	2.1
Total	49	100.0

Source: Anketa savetodavaca (Survey of advisers)

One fifth of the surveyed advisers (20.4%) were graduate agricultural economists, which implies they have a wide range of agro-economic knowledge.

Most of the surveyed advisers were young people with less than three years of experience (42.9%), or 4-6 years of experience (28.6%) in agricultural advisory.

Table 2. Year of experience of the surveyed advisers

Years of experience	Number of advisers	Structure (%)
Less than 3 years	21	42.9
4-6 years	14	28.6
7-10 years	9	18.4
over 10 years	2	4.0
No answer	3	6.1
	49	100.0

Source: Anketa savetodavaca (Survey of advisers)

When asked whether they had been required to do more agro-economic activities in their advisory work over the last 3-5 years, 75.5% of the advisers gave a positive answer, 10.2% gave a negative answer, while 14.3% did not answer at all or said they were not sure.
The advisers were also asked to assess their own knowledge of agro-economics from 1 to 5 (1 – unsatisfactory and 5 – excellent).

Table 3. The advisers' self-assessment on agro-economic knowledge

Grade	Number of advisers	Structure (%)
Excellent (5)	4	8.2
Very good (4)	7	14.3
Good (3)	32	65.3
Satisfactory (2)	6	12.2
Unsatisfactory (1)	0	0.0
	49	100.0

Source: Anketa savetodavaca (Survey of advisers)

Most of the surveyed advisers (65.3%) assessed their agro-economic knowledge as "good". Grades 4 and 5 ("very good" and "excellent") were mostly given by advisers who had formal agro-economic education.
A relatively high percentage of advisers who assessed their knowledge as "very good" and "excellent" is also a result of trainings that IPN has been continuously conducted since 2010, primarily through modules on *Farm management*, *European integrations* and other topics.
It is also interesting the advisers' assessment of previously organized agro-economic training courses. Most of the advisers (77.6%) thought the previous agro-economic training courses were not sufficient enough. Only 8.1% of the advisers considered there had been enough training courses on improving agro-economic knowledge, whereas 10.2% of the advisers thought there had not been enough training on topical agro-economic issues. Two advisers (4.1%) did not answer this question.
Finally, the advisers were also asked which agro-economic topics they need to be trained for in the future. There were offered 16 topics to the advisers where they could chose more than one item. The results are shown in Table 4.

Table 4. Agro-economic topics for future training courses

Topic	Number of answers	Structure (%)
Costs and calculations in agricultural production	20	8.5
Financing of agriculture and rural development	24	10.1
Market and prices in agriculture	19	8.0
Risks and insurance in agriculture	19	8.0
Monitoring and recording of farm data	8	3.4
FADN methodology	4	1.7
Farm management	6	2.5
Principles of cooperatives and their establishment	11	4.6
Business plans and project management	23	9.7
Agriculture and rural development strategy	9	3.8
Agricultural and rural development subsidies	8	3.4
EU pre-accession funds (IPA and IPARD funds)	41	17.3
Interest grouping (establishment of unions, associations, clusters, etc.)	17	7.2
Rural development	10	4.2
Other on-farm activities that can increase income of the family farms	17	7.2
Other topics*	1	0.4
Total	237	100.0

*Only one adviser suggested training on "Export agreements".
Source: Anketa savetodavaca (Survey of advisers)

The most of advisers (17.3%) said they need training on using the EU pre-accession funds (IPA and IPARD funds), which was expected because Serbia is about to start using money from these funds and advisers have not been trained on possibilities and applying procedures. Financing of agriculture and rural development ranked second (10.1%), and making business plans and project management ranked third (9.7%). Although the business plan making was the topic of several training courses in the past, it seems to be something that is always topical and useful.

Conclusion

Agricultural advisory has a long tradition in Serbia, where it started in the mid-19th century. Nowadays, the Agricultural Advisory Service of Serbia (PSSS) is organised through 34 centres, employing 259 advisers. PSSS is under charge of the Ministry of Agriculture and Environmental Protection and the Provincial Secretariat for Agriculture, Water Management

and Forestry (territory of the AP Vojvodina). The Ministry of Agriculture and Environmental Protection delegated the organisation of advisers' training to the Institute for Science Application in Agriculture – an appointed training institution on the territory of Central Serbia.

During the second half of the 20th century, the role of PSSS was mostly about collecting agricultural information, innovations and knowledge from research and educational institutions and transferring them to farmers, in order to increase production and labour efficiency and introduce some innovations and technological progress into farming practice. In other words, the mission of PSSS was mainly "production-oriented". The development of market economy put a focus on economic and organisational aspects of agricultural production. Hence, a wider scope of work and "market-oriented" mission has become the imperative for agricultural advisory. Since 2010 agro-economic topics have been constantly incorporated into the annual training plans for advisers' training courses organised by the Institute for Science Application in Agriculture.

In the mid-2015, the advisers employed in PSSS were subjected to a survey, by given a questionnaire. The goal of the questionnaire was to show the level of advisers' agro-economic knowledge, to indicate if there have been some changes in the structure and character of their activities in the last few years, or whether they deal with agro-economic issues more than before. Moreover, the questionnaire also asked for advisers' opinions on whether they need more advanced training on agricultural economics. The results confirmed the expected – PSSS lacks advisers with formal agro-economic education (only 6.6% of such advisers are currently employed in PSSS). A large number of the surveyed advisers (75.5%) confirmed that they had been lately required to do more agro-economic activities in their advisory work. Most of the advisers assessed their knowledge as "good" (average). However, most of the advisers (77.6%) thought the previous agro-economic training courses were not sufficient. When asked to choose among 16 of agro-economic topics for future training courses, most of the advisers (17.3%) said they need training on EU pre-accession funds (IPA and IPARD funds) most. The second-ranked topic was financing of agriculture and rural development (10.1%).

The programmes for improving PSSS should be created in such way to take into account new needs that advisory is facing, both when it comes to training programmes for currently employed advisers and training programmes for future staff. Moreover, the results of the questionnaire are also important for designing agricultural curricula of Serbian educational institutions, primarily universities, where courses in the field of agricultural economics have been recently left out from the curricula on biological and technological departments or put as the elective courses (according to the "Bologna Process" accreditation conditions). Graduate students of biological and technological departments at the faculties of agriculture in Serbia therefore today have less agro-economic knowledge, which contradicts the imperative imposed by the market-oriented economy.

It is evident that the Agricultural Advisory Service of Serbia needs to strengthen its capacities in terms of employing more agricultural economists, organising more follow-up trainings and intensifying regular training of its staff on agro-economic matters.

Abstract

Antioxidants are vital substances which possess the ability to protect the body from damage caused by free radical induced oxidative stress. Epidemiological studies specify that intake of fruits and vegetables have the ability to inhibit the damaging behavior of free radicals in the human body. The present research was undertaken to explore the antioxidant potential of the methanolic extract of two Algerian dry date varieties (Frezza and Mech-Degla). The research was under taken to determine the total phenolics and flavonoides using Folin-Ciocalteu's and aluminum chloride colorimetric methods. The antioxidant ability was assessed by using 2,2-diphenyl-1-picrylhydrazyl (DPPH), ferric reducing/antioxidant power (FRAP) and β-carotene-linoleic acid. The total phenolic content (TPC) of the two studied varieties ranged from 13.48-25.94 mg gallic acid equivalent (GAE)/100 g of fw and the total flavanoid content (TFC) ranged from 2.97-3.05 mg quercitin equivalent (QE)/100 g of fw. The DPPH assay (91.57% and 93.68%) and the FRAP assay (112.98 and 116.49 mg VitCE/100 g) showed the highest inhibition, whereas the FRAP assay (54.16 and 55.92 mg BHAE/100g ; 21.04 and 21.74 mg GAE/100 g ; 40.91 and 42.22 mg QE/100 g) and the β-carotene assay (24.19% and 24.10%) showed the lowest inhibition of methanolic extracts of two varieties Frezza and Mech-Degla, respectively. In the present research, it is found that date palm fruit extracts have remarkable antioxidant activities. Its phenolic and flavonoid contents could be responsible for its antioxidant activity.

Key words: *Date palm fruit, Total phenols, DPPH, ß-carotene and FRAP.*

Introduction

Date palm tree, *Phoenix dactylifera* L., is an important plantation crop for many countries. Worldwide production of dates in 2013 was 7 627 624.4 tons. With a production of 848 199 tons, corresponding to 11.12 % of the worldwide production, Algeria is the 4th world producer (FAOSTAT, 2013). This production ensures an important income for the national economy, providing at the same time a significant resource for local consumption.

Fruits and vegetables have been implicated in preventing or reducing the risk of coronary heart diseases, cancer and other chronic diseases. For these reasons, recommendations to increase the dietary intakes of fruits and vegetables have been suggested by many world authorities. The potential health benefits of fruits and vegetables have been partially attributed to their polyphenols contents (Abdullah Saleh et al., 2011).

These compounds are secondary metabolites that gather a large set of molecules, divided into fourteen chemical classes (Vermerris & Nicholson, 2006). They are found in all parts of higher plants (roots, stems, leaves, flowers, pollens, fruits, seeds and wood), where they have significant role in many physiological processes such as growth, reproduction and defence (Lugasi et al., 2003). These valuable molecules possess very interesting biological properties, which are used in various fields, such as medicine, pharmacy and nutrition.

In this present work we carried out a measurement of total phenolic content, total flavonoids and evaluation of their antioxidant activities (DPPH radical scavenging capacity, reduction capability and percentage inhibition of β-carotene) of methanolic extracts from two Algerian dry date varieties: Frezza and Mech-Degla.

Materials and methods

Plant material

Fresh ripe date samples used in this study consisted of two cultivars of dry dates locally known as Frezza and Mech-Degla dates. The samples were selected identically in terms of size, colour, ripening stage, without damage and calamity, and were stored in paper bags at 4 °C until use.

Chemicals and standards

Aluminum chloride, β-carotene, BHA (Butylated Hydroxyl Anisole), chloroform, DPPH (2,2-diphenyl-1-picryhydrazyl), ferric chloride, Folin-Ciocalteu's reagent, gallic acid, linoleic acid, methanol, potassium ferricyanide, quercetin, sodium carbonate, trichloroacetic acid, Tween 40, and vitamin C were purchased from Fluka Chemie (Switzerland), Merck (Germany) and Sigma-Aldrich (USA). All Chemicals and reagents used in the experiments were of analytical grade.

Moisture content

Moisture was determined according to standard AOAC method 920.151 (AOAC, 1998).

Extraction of the phenolic compounds

Ten grams of cleaned pitted fruits was extracted with 30 ml of methanol (80%) at room temperature (20°C) for 5 hours with continued agitation. After filtration and centrifugation (at 4000 g, for 10 min), the extracts were concentrated under reduced pressure at 40 °C in a rotary evaporator. The extracts were then redissolved in 10 ml of the same solvent. These concentrated extracts were used to determine total phenolics, flavonoids content, and antioxidant activities of date palm fruits. All the measurements were taken in triplicate and the mean values were calculated.

Total phenolics content

Total phenolics were estimated using Folin-Ciocalteu's reagent as described by Juntachote et al. (2007). 0.5 ml of each sample was mixed with 5 ml of distilled water and 1 ml of Folin-Ciocalteu's reagent, after 3 min, 1 ml of 7.5 % sodium carbonate was added. The final mixture was shaken and then incubated for 1 h in the dark at room temperature. The absorbance was measured at 640 nm using Shimadzu UV-120-01 spectrophotometer.

Total flavonoids content

Total flavonoids content were estimated using the colorimetric assay according to Gursoy et al. (2009). One ml of 2 % aluminium methanolic trichloride solution ($AlCl_3$) was mixed with 1 ml of the methanolic extracts. Test tubes were incubated at room temperature for 10 min and the absorbance was determined at 415 nm.

Antioxidant activities

Free radical scavenging by using DPPH radical

The DPPH radical scavenging capacity was determined using the method described by Mansouri et al. (2005). Twenty five µl of sample were added to 975 µl methanolic solution of DPPH (6×10^{-5} M) and vortexed, the mixture was left in the dark for 30 min and the absorbance measured at 515 nm.

DPPH radical scavenging capacity was estimated according to the following equation (Lu et al., 2011) :

$$\text{DPPH radical scavenging capacity (\%)} = \frac{(\text{Abs}_{515}\ \text{DPPH} - \text{Abs}_{515}\ \text{Sample})}{\text{Abs}_{515}\ \text{DPPH}} \text{ x } 100$$

Where Abs_{515} DPPH is the absorbance of the control solution (containing only DPPH), and Abs_{515} Sample is the absorbance in the presence of the date extracts.

The scavenging activity was calculated from the calibration curve. BHA (0-200 µg/ml), gallic acid (0-80 µg/ml), quercitin (0-200 µg/ml) and vitamin C (0-500 µg/ml) were used as a references to produce a standard curves. The same antioxidant capacity of the methanolic extracts of tow date cultivars was compared to those of the standards and all results were expressed as a microgram standard equivalent antioxidant capacity per gram of fresh weight (µg SEAC/g fw).

Ferric Reducing Power Assay (FRAP)

The reducing power was determined according to the method of Oyaizu (1986) with a slight modification (Gülçin, 2006). One ml of each extract was mixed with 2.5 ml of 200 mM sodium phosphate buffer (pH 6.6) and 2.5 ml of 1% potassium ferricyanide. The mixture was incubated at 50°C for 20 min. Then, 2.5 ml of 10% trichloroacetic acid were added. 2.5 ml of this mixture was added to 2.5 ml of distilled water and 0.5 ml of 0.1% ferric chloride and the absorbance was measured at 700 nm. Increased absorbance of the reaction mixture indicates an increase of reduction capability.

The reduction capability was calculated from the calibration curve. BHA (0-200 µg/ml), gallic acid (0-80 µg/ml), quercitin (0-100 µg/ml) and vitamin C (0-300 µg/ml) were used as a references to produce a standard curves. The reduction capability of the methanolic extracts of tow date cultivars was calculated and all results were expressed as a milligram standard equivalent per gram of fresh weight (mg SE/g fw).

β-carotene/linoleic acid bleaching assay

The total antioxidant activity was evaluated using β-carotene-linoleic acid test system (Kulisic et al., 2004 and Gursoy et al., 2009), with a little modification. Briefly, β-Carotene (2 mg) in 4 ml of chloroform was added to 25 µl of linoleic acid and 200 mg of Tween 40 emulsifier mixture. After evaporation of chloroform under vacuum at 50 °C by a rotary evaporator, 100 ml of distilled water saturated with oxygen was added by vigorous shaking to form emulsion A. 2.5 ml of this mixture were transferred into 0.5 ml of the samples. A control negative (without antioxidant) consisting of 0.5 ml of methanol and 2.5 ml of emulsion A was prepared. A second emulsion (B) consisting of 25 µl of linoleic acid, 200 mg of Tween 40 and 100 ml of distilled water saturated with oxygen was also prepared. Methanol (0.5 ml), to which 2.5 ml of emulsion B was added, was used to zero the spectrophotometer. Readings of all samples were taken immediately (t = 0) and after incubation (50°C) at 30 min intervals for 120 min at 490 nm. Measurement of absorbance was continued until the color of β-carotene disappeared.

Antioxidative activities of the extracts were compared with those of BHA (0-100 µg/ml), gallic acid (0-400 µg/ml), quercitin (0-100 µg/ml), vitamin C (0-400 µg/ml). The same antioxidative activities of the methanolic extracts of tow date cultivars was compared to those of the standards and all results were expressed as a microgram standard equivalent antioxidative activities per gram of fresh weight (µg SEAA/g fw).

The antioxidative activities (percentage inhibition) of β-carotene was calculated according to the following equation (Bourkhiss et al., 2010) :

$$AA\ (Inhibition\ \%) = \frac{A_{120\ (Sample)} - A_{120\ (Control)}}{A_{0\ (Sample)} - A_{120\ (Control)}}\ x\ 100$$

Where : $A_{120\ (Sample)}$ is the absorbance of the sample at t = 120 min, $A_{120\ (Control)}$ is the absorbance of the control at t = 120 min, $A_{0\ (Sample)}$ is the absorbance of the sample at t = 0 min and $A_{0\ (Control)}$ is the absorbance of the control at t = 0 min.

Statistical analysis

Pearson's correlation was carried out to study the relationship between the antioxidant activities (DPPH radical scavenging capacity, reduction capability and percentage inhibition of β-carotene), total phenolics and Total flavonoids. Data were reported as means ± standard deviation of triplicate experiments. Data were analyzed using SPSS statistical software (Version 21.0).

Results and discussion

Two varieties of date palm fruit from Algeria used in this study were dry dates namely Frezza and Mech-Degla (moisture content 11.51 and 15.57%, respectively).

Total phenolics content

The total phenolics content of the two cultivars ranged between 13.48 to 25.94 mg GAE/100 g fw (Table 1). Compared to other fruits, the two studied date varieties have nearly the same levels of polyphenols than those found by Dacosta (2003), in cherry, pear, peach, apricot and grapefruit which have levels varying between 60-90, 2-25, 10-150, 30-43 and 50 mg/100 g fresh weight respectively.

Dates like the other fruits are a good source of natural antioxydants and could potentially be considered as functional food (Al-Farsi et al., 2005)

Total flavonoids content

Total flavonoids of the two studied varieties Frezza and Mech-Degla are respectively 2.97 and 3.05 mg in terms of quercetin equivalent/100 g fresh weight of sample (Table 1). They account for 22 and 11.76 % of the rate of total polyphenols. Total flavonoids content of the two studied varieties are comparable with those of some fruits reported by Chun et al., (2005), who gave values of 0.63, 1.77, 5.07, 7.30 and 11.82 mg/100 g fresh weight respectively for honeydew melon, tomatoes, grapefruit, kiwifruit and oranges. Our results are slightly lower to that of some fruits reported by Lin, & Tang (2007), with a values of 14.6, 37.6 and 14.2 mg/100 g fresh weight respectively for strawberry, oriental plum and loquat.

Flavonoids are a group of polyphenolic compounds diverse in chemical structure and characteristics. They occur naturally in fruit, vegetables, nuts, seeds, flowers, and bark and are an integral part of the human diet. Dietary intake of flavonoids range between 23 mg/day estimated in The Netherlands and 170 mg/day estimated in the USA (Cook, & Samman, 1996 ; Heim, et al., 2002). Flavonoids are classified into eight groups: flavans, flavanones, isoflavanones, flavones, anthocyanidines, isoflavones, chalcones and flavonolignans. More than 8000 compounds of flavonoid structure have been identified (Hodek et al., 2002). Flavonoids are absorbed from the gastrointestinal tracts of humans and animals and are excreted either unchanged or as flavonoid metabolites in the urine and fecal slurries (Stevenson, et al., 2009 ; Crozier, et al., 2010). Most of the beneficial health effects of flavonoids are attributed to their antioxidant and chelating abilities. They have been used to treat a wide variety of human conditions including inflammation, allergy, headache, cancer, viral infections, gastric and duodenal ulcers (Cook, & Samman, 1996 ; Heim, et al., 2002 ; Ndhlala et al., 2007).

Table 1. Total phenolics and total flavonoids contents of two dry Algerian date cultivars

Values are means (n = 3) ± SD ; **fw :** Fresh weight ; **GAE :** Gallic acid equivalent ; **QE :** Quercitn equivalent.

Cultivar	Frezza	Mech-Degla
Total phenolics (mg GAE/100 g fw)	13.48 ± 0.39	25.94 ± 0.8
Total flavonoids (mg QE/100 g fw)	2.97 ± 0.34	3.05 ± 0.09

Antioxidant activities

DPPH scavenging capacity of date extracts

Results of comparison between the same radical scavenging capacities of the methanolic extracts of two date cultivars and those of the standards are shown in Table 2. With a 259.42 µg/g fw for total phynolics content, Mech-Degla date showed a level of total antioxydant capacity (93.68 %) slightly higher than Frezza (91.57 %) with a BHA, gallic acid, quercitin and vitamin C equivalents antioxidant capacity values of 300.33, 97.40, 238.14 and 870.40 µg/g fw, respectively. Total antioxidant activity was also found to increase in a dose dependent manner.

Table 2. DPPH scavenging capacity and standards equivalent antioxidant capacity per gram of fresh weight of date fruits (µg SEAC/g fw).

Values are means (n = 3) ± SD ; **TP:** Total phenolics; **TF:** Total flavonoids; **DPPHSC:** DPPH scavenging capacity; **BHAEAC, GAEAC, QEAC and VitCEAC:** BHA, Gallic acid, Quercitin and Vitamin C equivalent antioxidant capacity.

Cultivar	TP (µg/g fw)	TF (µg/g fw)	DPPHSC (%)	BHAEAC (µg /g fw)	GAEAC (µg /g fw)	QEAC (µg /g fw)	VitCEAC (µg /g fw)
Frezza	134.82 ± 0.39	29.69 ± 0.34	91.57 ± 0.91	293.79 ± 4.33	95.22 ± 0.94	232.33 ± 2.49	851.83 ± 25.48
Mech-Degla	259.42 ± 0.8	30.46 ± 0.09	93.68 ± 1.56	300.33 ± 4.37	97.40 ± 0.93	238.14 ± 2.53	870.40 ± 25.86

Ferric Reducing Power Assay (FRAP)

Reducing power is one of the mechanisms of antioxidant capacity which measure the conversion of a Fe^{3+} ferricyanide complex to the ferrous form. Results of reduction capability of the methanolic extracts of tow date cultivars are shown in table 3 and all results were expressed as a milligram standard equivalent per gram of fresh weight (mg SE/g fw).

With a vitamin C standard, the methanolic extracts of Mech-Degla date showed the highest level of reduction capability (116.49 mg VitCE/100g fw) and with a gallic acid standard, the methanolic extracts of Frezza date exhibited the lowest level of reduction capability (21.04 mg GAE/100g fw).

Table 3. Reduction capability (mg SE/100 g fw) of two dry Algerian date extracts.

Values are means (n = 3) ± SD ; **SE :** Standard equivalent ; **BHAE :** BHA equivalent ; **GAE :** Gallic acid equivalent ; **QE:** Quercitin equivalent ; **VitCE:** Vitamin C equivalent.

	Reduction capability (mg SE/100 g fw)			
Cultivar	**BHAE**	**GAE**	**QE**	**VitCE**
Frezza	54.16 ± 0.26	21.04 ± 0.1	40.91 ± 0.2	112.98 ± 0.52
Mech-Degla	55.92 ± 0.28	21.74 ± 0.11	42.22 ± 0.21	116.49 ± 0.56

β-carotene/linoleic acid bleaching assay

Results of comparison between the same Antioxidative activities of the methanolic extracts of two date cultivars and those of the standards are shown in Table 4. With a 134.82 and 259.42 µg/g fw for total phynolic content, Frezza and Mech-Degla dates showed the same level of Antioxidative activities (24 %) with a BHA, gallic acid, quercitin and vitamin C equivalents antioxidant capacity values of 12, 589, 33 and 515 µg/g fw, respectively.

Table 4. Inhibition of β-carotene bleaching (%) and standard equivalent antioxidative activities per gram of fresh weight (µg SEAA/g fw).

Values are means (n = 3) ± SD ; **TP:** Total phenolics; **TF:** Total flavonoids; **IBCB:** Inhibition of β-carotene bleaching; **BHAEAA, GAEAA, QEAA and VitCEAA:** BHA, Gallic acid, Quercitin and Vitamin C equivalents antioxidative activity.

Cultivar	TP (µg/g fw)	TF (µg/g fw)	IBCB (%)	BHAEAA (µg /g fw)	GAEAA (µg /g fw)	QEAA (µg /g fw)	VitCEAA (µg /g fw)
Frezza	134.82 ± 0.39	29.69 ± 0.34	24.19 ± 3.37	12.04 ± 4.9	589.07 ± 68.06	33.66 ± 0.7	514.37 ± 7.27
Mech-Degla	259.42 ± 0.8	30.46 ± 0.09	24.10 ± 1.35	12.11 ± 4.89	589.94 ± 68.15	33.73 ± 0.7	515.10 ± 7.29

Correlation

Pearson's correlation (Table 5) shows a very high positive significant relationship between phenol and reduction capability of all standards equivalents (r = 0.966, $p < 0.01$). However, no association could be found between phenol and inhibition of β-carotene bleaching (r = -0.019, $p > 0.05$) as well as flavonoid and reduction capability of all standards equivalent (r = 0.094, $p > 0.05$). A high negative significant correlation has been observed between flavonoid and inhibition of β-carotene bleaching (r = -0.713, $p > 0.05$).

Table 5. Correlation matrix between antioxidant activities (DPPH radical scavenging capacity, reduction capability and percentage inhibition of β-carotene) and antioxidants.
TP : Total phenolics ; **FLA :** Flavonoïds ; **DPPHSC :** DPPH scavenging capacity ;
IBCB : Inhibition of β-carotene bleaching ; **RCSE :** Reduction capability of all standards equivalent ; $^{**}p < 0.01$.

	TP	FLA	DPPHSC	IBCB	RC
TP	1				
FLA	0.135	1

IBCB	-0.019	-0.713	-	1	
RCSE	0.966**	0.094	-	-	1

Conclusion

The presence of compounds such as phenolics with a potential to scavenge free radicals, increase antimutagenic effects, stimulate the immune system and protect tissues from oxidative stress. Polyphenol's antioxydant defenses also have great importance in the protection of brain and nerve tissues against oxidative attacks as those causing Alzheimer's disease. The antioxidant mechanisms and different antioxidant activities should be further studied to gain more application for use as natural antioxidants. To understand their mechanism of action as bioactive components, further fractionation of methanolic extracts, isolation of phenolic compounds, and determination of their biological activities in vitro and in vivo are needed.

PHYSIOLOGICAL AND BIOCHEMICAL RESPONSES OF DURUM WHEAT (Tr.durum Desf.) TO LOW TEMPERATURES

Faouzia DEHBI*, Hamena BOUZERZOUR, Abdelhamid MEKHLOUF, Abderrahmane HANNACHI

* University Ziane Achour , Agro Veterinary Department, 17000 Djelfa, Algeria

Abstract

In the high elevation area of Algeria early genotypes of durum wheat (*Tr. Durum* Desf) suffer seriously from low temperature damage during cold season. Developing genotypes resistant to low temperature stress appear critical to ovoid crop failure and to improve grain yield. Cold tolerance is a complex mechanism linked to ecophysiological and biochemical changes.

The present study was conducted at the agricultural experimental station of National Institute of agricultural research of Algeria (INRAA). The objectives of this study were to determine the period risk of low temperature; to evaluate the genotypic variability for resistance to low temperatures through several physiological tests (crown, leaves, spike) and biochemical tests (proline and soluble sugars) and to investigate the relationships between the results of such tests, and the agronomics performances of a set of durum wheat. These tests enabled genotypes to be differentiated on the basis of their cold tolerance,

The results identified however early, freezing tolerant genotypes such as Cyprus1 and Waha which can be used as genetic source to improve tolerance to low temperatures.

Keywords: *Triticum durum* Desf., *low temperature, physiological and biochemical changes, yield.*

Introduction

In Algeria, cereal crops are practiced in a dry way; it is subjected to strong abiotic constraints (Baldy, 1974; Mekhlouf, 1998). The rainfall is low and uncertain; it is the main factor limiting the productivity of this crop (Bensedik and Benabdelli, 2000). Naturally, intermittent drought threatens the crop throughout the cycle. The other constraint is represented by low spring temperatures that reduce most often yields to their simplest expression (Laumont, 1961; Baldy, 1974; Fletcher, 1983; Abbassenne, 1998; Mekhlouf and al., 1998). This constraint leads to limit the expression of genetic potential of cultivars (Slatyer, 1974), hence, stagnation of yields (8q/ha) despite of many efforts through the intensification and support programs. Varietal selection using an empirical approach takes grain yield as a selection criterion. This approach has shown its limits, especially regarding the improvement of stress tolerance (Araus and al, 1998). For this purpose, the approach based on understanding the environment through frequency studies of the main climatic parameters, complete with phonological, morphological and physiological analysis of the plant is introduced as an alternative. This approach aims to characterize the abiotic constraints and locate it in time and to identify characteristics of tolerance to different types of stress.

The objective of this paper is to study the genetic variability of response to low temperatures and analyze the relationships with the characteristics of phenological, morphological, physiological and biochemical traits measured of several genotypes of durum wheat (*Triticum durum* Desf.).

Materials and methods

Twelve durum wheat (*Tr. durum* Desf.) genotypes were grown. The field trials were conducted from 1999 to 2003 at the agricultural experimental station of INRAA (latitude 36° 9'N and 5° 21'E, altitude 1080m). The site is representative of the high elevation area of eastern Algeria.

Grain yields, yield components and the number of days to heading were measured. The test of cold tolerance (Marshall and Kolb,1982) was carried out on the crown which was subjected to different temperatures ranging from -8 ° to -16 ° C with step of -2 ° C. The same test on spike at levels of temperatures of -3°C to -5°C was used. The effect of cold was evaluated on a scale of 1 to 3 (Mekhlouf et al., 2001). Proline and soluble sugars were measured during two seasons of experimentation on vegetation samples taken from the genotypes planted in field at tillering stage (Bridger et al., 1995).

Data analyses was performed using the statistical software Irristat version 5 yield and its components were analysed according to a factorial experiment conducted in a completely randomized block design with three replication. Least Significant difference (LSD), at 5% was used for means separation. Principal component analysis was performed on the basis of the correlation matrix among the measured variables

Results and Discussion

Frequency of climate and risks: freezing and water deficit

Figures 1 and 2 highlight the levels of risk on cereals sown each year in semi-arid area. The water deficit is beginning to appear as early as February and becomes more intense as the plant grows (Figure1). Figure 2 highlights the presence of late frosts in spring coinciding with the stage of high sensitivity of the crop. The varieties that spikes emerged during April are in danger of freezing; the effect is measurable on the number of kernels per spike.

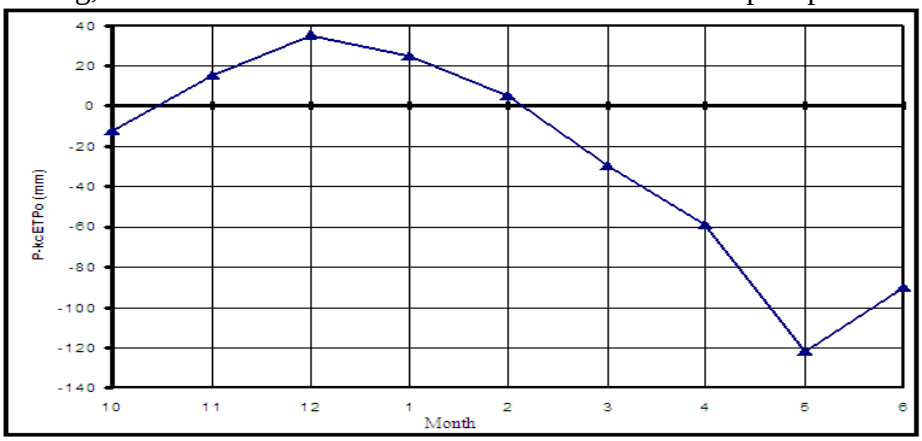

Figure 1. Variation of the average rain deficit for the experimental site over the period 1980/2000

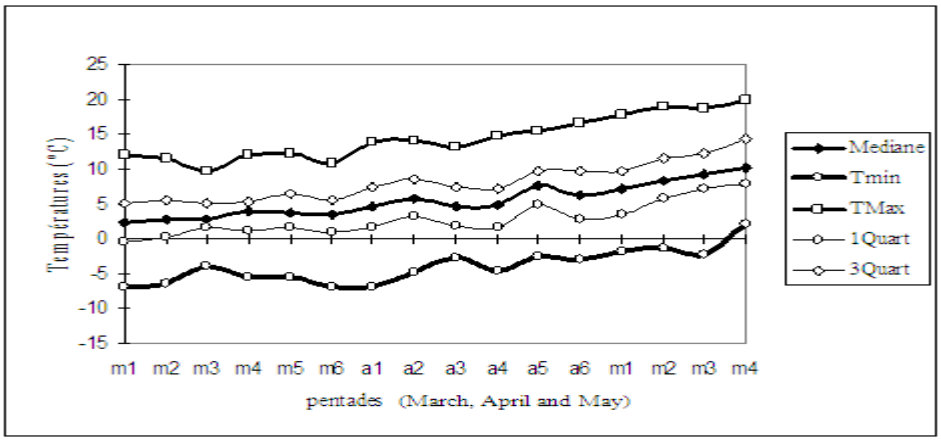

Figure 2.Frequency of the minimal temperatures, pentad of sensitive phase of durum wheat.

Environmental effect on the expression of the variables

The year effect is by far the most important, explaining much of the observed variation in the variables analyzed (Table.1). This effect highlights the high variability of growing conditions which is subject of durum wheat in the highlands. The genotype effect is significant only for the duration of the vegetative phase and harvest index (Table 1). The ranking of genotypes for these two variables remains relatively constant from one year to another, showing little interaction.

Table 1. Average squares of variance analysis of the variables measured during 4 years.

Source of Variation	Df	PVG (D)	HT (cm)	NE (/m^2)	PMG (g)	BIO (100kg/ha	NGE	GY (100kg/ha)	HI (%)
year (A)	3	859*	1594*	961666*	1019*	27347*	3056*	3574*	222.6*
Blocs/year	8	7.2	56.3	1725	3.7	125	8.7	23.5	7.3
Genotype (G)	11	199*	522ns	21888ns	32ns	979ns	48ns	217ns	173.9*
G x A	33	28*	286*	18956*	30*	1580*	103*	216*	64.8*
Error(/Residus)	88	12.2	78.2	3543.2	6.3	156.6	14.4	30.1	18.6

PVG= vegetative phase, HT= straw height, NE = spike per m², PMG = 1000 grain weight, BIO= dry matter or biomass, NGE= seed number/spike, GY= grain yield, HI= harvest index; Df= degrees of freedom, D=day
ns, *,** = not significant and significant effect at 5 and 1 % respectively.

The change in growth conditions between the different seasons induced very different genotypic responses for the remaining variables. This environmental variation leads to a change in ranking of genotypes between years. 1999/2000 and 2000/2001 seasons have been less favourable to the expression of grain yield, with an average of 3.29t/ha. Both following seasons have been relatively more favourable; with an average yield of 5.01t/ha (Table 2). The difference of 1.72t/ha between the average performance of favourable and unfavourable seasons was significant. It is associated with a long duration of vegetative phase, a higher biomass and yield components taking values over the average of four seasons of study (Table 2). Quite similar yields are obtained in the two unfavourable seasons through very different performance development itinerary. These results confirm those of Ceccarelli and al. (1991) and Bahlouli and al. (2004) who find that the same level of grain yield is obtained in different combinations of characters.

Thus, the 1999-2000 season allowed the expression of the number of spike per m^2 but unfavourable to the number of kernels per spike, whereas the contrary is recorded in 2000/2001. The differences in biomass, the number of days to heading, thousand kernel

weight and harvest index are not significant between these two years (Table 2). Kirby and al. (1992) mentioned the phenomenon of compensation that is set up between the components of yield. The number of spikes per m^2 is formed early in the beginning of the cycle, once the main strand begins its elongation immediately after the completion of meiosis stage (Hoshino and Tahir, 1987). This component is determined once the swelling stage is achieved. Winter water stress and / or low temperatures of early spring can cause a significant reduction in this component (Gate, 1995). The number of kernels per spike began its formation just before heading, at the meiosis stage, and ends 10 days after heading (Wardlaw, 2002). It is very sensitive to low spring temperatures (Bouzerzour and Benmahammed, 1994, Mekhlouf and al. 2006). Water stress and high temperatures for the period of 10 days before and after the date of achieving the heading stage are also deleterious to this component (Moncor and Wardlaw, 1995).

Table 2.Season and genotypic main effects of the measured variables

	PVG (d)	HT (cm)	NE (/m^2)	PMG (g)	BIO (100kg/ha)	NGE …	GY (100kg/ha)	HI (%)
Season main effect

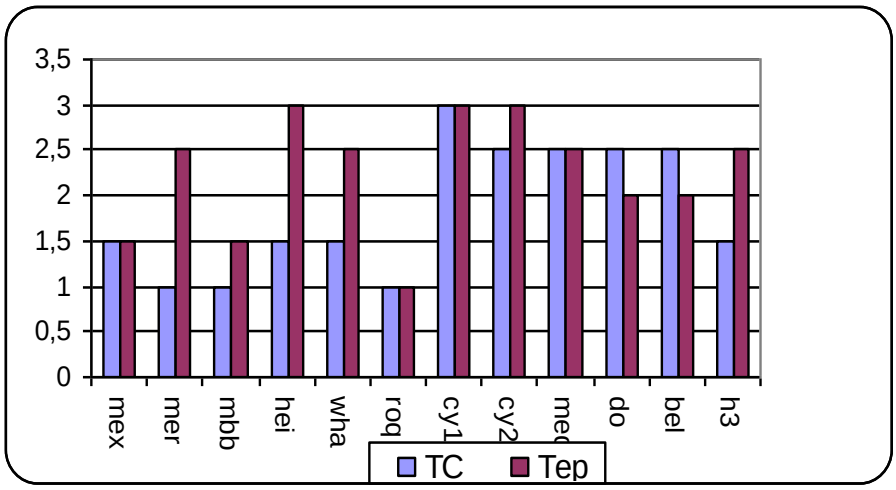
Responses to low temperatures

The cold test performed on the crown showed Cyprus1, Cyprus2, Durum d’Oran, Medola and Beliouni3258 as tolerant and Merouani, MBB, and hedba3, Roquéno as sensitive (figure 3). The test performed on spike confirms the tolerance of genotypes Cyprus1, Cyprus2, Heider //Martes/ /Huevos de oro (Figure 3).



TC: crown test, Tep : spike test

Figure 3: Response of the genotypes to the low temperatures.

The capacity of accumulation of proline and soluble sugars varies according to seasons and genotypes. The differential ability of accumulation of these substances in low temperatures is taken as a measure of tolerance of the genotype (Heber and al., 1971; Heller and Green,1981). Average of two seasons, Mexicali, Medolla and Durum d'Oran accumulate more proline, while Heider/Martes//Huevos de oro, Roqueno and Cyprus1 accumulate more soluble sugars (Figure 4).

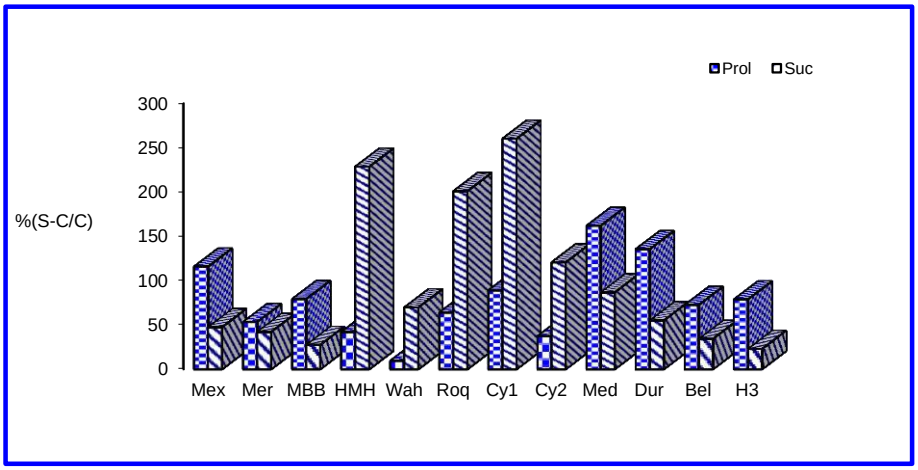


Figure 4. Capacity of accumulation, under low temperatures, of proline and soluble sugars 100 [(Stress-Control)/Control], mean of 2 seasons

H_3 = Hedba$_3$, MBB = Mohammed Ben Bachir, Dur = Durum D'Oran, Med= Medolla, Mer= Marouani, Cy_1= Cyprus1, Cy_2= Cyprus2, Wah= Waha, HMH= Heider/Martes//Huevos de Oro, Mex= Mexicali$_{75}$, Roq= Roqueno, Bel= Beliouni$_{3258}$).

Results revealed also that in the stressful conditions, genotypes Cyprus1, Heider/Martes // Huevos de oro and Medolla were high cold tolerance. This tolerance is confirmed by the level of accumulation of proline and sugars. This ability to accumulate these substances as a result of heat stress appears to be related to cold tolerance and has been noted by several authors (Santarius, 1973; Line Berger and Steponkus, 1980, Heber et al, 1971), who note that cell destruction can be prevented by the accumulation of these substances. In parallel, the genotypes Roqueno presents conflicting results. Indeed, this variety showed significant levels of soluble sugars and proline and sensitivity to low temperatures according to various tests of cold used (figure 3 and 4). Results showed also that some genotypes such as Cyprus1,

Cyprus2 and Heider/Martes//Huevos de oro present both an adaptation to cold through physiological tests and a significant accumulation of proline and soluble sugars in samples stressed. These results confirm those obtained by Havaux and Lannoye (1982), indicating that the accumulation of free proline is more marked as the plant is more tolerant to cold.
The principal component analysis (PCA) accounted for 74.1% of the variation. PCA1 accounted 33.4% of the variation and represented number of days to heading, the number of kernels per spike, harvest index, biomass and straw height toward its positive direction (Figure 5). And spike cold test, thousand kernel weight variance and harvest index toward its negative direction. PCA1 represented the overall variation between seasons for all variables measured except grain yield (Figure 5). PCA2 represented the number of days to heading, the number of spike per m², grain yield, biomass and differences among soluble sugars measured during seasons 2001 and 2002. Along PCA2 axis, are opposed phenology of production capacities and accumulation of soluble sugars and proline., in this case grain yield, biomass and soluble sugars. According to their position along the axis PCA1 and PCA2: along PCA1 genotypes Heider // Mt // Ho, Waha and Cyprus1 had a tolerance to late cold, low and varying thousand kernels weight and low across season straw height, the number days to heading, the biomass, the number of kernels per spike and harvest index. Along the same axis, genotypes Roquéno and durum d'Oran showed the opposite characteristics (Figure 5). They had below average thousand kernels weight, are sensitive to cold late; a low across season variance thousand kernels weight but high thousand kernels weight, high across season variances for straw height, biomass, harvest index, number of kernels per spike and number days to heading (Figure 5). The genotype Durum d'Oran (PCA2,) is less productive. Heider / Mt // Ho, Waha and Cyprus1 have an intermediate productivity. Roqueno is the most productive genotype. Along axis 2, local genotypes Medolla, Durum d'Oran and Beliouni$_{3852}$ oppose varieties introduced Mexicalli75 and Cyprus2. Local genotypes are characterised by a high number of days to heading, low number of spikes per m², low grain yield, a significant biomass production and low accumulation capacity of soluble sugars. In contrast, the introduced genotypes are characterised by an early heading and high number of spikes per m², high grain yield and , biomass but a low accumulation of soluble sugars under stress.

Conclusion

In the high elevation area of eastern Algeria, durum wheat suffer seriously from environmental stress factors that can prevent the expression of the genetic potential . The results of the present study showed that tests used were effective in sorting out the genotypes which were low temperatures tolerant those wich were sensitive. The measured agronomic traits varied between seasons and genotypes indicating the presence of significant genotypic variability and differential responses to the growth conditions experienced. The results identified however early, freezing tolerant genotypes such as Cyprus1 and Waha which can be used as genetic source to improve tolerance to low temperatures.

Abstract

The aim of this study was to determine the effect of regulated deficit irrigation (RDI) on potato growth and plant water regime in the field conditions and to compare these effects with the conventional method of irrigation. The field potato (*Solanum tuberosum* L. cv Liseta) experiments were conducted during 2007. and 2008. In 2007. a static approach in regulated deficit irrigation technique was applied and the plants were irrigated with 70% of water compared to plants that are optimally irrigated (FI) during the whole season, while a dynamic approach was applied in 2008. where the amount of water for irrigation was reduced from 70% to 50% during the last 3 weeks of the irrigation period. During these two seasons, the following parameters were measured: water potential and stomatal conductance, plant height, leaf area and leaf area index (LAI). The results showed that in the both seasons the regulated deficit irrigation didn't significantly affect the plant growth parameters as plant height, leaf area and LAI compared with optimally irrigated plants, but the differences were expressed between individual harvests. Analysis of the plant water regime parameters point to the differences between two seasons in a way that in 2007. the chemical signals were more responsible for the reduction of stomatal conductance, while in a 2008. season the reduction of stomatal conductance was followed by a decrease of leaf water potential that indicated the hydraulic drought signals.

Key words: *regulated deficit irrigation (RDI), potato, plant growth, water regime*

Introduction

Agriculture is highly sensitive to climate change and especially, to drought. The increase in temperature can increase duration of the crop growing season in regions with a relatively cool spring and shortened the season in regions where high summer temperature already limits production. The clean freshwater becoming a limited resource and its use for crop irrigation is in competition with the demand for household consumption, as well as with the need to protect the aquatic ecosystems. It is obvious that saving clean water, increasing agricultural productivity per unit of water (“more crop per drop”) and producing safe food are becoming of strategic importance for many countries (Luquet et al., 2005).The reduction of yield in drought conditions is most likely due to the decrease of growth, but also as a result of shortening the growing season (Samara et al., 2005). In drought conditions shoot growth inhibition is associated with the closure of stomata (Holbrook et al., 2002), which caused a decrease in transpiration, conservation and plant water use efficiency (Tahi et al., 2007). In Serbia and countries in the region, drought is also a significant stress factor, and its negative impact particularly affects the breeding and productivity of crops, especially vegetables, including potatoes.Potato is an important crop worldwide. The crop is very susceptible to water stress and hence irrigation is needed for achieving acceptable yield and quality (Liu et al., 2006).The potato plants have high demands for water and irrigation is necessary for a successful growth (Fabeiro, 2001). In the last decades, one of the management options to overcome the agricultural drought is the use regulated deficit irrigation (RDI) and they are called deficit irrigation method. DI have been extensively and successfully tested on many

field and horticultural crops without significant loss of economic yield (Sepaskhah and Ahmadi, 2010). RDI method is based on the understanding of the physiological responses of plants to water supply and water deficit, especially the perception and transduction of root-to-shoot drought signals (Chaves et al., 2002; Morison et al., 2008). Regulated deficit irrigation (RDI/DI) is a method that irrigates the entire root zone with an amount of water less than the potential evapotranspiration during whole or specific periods of the crop cycle (English & Raja, 1996). The principle of the RDI technique is that plant sensitivity to drought is not constant during the growing season and that intermittent water deficit during specific periods of ontogenesis may increase water savings and improve yield quality (Loveys et al., 2004). When the roots are in contact with dry land becomes a source of chemical signals ABA primarily as inhibitors of growth. The increased content of ABA leads to partial closure of stomata, which causes the reduction of transpiration and leaf growth, but also increase plants water use efficiency (Davies et al., 2002). Whole plant growth is usually limited by dry matter production and leaf area expansion and, therefore**,** traditional plant productivity analysis is based on the investigation of several biomass and assimilatory area parameters

Materials and methods

Experimental design and cultivation

The experiments were carried out during the growing seasons of 2007 and 2008 in a vegetable commercial farm (“Salate Centre”), located 10km north of Serbian capital, Belgrade. The soil of the field was silty-clay and it was developed on alluvial deposit.

Potato (*S. tuberosum* L.) cultivar Liseta was used for investigation.The field was organized as split plot design with six plots (three per treatment). The seed tubers were planted in the beginning of April at the depth of 10 cm, with distance between plants in a row of 30cm and distance between rows of 75 cm. Seed tubers were ridged with 15cm soil and ridges were formed about 30 days after planting. During the vegetation season plants were treated against weeds and fungal disease. Fertilization included an initial application of nutrients (N, P, K and micronutrients).

Irrigation scheduling and treatments

Irrigation amount was controlled by programmable irrigation equipment that supplied their irrigation through a drip line system to each plot.The irrigation method used was a drip-subsurface method. The subsurface irrigation system was supplied by Netafim (A.C.S. Ltd.Netafim, Israel). For the FI and RDI treatments, one drip line was placed 10cm below the top of the ridge. The distance between emitters in FI and RDI treatments was 30 cm and these were place exactly in the middle between two plants.With the RDI treatment is started after the phase of tuber initiation (when 80% of tubers more than 20 mm long). In the last 3 weeks of the irrigation period, 70% RDI was replaced by 50% (RDI plants received 50% of FI treatment). Irrigation was done at least twice per weekand done with a time domain reflectometer (TDR, TRASE, Soil Moisture Equipment Corp.,USA) using vertically installed probes.

Experimental measurements

The leaf water potential (Ψl) was measured using the pressure chamber (Scholander et al., 1965). The method is based on the extraction xylem sap from the leaves under the pressure of the gas usually nitrogen.Stomatal conductivity was measured using diffusion porometer AP4 (Delta-T Devices). During the experimental period we measured the: water potential and stomatal conductance, plant height, leaf area and leaf area index (LAI). Leaf area was determinate destructively by sampling leaves from plants and than scanned by scanner

(Mustec Scan Express A3 USB). Leaf area index (LAI) is the ratio of total leaf area of the plant to the soil surface.The measured traits have been analyzed for statistically significant differences by Students unpaired t - test (Sigma Plot 6.0 for Windows – SPW 6.0, Jandel Scientific, Erckhart, Germany)

Results and Discussion

Leaf water potential (Ψl) and stomatal conductance (g_s)

Fig 1. shows the changes in leaf water potential and stomatal conductivity of plants under the influence of FI and RDI irrigation regimes in 2007. year. Between harvest the values of stomatal conductivity were decreased by 68% in FI and RDI regime. The values of stomatal conductivity with FI and RDI irrigation regimes at the end of the experiment were: 0,19 and 0,21 mol m^{-2} s^{-1}. Maximum values of water resources leaves were recorded for FI irrigation regimes in phenological stage when tuber reached 50% of its total mass, while harvesting H3, and the RDI maximum values were at the stage of flowering plants during the harvest H1. For FI, RDI maximum values were: -0.82 and -0.97MPa. Decrease the values in water potential was recorded with FI irrigation regimes between harvests H3 and H4 in phenological development phase where tuber reached 50-60% of their final mass. Values water potential at the end of the experiment were the FI -1.12 MPa, RDI-1.0 MPa. In the period in 2008. (Fig.2) were similar results as in 2007. The decrease in water potential and conductivity of the stomata was consistent in all irrigation regimes. The results obtained showed that RDI the plants at the end of the experiment had a higher level of stress. The decrease in water potential RDI plants indicates that the water stress in the zone of the root system was sufficient to cause reduction of water potential of leaves. Our results are in agreement with the results Wakra et al., (2004) who examined the beans in water resources affected by RDI irrigation regimes where there has been a decrease in the value of water resources in relation to the control. Similar results in studies of effects RDI irrigation regimes on tomato plants were given by Topcu et al., (2006). Values conductivity stomata, in all irrigation regimes, between the third and fourth measurements were significantly reduced. The measured values were: FI at 0,40 mol m-$^{-2}$ s^{-1} (H3) and 0,32 mol $m^{-2}s^{-1}$ (H4), RDI 0,38 mol $m^{-2}s^{-1}$ (H3) and 0.26 mol $m^{-2}s^{-1}$ (H4). The changes of dynamic conductivity of stomata was followed by canges in leaf water potential.Thus, the maximum values of water potential were the harvests H1 and then there was a decrease in the value of the harvest H4. Values water potential at the last harvest were: -1.01 MPa (FI) and -1.06 MPa (RDI).Results of the correlative relationships of parameters of water regime also indicate differences between the investigated season and so that are the chemical signals were more responsible for the reduction of conductivity stomatal cells in 2007. year, while in 2008. year decrease in conductivity stomata was accompanied by sheets of falling water potential (hydraulic signals drought).Reduced stomatal conductance in early stages of water stress inhibits transpiration rate more than it reduces the intercellular CO_2 concentration that is the driving factor for photosynthesis.Crop water use or transpiration (water diffusion to the air through the stomata) is mainly controlled by stomatal conductance. In terms of the efficient use of water in agriculture, stomatal response to the water status of the soil and plant system has been a critical area in crop physiology.

Reactions stomatal cells are of particular importance for reactions of plants to applied methods of irrigation. Such reactions stomatal cells is of particular importance because it allows the plant to dry when exposed to water more efficiently exploit the process of growth and metabolism and thus reduce the adverse effects of dehydration (Jones, 1980). According Maroco et al., (1997), stomata response to drought is more associated with the water content in the soil than with leaf water status. This indicates that the stomata respond to chemical signals which produces the root (Davies and Zhang, 1991). By reduction, in all irrigation

regimes, there is in the initial stages of the experiment, where a sudden drop in between the first and second measurement, the phase of flowering plants. This reduction in conductivity of the stomata was more pronounced than the reduction in water potential and this indicates that the chemical signals, rather than sheets of water regime (hydraulic signals) were more responsible for the reduction of conductivity stomata cells during this period The decline in conductivity stoma was reflected in the later stages of plant development 'and it is similar to the results that were obtained on potato Liu et al., (2005). These authors found that changes in the conductivity of the stoma by irrigation regimes applied in correlation with the interaction of chemical and hydraulic signals In the period in 2008. The decrease in conductivity of the stoma was accompanied by decreasing resources and leaves. Liu et al., (2004) in their results were given to the conductivity of the stoma in plants sensitive to desiccation of potato land in the initiation phase. Tuber and their growth, and these results confirm previous research on potatoes (Jefferies, 1989). Based on our results, we can assume that the degree of land drainage in the applied irrigation regime was sufficient to induce signals that are induced closure of stoma. It can also be assumed that the stoma closure was the result of induction of both types of signals, as well as their interactions.
However, recent investigations in field grapevines suggest if severe soil drying saving 50% water of control plants is applied during deficit irrigation feedback hydraulic signals
may play a dominant role (Santos et al., 2007; Rodrigues et al.,2008).

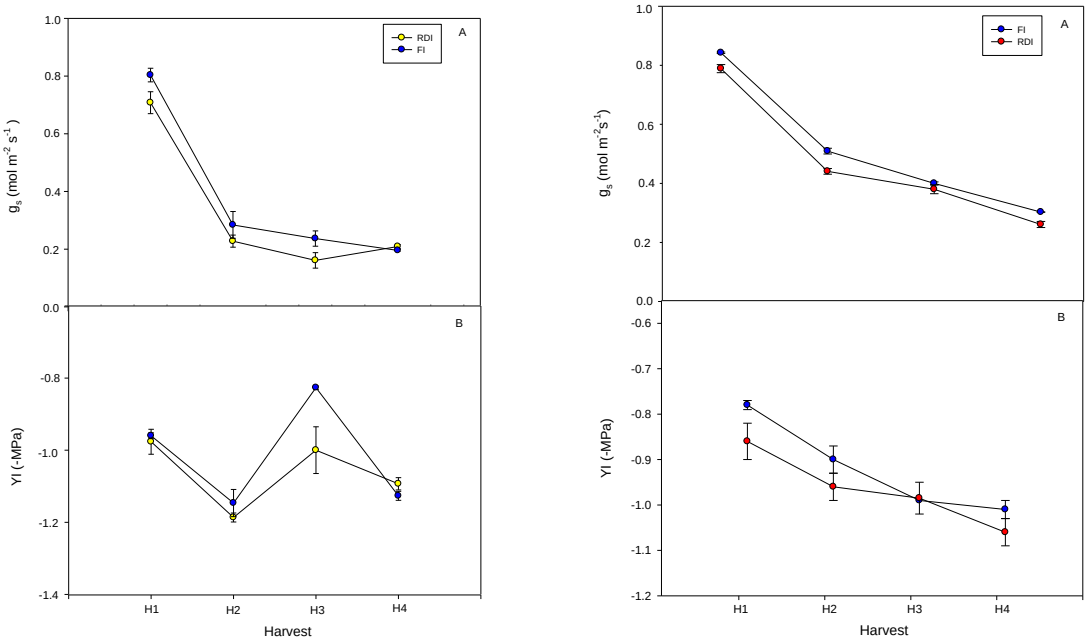

Fig 1. and 2. shows the changes in leaf water potential and stomatal conductivity of plants under the influence of FI and RDI irrigation regimes in 2007. and 2008. year

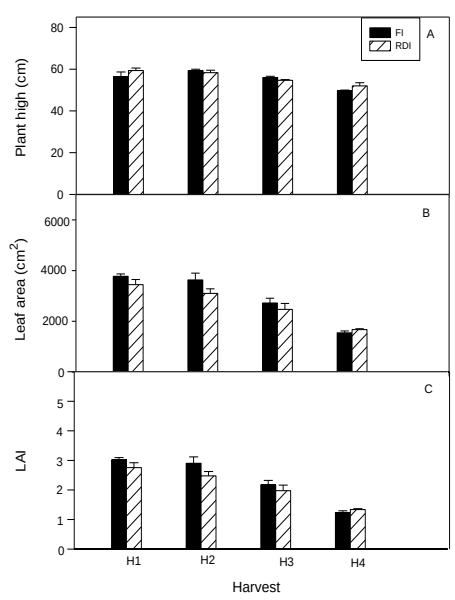
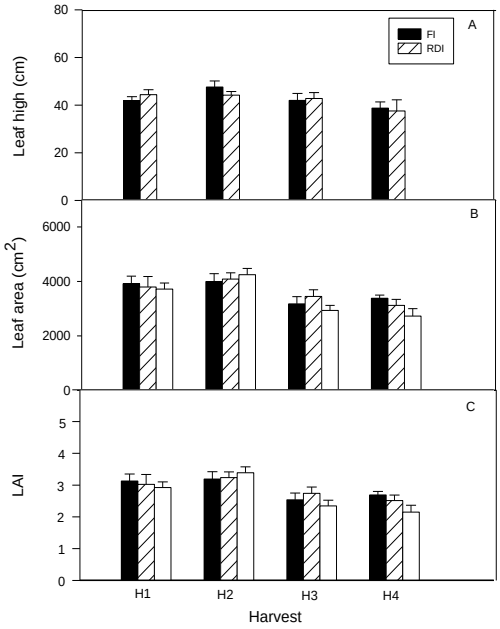
Plant height, leaf area and leaf area index (LAI)

Effects of irrigation regime (FI and RDI) on plant height , leaf area and leaf area index (LAI) during the 2007 are presented in figure 3.and 4. In our experiment there was no significant difference between FI and RDI irrigation regimes in plant height , leaf area and leaf area index during the 2007 year . Differences in values of these parameters have emerged within the regime, irrigation , between individual harvests . During the growing season expressed variation in leaf area between harvest H3 and H4 in all investigated regimes of irrigation during the 2007 years and this is probably due to the phenological phases in which the plants are contained, and this is the period of accumulation of dry weight in tubers .Plants were tested in both regimes of irrigation during 2007. year, were about the same height Maximum values of plant height were observed in all the studied irrigation regimes in the flowering stage in harvests H1 and H2. At the end of the experiment the height of FI and RDI plants was : 49.6cm and 52.0cm. The results showed that during the season in all investigated irrigation regimes were uniformly decline in plant heigh .The maximum value of the leaves area , in all investigated irrigation regimes were in the flowering stage , the harvest H1. FI and RDI irrigation regime values were : 3775 and 3446 cm^2 , and then there was a decline in the value to the end of the test period.This reduction was 40 % for FI plants, 32% for RDI plants . Leaf area, at the end of the experiment in irrigation regime FI and RDI were: 1544 cm2 , 1672 cm^2 . There was a reduction in leaf area at 8 % RDI irrigation regime in relation to optimally irrigated plants.Results for LAI values also show , for all irrigation regimes pronounced difference between harvest H3 and H4 and t-test was statistically highly significant difference ($P<0.001$) between individual harvests in FI and a significant difference ($P <0.01$) in the RDI of irrigation . LAI values for FI , RDI irrigation regime at the end of the experiment were : 1.23 and 1.33.In 2008. height of plants in FI and RDI was : 38.7 cm, 37.5 cm at the end of the experiment.Maximum values of the leaves area were at harvest H2 , at the stage of flowering potato plants in all investigated irrigation regimes . The FI values in the RDI were:3994, 4086cm^2, and then there was a decline in the value to the end of the test period . Leaf area in the RDI plants at the end of the experiment was : 3382cm^2, 3122 cm^2. Reduction of leaf area in RDI was 7.7 % compared to FI . Between 2008 the results show that the maximum values of these parameters for all irrigation regimes were in phonological fase of flowering plants and a decline in the value of going to the end of the growing season . RDI irrigation regime influenced the reduction in leaf area and LAI compared to FI plants . RDI irrigation regime has reduced the amount of irrigation water and leaf expansion thus avoid the effect of the excessive proliferation of plants .In the literature, there are a lot of controversial information to explain the effect on the LAI . Results Jamieson 's (1985) and Greenwood et al . , (1982) have shown that the application of irrigation deficit reduction in the LAI due to a decrease in potato transpiración surface and that this effect stimulates the development of roots and tubers. The measured maximum values for LAI , in all investigated irrigation regimes were at harvest H2 . In FI, RDI avalues were 3,11 ,and 3,20 , and then there was a gradual decline in values in all investigated irrigation regimes . The values of LAI at the end of the experiment in FI, RDI plants were : 2.69 and 2.51 . LAI in RDI plants was lower than the reduction in plant FI.RDi plants reduction was 6.7 % compared to the FI irrigation regime.





Fif.3 and 4. Effects of irrigation regime (FI and RDI) on plant height, leaf area and leaf area index during the 2007.and 2008.year

Conclusion

The results showed that that plants in regulated deficit irrigation at the end of each experimental season were exposed to increasing levels of stress. The decrease in plant water potential regime of regulated deficit irrigation also indicates that the water stress in the zone of the root system was sufficient to cause reduction of water potential of leaves. Measuring the impact of regulated deficit irrigation on stomata reaction showed that it was in 2007. there was a reduction of conductivity stomata in the regime of regulated deficit irrigation in the early stages of the experiment when there was still no change in water potential of leaves and this may indicate that chemical signals, (hydraulic signals) were more responsible reduction of conductivity stomatal cells during this period. In 2008.year decrease in conductivity stomata was accompanied by decrease in water potential of leaves of all investigated regimes of irrigation, which indicates a hydraulic signals drought. In the experiment in the field there were no significant differences between the effects of different irrigation regimes on plant height, leaf area and LAI at the end of the experiment, but the differences were demonstrated between individual harvests. Regulated deficit irrigation regimes influenced the reduction in leaf area and LAI in relation to optimally irrigated plants.

Abstract

Growing apricot depends on many factors that lead to great variations in yields. The most common factors affecting the yield of apricots are extremely low winter temperatures, late spring frosts and the occurrence of apoplexy which causes drying out and decay of trees.

The aim of this paper is to compare biological and pomological characteristics of cultivars and selections from Novi Sad (Serbia) with apricot cultivars "Hungarian Best" (leading cultivar in the apricot orchards in the continental part of Bosnia and Herzegovina (BiH) in agro-ecological conditions of Banja Luka, BiH.

Tests were conducted during the period 2012-2014 at the plantation which was planted 2009 in Banja Luka. In the plantation there is following cultivars and selections of apricot: Aurora, NS-4, NS-6, Novosadska rodna, Novosadska kasnocvetna, SK-1, SK-3, SK-16a, SK-13a and Hungary best. Phenological stages of flowering and ripening was monitored. It was measured fruit weight, fruit length and width and stone weight. It was determined flesh/stone ratio and fruit shape index. Soluble solids contents were determined by refractometer.

All tested cultivars of apricots, besides Aurora, have achieved higher average fruit weight compared to the standard. Flesh/stone ratio of the fruit in a selection SK-13a and SK-16a was significantly higher than in Hungary Best cultivar. All studied cultivars ripened in the first half of July. The exception was Aurora cultivar, whose harvest was performed in mid-June.

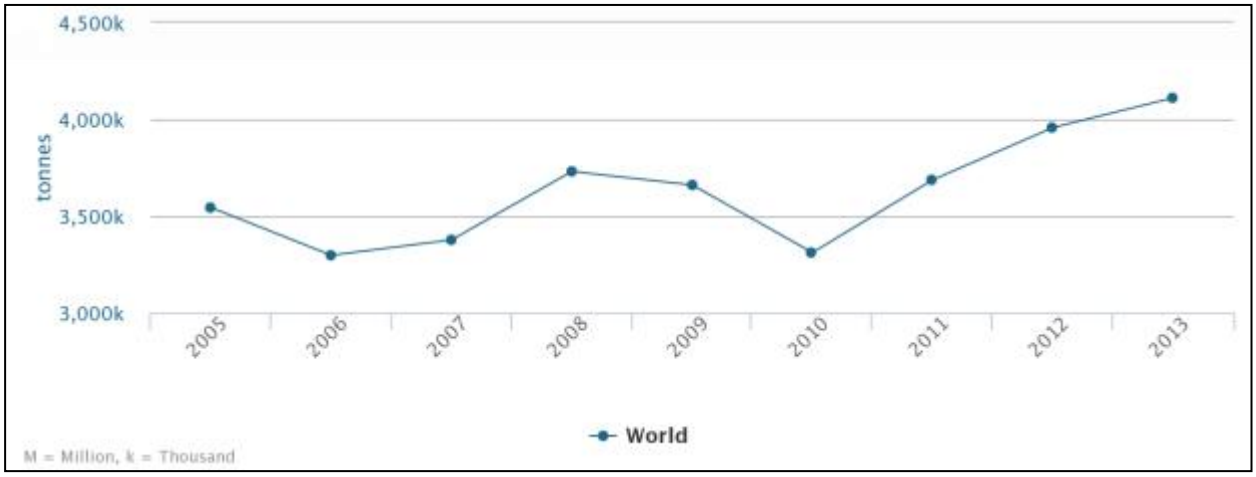
Of all tested cultivars and selections, only Aurora cultivar cannot be recommended for growing in continental conditions because it is very sensitive to low temperatures during the winter and often suffer from spring frosts. Other tested cultivars can be recommended for cultivation because being better in many indicators than standard cultivar.

Key words: *apricot, cultivar, flowering, fruit quality.*

Introduction

Apricot is a respectable fruit species that has a various usage and is particularly versatile use of the fruit. Fruits can be used for eating fresh or in the form of different products, such as jam, marmalade, compote, sweet, juice, dried fruits, apricot brandy and others. In varieties of apricot with a sweet taste kernel, the kernel according by its nutrient value and usefulness can be successfully used as a substitute for almonds, hazelnuts or walnuts in processing and confectionery industries.

The apricot production in the world is about 4.1 million tons (FAO, 2013). It is grown on about 504 000 ha (FAO, 2013). The largest producers are Turkey with 811,609 tons (FAO, 2013), which are 19.7% of total world production, followed by Iran and Uzbekistan. There is an evident tendency to increase production at the global level (Fig. 1). In Europe, the average annual production is 846 000 tons. The biggest producers are Italy, France, Spain and Greece.



Graph 1.The apricot production in the world in the period of 2005 - 2013

Situation in apricot production in our neighbouring countries is different. The average annual production in Serbia is 22952 tons with 1,8 million trees on approximately 3500 ha. The average yield of 13.9 kg per tree reflects mainly extensive growing of apricot (Djuric and Keserovic, 2007). In Croatia, according to Food and Agriculture Organization of the United Nationsfao (FAO) data, apricot is grown on about 400 hectares, with an annual production of about 1,000 tons.

Situation in apricot production in BiH is similar to the situation in Croatia. The average annual production is around 837 t. If we consider separately the Republic of Srpska (RS), according to data of the Statistical Office, apricot production is around 225t (2014), and in favourable years is around 400 t (2011). In plantations in 2014 there were 3400 trees and the average yield was 6.5 kg per tree. In favourable year yield is much higher, so in 2001 an average yield was 13.4 kg per tree.

The apricot production varies from year to year, as the most important causes of variations in production are: extremely low winter temperatures, occurrence of frosts in late spring and drying of trees (apoplexy).

To remedy the situation, in apricot production is necessary to implement a series of measures, primarily apricot need to be planted in appropriate agro-ecological conditions, use seedlings with intermediate, combined varieties in plantations, carry the summer pruning and irrigation (Keserovic et al., 2010).

There are around 2000 varieties of apricots, and in the last two decades has been created many new varieties (Milatovic, 2013). In the continental part of the RS and BiH in the apricot orchards and gardens, by representation, leading variety is Hungarian Best. In Serbia, more precisely, in Vojvodina province, where is favorable natural conditions for growing apricots, breeding process gave apricot variety and selections: NS-4, NS-6, NS rodna and NS kasnocvetna, SK-1, SK-3 , SK-5, SK-16a and SK-13a. These varieties are characterized by a later and longer blossoming, good yield, larger and better fruits than in Hungarian Best as the leading variety of apricot.

Knowing the state of apricot production in the RS and BiH, it is necessary to test biological, pomological and technological value of new varieties and selections of apricot in our agroecological conditions. That is the goal of this study. Based on results we can recommend which varieties should be given priority in growing new plantations of apricot.

Materials and Methods

The study of pomological characteristics of fruits of apricot varieties and selections were performed in 2013 and 2015 in the collection orchard of the Department for Fruit growing and Viticulture of Public Institution Agricultural Institute of Republic of Srpska, Banja Luka (Figure 1). Experimental orchard is planted in 2009. Cherry plum (*Prunus cerasifera* Ehrh.) was used as rootstock, and as intermediate plum cultivar Stanley was used. In the collection orchard there is 10 of trees of following apricot cultivars and selections: NS-4, NS-6, NS rodna and NS kasnocvetna, Aurora, SK-3, SK-16a, SK-13a, SK-1 and Hungarian Best as a standard variety. An average sample of 25 fruits of every variety has been taken in 2013 and 2015. We carried out following pomological measurements: fruit weight, width and height of the fruit and weight of kernel. It is also determined flesh ratio (%) and soluble solids content that is determined by refractometer. The exception is the variety Aurora, which didn't have fruits due to late spring frosts during the flowering in 2015.
The significance of differences was determined on the basis of an analysis of variance with the use of F test for two-factorial. For individual comparisons was used LSD test. Statistical analysis did not include the variety Aurora because it didn't have fruits in 2015.

Figure 1. Experimental orchard of apricot at Economy PI AIRS, Banja Luka (01/06/2015)

Results and Discussion

Table 1 shows average results of measurement of pomological-technological properties of fruits of apricot varieties and selections during the two-year test. In studies in Novi Sad (Rahovic et al. 2013) picking apricot varieties and selections was done earlier than in our research.
All the Novi Sad varieties and selections in 2013 had higher average fruit weight than the standard variety. The highest fruit weight in 2013 have made selections SK-13a (88.46 g) and SK-16a (88.47 g), while in 2015 the largest fruit weight achieved NS 4 (81,75g). In 2015, all studied varieties had higher fruit weight compared to the standard, except variety NS kasnocvetna and selection SK-16a. Statistical analysis of data for fruit weight in the two

observed years has shown statistically highly significant effect of the variety, the effect of year was not statistically significant, while the interaction effect of variety and year was statistically highly significant.

Tab1. Pomological and technological properties of the tested apricot variety and selections in 2013 and 2015, location of Banja Luka

VARIETY	Year	Date of harvest	Fruit weight (g)	Fruit width (cm)	Fruit height (cm)	Stone weight (g)	Flesh Ratio (%)	Soluble solids (%)

	2015	15.07.	81.75	5.46	5.48	3.20	96.08	19,33
NS rodna	2013	12.07.	81.46	5.38	5.34	2.93	96,40	15,50
	2015	15.07.	74.94	5.28	5.26	3.31	95.58	20,33
SK-1	2013	12.07.	82.81	5.48	5.32	2.78	96.64	15,20
	2015	10.07.	74.81	5.28	5.20	3.10	95,85	20.66
Hungarian Best	2013	15.07.	51.26	4.66	4.60	2.18	95.75	16,00
	2015	13.07.	66,44	5.18	4.98	3.15	95.25	17,66

NS 6 in 2013 and NS kasnocvetna and SK-16a in 2015 had lower values for height and width of the fruit compared to the standard. The highest flesh ratio in 2013 had a selection of SK 16a (97.11%), and SK - 13a (97.16%) in 2015.

All cultivars in 2015 have achieved higher soluble solids compared to 2013. The highest content of soluble solids in 2015 had NS Kasnocvetna (22.66%), while the lowest content of soluble solids had cultivar SK -3 (17.66%) and the standard variety.

Results of statistical data analysis for pomological and technological properties of the fruit in a two-year research are given in Table 2.

The highest average fruit weight in the two-year research has made selections SK - 13a (81.98 g), while the lowest fruit weight had variety NS kasnocvetna (57.85 g). The highest coefficient of variation for fruit weight had variety Hungarian Best (30%). Results of weight in varieties NS 6 NS 4 and NS rodna were similar to the results of research in the region of Belgrade (Milatovic *et a.* 2015) All varieties except NS kasnocvetna had higher fruit weight than Hungarian Best, which is the standard variety. The highest average fruit width in the years of research had selections SK-1 (5.38 cm) which also had the second highest fruit height (5.26 cm). Minimum width and height of the fruit had NS 6 (4.82 cm and 4.68 cm). All tested varieties, except the varieties NS 6 and NS kasnocvetna, had a greater width of the fruit compared to the standard variety (Hungarian Best). Most varieties has reached a greater height of the fruit compared to the standard, except for varieties NS 6 and SK-3. NS rodna and NS 4 have achieved similar values for the width and height of the fruit as in research in the area of Belgrade (Milatović *et al.* in 2015), while the cultivar NS - 6 achieved a lower value. In conperation to our study, Mratinić *et al.* (2010) recorded similar measurements of height and width of fruit in NS 4 variety. Statistical analysis of the data for width of the fruit in two years there was a statistically highly significant effect of variety, the effect of year is

statistically significant, while the interaction effect between variety and year statistically highly significant.

Tab2. Pomological and technological properties of the tested apricot variety and selections in, location of Banja Luka (average 2013 and 2015)

VARIETY	Fruit Weight (g)	CV (%)	Fruit width (cm)	CV (%)	Fruit height (cm)	CV (%)	Stone weight (g)	Flesh Ratio (%)	Soluble solids (%)
NS 6	66,04	16.1	4.82	12.8	4.68	12.2	2.92	95.47	17,25
SK-3	75.74	19.1	5.17	7.8	4.77	8.6	2.40	96.84	16,33
SK-13a	**81.98**	18.3	5.36	8.3	5.22	7.7	2.36	**97.12**	17,96
NS Kasnocvetna	57,85	16	4.85	5.1	4.84	5.7	**3.90**	93.26	**18,83**
SK-16a	73.17	26.9	5.16	10.2	5.13	8.2	2.40	96.61	18,08
NS 4	74.77	14.9	5.31	6	5.22	7.6	2.68	96.46	17,42
NS rodna	78,20	14	5.33	6.8	**5.30**	5.8	3.12	95,99	17,92
SK-1	78,81	13.8	**5.38**	6.1	5.26	5.9	2.94	96.25	17,93
Hungarian Best	58.85	30	4.92	10.3	4.79	8.5	2.67	95,50	16.83
Average varieties	69,10		5.02		4.89		2.79	95.71	17,58
Average year									
2013	72,62		5.10		4.93		2.77	96.05	15,49
2015	70.61		5.19		5.10		2.87	95.84	19,74
LSD (years)									
0.05	50,81		1.35		1.21				
0.01	66.78		1.78		1.59				
LSD (variety)									
0.05	107.79		2.87		2.57				
0.01	141.65		3.77		3.37				

The largest coefficient of variation for the fruit width had NS 6 (12.8%) and the smallest NS kasnocvetna (5.1%). For the height of fruit the largest coefficient of variation had a NS 6 (12.2%) and the smallest NS kasnocvetna (5.7%). Statistical analysis of data for the height of the fruit in two years showed that there was a statistically highly significant effect of variety, effect of year and the effect of the interaction between variety and the year.

The highest kernel weight had the NS Kasnocvetna (3.90 g), and the smallest selection SK-13a (2.36 g). The average weight of kernel of all tested varieties was 2.79 g. The average flesh ratio of all tested varieties was 95.71%. The highest flesh ratio had a selection of SK 3 (97.12%), wich was higher compared to research in Vojvodina (Rahovic *et al.,* 2013). The lowest flesh ratio was recorded in the variety NS Kasnocvetna (93.26%). Most varieties in the experiment achieved a higher flesh ratio compared to the standard. Exceptions are varieties NS Kasnocvetna and NS 6.

The highest average percentage of soluble solids had NS Kasnocvetna (18.83%) and the smallest selection SK - 3 (16,33%), which is also the only one that had a lower soluble solids content than standard varieties. In our research, the variety NS 4, NS 6 and NS rodna have achieved a higher content of soluble solids in relation to research in the area of Belgrade (Mratinic *et al.,* 2010; Milatovic *et al.,* 2015).

Conclusion

Based on two years study (2013 and 2015) pomological and technological characteristics of variety and selections of apricot from Novi Sad in agroecological conditions of Banja Luka can be concluded:

- The ripening of the fruit is average was in the second decade of July;
- Most of the tested varieties achieved an average higher fruit weight compared to the standard cultivar Hungarian Best. Varieties SK-13, SK-1 and NS rodna stand out by size of fruits.
- Average values of fruit dimensions (width and height) are generally higher than the standard variety. The exception is the NS 6, which has a lower value;
- Largest kernel has NS Kasnocvetna which contributed that varieties achieve the most unfavorable flesh ratio (93.26%);
- Tested apricot cultivars and selections are generally performed better flesh ratio compared to the standard variety. In particular selection SK-13a (97.12%), SK-3 (96.84%) and SK-16a (96.61%) stand out;
- The content of soluble solids in 2015 was higher compared to 2013. Flesh ratio in two-year test ranged from 16.83% (standard variety) to 18.83% (NS Kasnocvetna). All study apricot cultivars and selections had higher soluble solids compared to the standard.
- Varieties NS rodna, NS 4 and selection SK-16, SK-13a and SK-1 stand out in results of fruit quality;
- Variety Aurora due to very early flowering and sensitivity to low temperatures during the winter is not suitable for cultivation in an area with a continental climate.

Abstract

After mushrooms are harvested a large amount of used compost that has a high content of organic matter and the rich mineral composition remains. Such accumulated compost is a good material to improve the physical properties of soils and plant nutrition. The aim of this study was to investigate the possibility and feasibility of using spent mushroom compost from *Agaricus bisporus* as an alternative growing media for greenhouse production of *Pelargonium peltatum* L. and *Petunia hybrida* Juss. seedlings. The experiment was conducted under greenhouse conditions at the Faculty of Agriculture, University of Banja Luka (Republic of Srpska - RS, Bosnia and Herzegovina - BiH) in 2014. It was arranged in a split - plot design with four replicates and two treatments (commercial substrate and mixture of commercial substrate and spent mushroom compost) for each variety. Morphological parameters, were recorded regularly during growth and development of seedlings. At the end of experiment, seedlings were sampled and root and above-ground fresh and dry weight were recorded. Obtained results showed significantly higher values of all investigated parameters of seedlings grown on spent mushroom compost. Thus it can be concluded that use of spent mushroom compost, as additional of commercial substrate in the production of geranium and surfinia seedlings is possible and economically justified as well as environmental friendly.

Key words: alternative substrate, geranium, surfinia, seedlings.

Introduction

Peat is the most widely used substrate for the cultivation of horticultural plants, but its high price and increasing exploitation, lead producers for the search of alternative substrate or at least their partial replacement. As one of the alternatives in the production of flowers and vegetables, it can be used compost from microbial decomposition of various organic substances (Karasek, 2002). Mushroom production is becoming more popular in our environment. The most important advantage of this branch of agriculture is that it can all take advantage of the production cycle. After mushrooms are harvested a large amount of used compost that has a high content of organic matter and the rich mineral composition remains (Lazic et al., 2001). Such accumulated compost is a good material to improve the physical properties of soils and plant nutrition. Numerous researchers confirms that disused mushroom compost can be used as substrate for successful cultivation of many crops (Maher, 1994; Chong et al., 1994; Polat et al., 2009; Gonani et al., 2011). However, care should be taken on the amount of used mushroom compost. Lemaire et al. (1985) reported that the used mushroom compost can't be used alone due to weak water permeability, high salinity and a neutral pH which is not suitable for all horticultural plants. Çelikel and Çağlar (1997) reported that higher yield and earliness for tomato and cucumber growth were found in mixtures of peat and spent mushroom compost (1:1) than the plants that were grown in a garden soil.

Therefore, the aim of this study was to determine the effectiveness of the use of spent mushroom compost from growing mushrooms - *Agaricus bisporus* in the production of geranium (*Pelargonium peltatum* L.) and surfinia (*Petunia hybrida* Juss.) seedlings.

Material and methods

The study was conducted in greenhouses on the family farm Šušak in Prnjavor municipality, and in greenhouses of Faculty of Agriculture, University of Banja Luka (RS/BiH) in 2014 period. As an initial planting materials were used already rooted cuttings of geranium (*Pelargonium peltatum* L.) and surfinia (*Petunia hybrida* Juss.). For rooting cuttings were used a commercial substrate suitable for sowing seeds and cuttings Fruhstorfer Erde type: *Aussaat und Stecklingserde* from Hawita EU manufacturer. The substrate contains perlite for better aeration and friability. Other substrate characteristics are: pH 5.9; N mg/l=80; P_2O_5 mg/l=60; K_2O mg/l=90; EC 50 ms l; retention capacity 700 ml/l. Experiment was set up as a spli-plot design with four replications and two treatments - a commercial substrate (A1) and a mixture of spent mushroom compost and commercial substrate at a ratio of 70:30 (A2). The trial consisted of a total of 80 plants, for each variety, which are divided into two groups with 40 plants in each group and 10 plants per replication. Commercial substrate: Klasmann-Deilmann substrate - *TS 3* which is suitable for pricking out seedlings, pH 5.5-6.5 and that is enriched with NPK fertilizer 14:16:18 in the amount of 1.0-1.5 kg/m^3 was used as a control for geranium seedlings. Commercial substrate: *Baltisches substrat* from Hawita EU manufacturer, enriched with Fe as such is particularly suitable for plants like surfinia and other from familly *Solanaceae*, with reduced pH 5.2 was used as a control for surfinia seedlings. Spent mushroom compost was previously mixed with garden soil and composted for six months and was used as a treatment for both variety. In the laboratory of Soil Science, Faculty of Agriculture, University of Banja Luka chemical analysis of composted substrate was conducted and its composition is given in Table 1.

Table 1. Agrochemical analysis of spent mushroom compost

pH		organic matter %	AL-P_2O_5 mg/100g	AL-K_2O mg/100g
H_2O	KCl			
7,32	7,00	14,3	72,0	280

During the experiment was carried out measurements of morphological indicators of growth and development of plants (plant height, number of leaves, number of flowers and number of flower branches). In order to examine the growth and development of roots and above-ground parts of seedlings under the affect of different substrates, the root was cleaned from the substrate, washed with distilled water, dried with paper towels, then was measured fresh weight of above-ground parts and roots of each plant separately. Weighed above-ground parts and roots are packed in separate paper bags, properly labeled and placed in an oven to dry. Drying the plant material is lasted to a constant weight at a temperature of 70^0C, after which it was carried out the weighing of dry roots and above ground parts. The mass of fresh and dry matter was measured and expressed in grams (g). The obtained data were statistically analyzed using analysis of variance and the differences between specific substrate used F - test, using a computer program VVSTAT (Vukadinovic, 1994).

Result and discussion

In order to determine the influence of the alternative substrate on the growth and development of geranium (*Pelargonium peltatum* L.) and surfinia (*Petunia hybrida* Juss.) seedlings through plants morphological indicators and the fresh and dry weight of roots and above-ground parts, the following results were obtained. During the experiment, measurements were made of morphological indicators of plant growth and development. Table 2. and Table 3. shows the average value of the indicator. Plants treatment showed better results in terms of morphological characteristics (plant height, leaf number, number of flowers, number of

flowering branches), as the average values of all investigated parameters were significantly higher than the average value of the control plants.

Table 2. Influence of spent mushroom compost on morphological indicators of growth and development of geranium seedlings (Pelargonium peltatum L.*)*

Treatment variant (A)	*Plant height*	*Number of leaves*	*Number of flowers*	*Number of flower branchs*
Control (A1)	7,60[a]	9,74[a]	0,89[a]	1,01[a]
Treatment (A2)	9,61[b]	12,02[b]	1,45[b]	1,21[b]
Average	8,60	10,88	1,17	1,11
Analysis of variance - F	*32,31***	*26,29***	*31,91***	*12,49**
LSD	*Plant height*	*Number of leaves*	*Number of flowers*	*Number of flower branchs*
0,05	*0,9816*	*1,2343*	*0,2768*	*0,1597*
0,01	*1,6280*	*2,0471*	*0,4591*	*ns*

Plant height, number of leaves and number of flowers of geranium seadlings were under a very significant ($p \leq 0.01$) influence of the substrate. Highest recorded plant height 9.61 cm belong to variant A2, while lowest 7.60 cm belonging to the control plants (A1). The highest average number of leaves (12.02) was determined in A2 variant, and the lowest of 9.74 belonging to the control plants, whereby the difference between the variant was 23% in favor of variant A2. The highest average number of flowers of the treatment was 1.45, which was 63% more flowers than in the control group of plants (A1 0.89). Number of flower branches was under significant ($p \leq 0.05$) influence of the substrate. The highest average number of flowerbranches of the treatment was 1.21, which was 20% more flower branches than in the control group of plants (1.01) (Tabela 2.).

Table 3. Influence of spent mushroom compost on morphological indicators of growth and development of surfinia seedlings (Petunia hybrida Juss.)

Treatment variant (A)	*Plant height*	*Number of leaves*	*Number of flowers*	*Number of flower branchs*
Control (A1)	16,06[a]	25,97[a]	0,64[a]	7,25[a]
Treatment (A2)	17,20[b]	28,05[b]	1,16[b]	8,79[b]
Average	16,63	27,01	0,90	8,02
Analysis of variance - F	*11,98**	*22,75***	*25,28***	*16,02***
LSD	*Plant height*	*Number of leaves*	*Number of flowers*	*Number of flower branchs*
0,05	*0,8131*	*1,0671*	*0,2531*	*0,9384*
0,01	*ns*	*1,6166*	*0,3834*	*1,4217*

Plant hight was under significant ($p \leq 0.05$) influence of the substrate. The highest average value of the plant height was 17.20 cm and was observed in plants treatment, and the difference between the control group of plants and the treatment was 7% in favor of the treatment group. Treatment with the substrate had a significant ($p \leq 0.01$) impact on the number of leaves, number of flowers and number of flower branches of surfinia seedlings. The highest

average number of leaves (28.05) was determined in A2 variant, and the lowest of 25.97 belonging to the control plants, whereby the difference between the variant was 8% in favor of variant A2. The highest average number of flowers of the treatment was 1.16, which was 81% more flowers than in the control group of plants. The highest average number of flower branches was determined in A2 variant, and the lowest of 7.25 belonging to the control plants, whereby the difference between the variant was 21% in favor of variant A2 (Table 3.).
After analyzing the morphological indicators of growth and development of geranium (*Pelargonium peltatum* L.) an surfinia (*Petunia hybrida* Juss.) seadlings, measurement of fresh and dry weight of plants were carried out and the obtained results are shown in Table 4. and Table 5.

Table 4. Influence of spent mushroom compost on fresh and dry above-ground part and root mass of geranium seedlings (Pelargonium peltatum L.)

Treatment variant (A)	*Fresh above-ground mass (g)*	*Dry above-ground mass (g)*	*Fresh root mass (g)*	*Dry root mass (g)*
Control (A1)	18,00[a]	2,31[a]	2,25[a]	0,40[a]
Treatment (A2)	23,67[b]	2,83[b]	2,50[b]	0,43[a]
Average	20,83	2,56	2,37	0,42
Analysis of variance - F	*25,55***	*8,28**	*37,49***	*0,19*
LSD	*Fresh above-ground mass (g)*	*Dry above-ground mass (g)*	*Fresh root mass (g)*	*Dry root mass (g)*
0,05	*3,1123*	*0,4951*	*0,1133*	*ns*
0,01	*5,1617*	*ns*	*0,1880*	*ns*

Based on the data of Table 3, it can be seen that the fresh mass of above-ground part was under a very significant ($p \leq 0.01$) influence of the substrate. The highest recorded average value 23.67 g belonged to the treatment (A2). The lowest recorded value was 18.00 g and belonged to the A1 variant. Dry above-ground parts mass, was under significant ($p \leq 0.05$) influence of the substrate. The greatest value of the dry weight of above-ground parts belonged to the variant A2 (treatment with the substrate) 2.83 g in relation to variant A1 (control) 2.31 g. Fresh root mass, was also under very significant ($p \leq 0,01$) influence of the substrate. Highest recorded value was in A2 variant plants 2.50 g compared to lowest recorded value in variant A1 (2.25 g). Statistical significance was missed in dry mass of roots (Table 4).

Table 5. Influence of spent mushroom compost on fresh and dry above-ground part and root mass of geranium seedlings (Petunia hybrida Juss.)

Treatment variant (A)	*Fresh above-ground mass (g)*	*Dry above-ground mass (g)*	*Fresh root mass (g)*	*Dry root mass (g)*
Control (A1)	18,50[a]	1,88[a]	1,41[a]	0,21[a]
Treatment (A2)	19,32[b]	2,11[b]	3,53[b]	0,33[b]
Average	18,91	2,00	2,47	0,27
Analysis of variance - F	*6,00**	*12,31**	*34,34***	*10,42*[*]

LSD	*Fresh above-ground mass (g)*	*Dry above-ground mass (g)*	*Fresh root mass (g)*	*Dry root mass (g)*
0,05	*0,8216*	*0,1587*	*0,8874*	*0,0928*
0,01	*ns*	*ns*	*1,3443*	*ns*

The average fresh and dry weight of above ground part were under the statistically significant ($p \leq 0.05$) influence of the substrate. The highest recorded average fresh weight value of treatment was 19.32 g and dry weight value was 2.11 g. The lowest recorded value were 18.50 g and 1.88 g and belonged to the A1 variant from both variant. Fresh root mass was under very significant ($p \leq 0.01$) influence of the substrate. Highest recorded value was in A2 variant plants 3.53 g compared to lowest recorded value in variant A1 (1.41 g). Dry root mass was under significant ($p \leq 0.05$) influence of the substrate. The highest value of the dry weight of root belonged to the variant A2 (treatment with the substrate) 0.33 g in relation to variant A1 (control) 0.21 g. (Table 5).

Pine bark and peat formed by decomposition of *Sphagnum* moss are the two most commonly used substrate components that are currently used for the production of horticultural plants. Although many times so far it’s proven the effectiveness and justification of the use of these substrates, the developed countries are increasingly using alternative natural substrates. This is due to high cost and availability of existing substrates, as well as unplanned use of forests and environmental degradation (Wright et al., 2009). That is why the alternative substrates are very important in a container production of horticultural crops. Any potential replacement for peat must have the appropriate physical and chemical characteristics, must be available in significant amounts, consistent and compatible with the economic potential markets, and one of the materials that meet these requirements are coconut fibers (Evans and Stamps, 1996). The use of agricultural waste and other composted materials in replacement for peat and pine bark is not new in the world, but among local producers this is a novelty. Also, the use of organic fertilizer, has great application in improving the content of nutrients in the soil. After harvesting the mushrooms, millions of tons of "spent" substrates become available for other purposes. The use of this substrate has a number of advantages, which are recognized by many plant producers, but they also depend on the types of mushrooms that are grown. Delgado et al. (2008) compared the cultivation of geranium in commercial compost with peat and the substrate which was enriched with 10% of chicken feces, where it came to the result that after three months of growing plants on a substrate with chicken feces increased number of leaves, number of flowers and stem length, and thus increased dry weight of the overhead part of geraniumwere recorded. In the cultivation of marigold (*Tagetes patula* L.) does not recommend the use of spent mushroom compost in an amount greater than 50% relative to the amount of commercial substrates, due to the impossibility of controlling the substrate and the low salinity water capacity (Young et al. 2002). Çiçek et al. (2014) studied the impact of fresh and spent substrate from mushroom growing on the growth of chrysanthemum (*Chrysanthemum morifolium* 'Vista'). The best results have indicated a mixture containing 12.5% of fresh substrate and 25% of spent substrate of mushroom growing.

Conclusion

This study confirmed that the spent mushroom compost can be used in the production of *Pelargonium peltatum* L. and *Petunia hybrida* Juss. seedlings as a supplement to commercial compost in the amount of 70%. Efficient use of spent mushroom compost is reflected in an increase in the average measured value of morphological indicators of growth and development (plant height, leaf number, number of flowers and number of flowering branches) and the increase in fresh dry mass of above ground parts or root relative to the average value of control plants seedlings. Based on the results, it can be concluded that the

use of spent mushroom compost from growing mushrooms (button mushrooms - *Agaricus bisporus*), as well as the addition of a certain amount of commercial substrates in the preparation of alternative substrates in the production *Pelargonium peltatum* L. and *Petunia hybrida* Juss. seedlings is recommended because of a positive impact on the growth and development of roots and above-ground parts, and with all that is economically viable and suitable for the environment.

Abstract

Modern agricultural production implies irrational application of large amounts of pesticides and fertilizers, which significantly reduces the quality and fertility of agricultural land, adversely affect the environment and reflect on food quality and human health. French beans (*Phaseolus vulgaris L.*) is the crop which in our production conditions are grown in the greenhouse as early in the spring or autumn that matures in October. The aim of this study was to investigate the effect of microbiological fertilizer individually and in combination with mineral fertilizer on the physical and chemical properties of the fruit French beans. Sampling as well as fruit length, width and weight were recorded at the stage of full maturity. As part of chemical analysis of the fruit, total content of nitrogen, nitrate, protein and dry matter was determined. According to the results of research the largest value of analyzed physical parameter were registered in variety of microbiological fertilizer in combination with mineral one. The largest values of chemical composition parameter of French beans fruits were registered in variety with only mineral fertilizer. Significantly, the lowest nitrate content was observed in variants with an example of only microbiological fertilizer applied.

Key words: *French bean, greenhouse, fertilizer.*

Introduction

French beans (*Phaseolus vulgaris L.*) belong to the family *Fabaceae*. Peas and beans are most spread species from the genus *Phaseolus* and occupying more than 85% of the areas under all the species of this genus in the world and can be regarded as varieties of the same plant species *Phaseolus vulgaris L.* (*Satiriou and Traka-Mavrona, 2008; Baćanović, 2010*).

French beans (*Phaseolus vulgaris*) is the crop which are grown in the greenhouse as early in the spring or autumn that matures in October (*Đurovka, 2006*). It is grown because of pods that represent useful part of human diet because of their low energy value and wealth of mineral substances (*Zdravković, 2000*). Legumes, including beans are the primary source of proteins in the human diet. Also, it features a wealth of carbohydrate and minerals (*Lott et al., 2000*), and is a good source of Ca, Fe and vitamin C (*Grubben, 1977; Almeida Costa et al., 2006*). French beans can be grown in all soil types, from sandy loam to clay soil (*Indrakumar Singh, 2009*). At the root of beans and other legumes, are bacteria of the genus *Rhizobium* which fix atmospheric nitrogen in the process of nitrogen fixation rendering it into ammonia form that is accessible to plants and microorganisms. Microbiological preparations used as a microbiological fertilizer are containing selected cultures of microorganisms that are used to inoculate the seeds and seedlings or are introduced in the soil in order to intensify certain microbiological processes that increase the content of available nutrients, and in leguminous plants can be used as the sole feed (*Djurić, 2008*). The increasing cultivation of plants without using the fertilizers and pesticides, as well as the ability of microorganisms to provide the necessary plant nutrient, indicating that the microbiological fertilizer occupy an important place in agricultural production. (*Tyler et al., 2008*). French beans responds well to inoculation of the seed with bacterial fertilizers (*Jarak et al., 2010*). Inoculation of legume

seed is well studied, and the exploitation of these beneficial symbiotic communities is a mark of successfully applied agricultural microbiology (*Alves et al., 2003*). Microbiological preparations when used in vegetable production, as individual or combined cultures, have positive impact on the length of the plant (stem and roots), plant weight (raw and dry), nitrogen content in the plant, quality and yield (*Djurić, 2008*).
Modern agricultural production means irrational application of large amounts of pesticides and fertilizers, which significantly affects the quality and fertility of agricultural land, adversely affect the environment, which affects the quality of the food and the health of people (*Marinković et al., 2014*). Therefore, the aim of the study was to investigate the effect of microbiological fertilizer individually and in combination with mineral fertilizer on the yield and chemical composition of French beans.

Materials and methods

The survey was conducted in 2014 in the greenhouse of 360 m^2, in the village of Hodbina, Mostar (Bosnia and Herzegovina). The experiment used the seed of domestic yellow beans that were planted in the seeding substrate Potgraund H 20.08.2014. Just before sowing the seed part is immersed in microbiological fertilizer, a combination of six bacteria belonging to the nitrogen-fixing-*Azotobacter chroococcum A. vinelandii, Derxia sp*. and mineralizers phosphorus of *Bacillus licheniformis, B. subtilis, B. megaterium*.
Planting seedlings is done 26.08.2014. Plants are planted in double strips, where in the distance between the strips was 80 cm and 50 cm spacing in the row and 40 cm between rows. The trial was a randomized complete block design with 4 replications. Variations on the basic experimental plots are as follows: 1. Microbiological fertilizer 2. Microbiological fertilizer+mineral, 3. Mineral fertilizer and 4.Control.
The method of cultivation in these variants differed mainly in the diet. Alternative 1 was adopted microbial fertilizer which is applied to the root. Another variant is contained microbial fertilizer addition crystalline formulation of fertilizer 20:20:20, 15:30:15, 15:5:30 pm. The third variant was used as fertilizers. The control variant was not fertilized. Protection of French beans implied usual methodology for greenhouse production of beans in this area. At the stage of full maturity sampling was done (14.10. 2014) and weight, width and length of 40 pods per variant was determined. As part of the chemical analysis of the fruit is determined by the content of total nitrogen (the Kjeldhal), nitrate (spectrophotometry), the content of dry matter (drying oven to constant weight to 130^0C) and proteins (from nitrogen). The results were processed with statistical method of analysis of variance and tested with LSD test.

Picture 1: Planting of beans Picture 2: Flowering phase Picture 3: Measuring the length

Results and discussion

According to the survey (Table 1.), It can be seen that the values of the physical parameters of the largest varieties of beans Microbiological + Mineral, a minimum width in variants only microbiological fertilizer, while the remaining two physical parameters (weight, length) was the lowest in the control treatment. Results of analysis of variance with the physical parameters of beans showed that the investigational factor had statistically significant effect on the weight and length of pods, while the width of the pods that effect was not statistically significant. According to Tukey test weight and length husk was statistically significantly higher in variants Microbiological+Mineral concerning variant only microbiologically and control. Between the varieties of microbiological control and there was no statistical significance. Also, while the difference in weight and length of the follicle was not statistically significant between the Microbiological+Mineral and Mineral.

Table 1. The effect of the fertilization on the physical parameters of French beans

Variety	Weight (g)	Length (cm)	Width (cm)
Microbiological	11,39[b]	18,66[b]	1,39
Microbio.+ Mineral	14,65[a]	20,64[a]	1,6
Mineral	13,87[a]	19,81[a]	1,54
Control	10,86[b]	18,51[b]	1,42
$W_{0,05}$	1,18	0,84	ns
$W_{0,01}$	1,56	1,11	ns

Table 2. The effect of the fertilization on the chemical parameters French beans

Variety	Nitrogen (%)	Nitrate (mg/kg)	Proteins (%)	Dry matter content (%)
Microbiological	0,16[b]	242,54[b] (*)	0,99[b]	7,95
Microbio.+ Mineral	0,19[b]	539,1[a]	1,2[b]	8,05
Mineral	0,59[a]	540,19[a]	3,71[a]	8,4
Control	0,14[b]	285,21[b]	0,87[b]	8,1
$W_{0,05}$	0,19	204,45	1,45	ns
$W_{0,01}$	0,29	309,63	2,20	ns

According to the results of analysis (Table 2.) of variance test factor had also an impact on the chemical parameters beans, statistically significant effect on the content of peat, significantly the protein content and nitrate, while the dry matter content was no statistical significance of the test parameters.

Previous studies the application of inoculation in the production of green beans has shown that inoculation of bean seeds individual strains of rhizobium, or mixtures thereof, provide nitrogen almost completely, while nodulation, number of legume, nitrogen content in the grain and the yield depends of the different sort of beans and characteristics of rhizobium (*Marinković, 2006*).

Highest content of nitrogen and protein was observed in variants with mineral fertilizer, which is, according to the Tukey test, statistically highly significant in comparison to the other two variants, between which there was no statistical significance. According to research *Almeida Costa et al, 2006*, in French beans protein content ranged from 1.7 to 1.9 g / 100 g. The smallest content of nitrate is observed in only variant microbial fertilizer, then in the

control according to the Tukey test statistically significantly less than in the other three variants, between which there was no statistical significance of the values of the test parameters.

Conclusion

The results showed that microbiological fertilizer in combination with mineral has positive impact on the physical parameters of beans. Weight and length of pods have the highest value in the variant microbiological + mineral fertilizer, while value in the control variant was the lowest. Width value of French beans was uniform in all variants and it is not statistically significant.

All tested chemical parameters have the highest values in the variant of mineral fertilization.

TECHNOLOGICAL CHARACTERISTICS OF BLACK WINE VARIETIES IN THE CONDITIONS OF THE TREBINJE (BOSNIA AND HERZEGOVINA) VINEYARD

Tijana BANJANIN*, Mirko KULINA

Faculty of Agriculture, University of East Sarajevo, Republic of Srpska, Bosnia and Herzegovina
*Corresponding author: tijanapekic@hotmail.com

Abstract

The aim of this paper is to present technological characteristics of four black wine varieties (Pinot Noir, Merlot, Vranac and Cabernet Sauvignon) in the conditions of the Trebinje vineyard during the vegetation in 2013. Research of technological characteristics include mechanical compounds of grapes and berries as well as quality of the grapes and berries (sugar, acid presence and pH). The biggest mass of the cluster, grape peduncle and berries in a cluster as well as the biggest mass of 100 berries and mass of 100 berries flesh had Vranac variety while the smallest had Cabernet Sauvignon variety. The biggest mass of berries skin and mass of seeds in 100 berries had Vranac variety and the smallest had Pinot Noir variety. Sugar content varied between 17.9% (Vranac) and 23.7% (Merlot). Vranac variety had the smallest acid content (3.6 g l^{-1}) while Cabernet Sauvignon variety had the biggest (5.9 g l^{-1}). The smallest pH also had Vranac variety (3.08) while the biggest had Merlot (3.37).

Keywords: *technological characteristics, mechanical compounds of grapes and berries, grapes quality, Trebinje vineyards*

Introduction

Selection of appropriate grape variety has a great importance in modern viticulture (*Kerridge et Antiliff*, 2004). In the area of Herzegovina there is large a number of varieties, out of which some are native (Žilavaka, Blatina, Trnjak, Bena etc.), while a certain number of varieties is introduced. Among introduced varieties the most important are Smederevka, Prokupec, Vranac and Plavdina. In the last decade the renovation of vineyards in Herzegovina started so some other varieties such as Merlot, Cabernet Sauvignon, Pinot Noir, Muscat, Shiraz, Chardonnay and others are introduced. The aim of this paper is to study the economic and technological characteristics of four black wine varieties (Pinot Noir, Merlot, Vranac and Cabernet Sauvignon) that were grafted on vineyard Berlandieri × Riparia Kober 5BB in agroecological conditions of Trebinje.

Material and methods

The study of economic and technological characteristics of the studied grapevine varieties is done during the vegetation of 2013. The experiment was set up at the location of Zasad polje, Trebinje. The vineyard was established in 2008 at an altitude of 273 m. Planting distance was 2.4 x 0.9 m. During the research year in experimental orchards, basic measures of pruning were applied, as well as protection from the most important causes of diseases and pests. During the experiment, the orchard was irrigated by the "drop by drop" method.

As for the economic and technological characteristics of tested varieties, mechanical composition of cluster and berries and chemical composition of stum was determined. The mechanical analysis of cluster and berries determined the following indicators: the composition of the cluster (cluster mass, the mass of peduncles and berries in a cluster) and the composition of the berries (weight of 100 berries, weight of flesh, fruit skin and seeds in 100 berries) expressed in grams. As for the parameters of the chemical composition of the stum pH, sugar and acids content in the stum were investigated.

Results and discussion

Absolute and relative values of the parameters of the mechanical composition are different for different varieties of vines and for different growing conditions. Knowledge of mechanical composition of berries and cluster has a special practical importance in assessing the grapes as raw material for processing and consumption in fresh condition (*Blesić*, 2006).

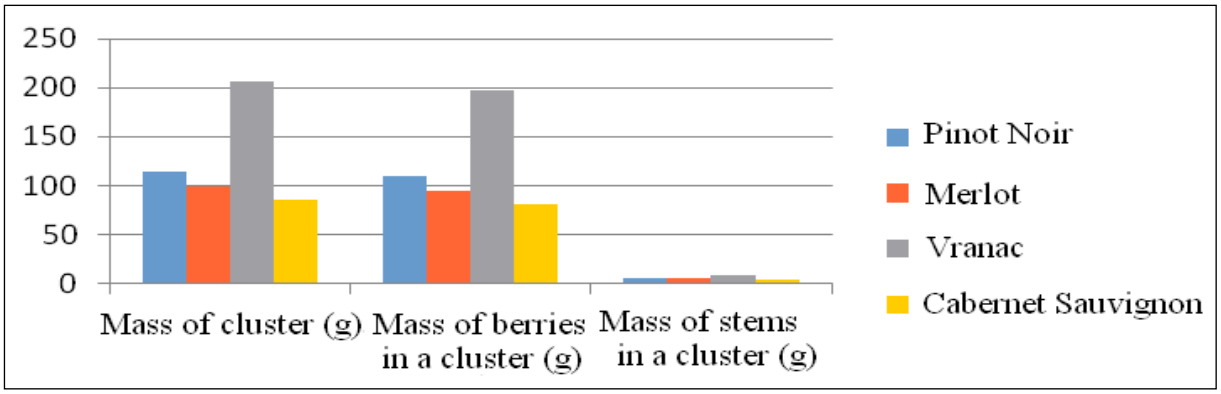
Mechanical composition of cluster. The relationship between certain parts of the cluster depends on the grape variety, the health condition of the grape, ecological conditions of cultivation and harvesting time. The values of certain parameters of the mechanical composition of the cluster of the tested varieties are presented in Table 1.

Table 1. - The values of the mechanical composition of the cluster of the tested varieties

Variety	Pinot Noir	Merlot	Vranac	Cabernet Sauvignon	LSD 0.05	LSD 0.01
Mass of cluster (g)	114.95	98.73	206.93	85.35	29.21	39.04
Mass of stems in a cluster (g)	5.58	4.85	8.87	3.78	1.27	1.70
Mass of berries in a cluster (g)	109.36	93.89	198.05	81.56	28.85	38.56

The mass of the cluster is a quite steady ampelographic property and it is defined by the biological characteristics of varieties of vines. Out of all tested varieties, Vranac variety had the highest cluster mass (206.93g) and Cabernet Sauvignon had the lowest (85.35g). Analysis of the significance of differences of the average cluster mass of the tested varieties shows that there is a highly significant difference in mass of the cluster between the varieties of Pinot Noir and Vranac, Merlot and Vranac, Cabernet Sauvignon and Vranac.

A significant statistical difference in terms of the mass of the cluster can be found between the varieties of Pinot Noir and Cabernet Sauvignon. Our results in terms of the mass of the cluster are consistent with the results of other authors (*Avramov et al*., 2003; *Pajović et al*., 2009; *Popović et al*. 2013), however, they deviate slightly from the results of *Vukosavljević et al*. (2011) and *Ranković- Vasić et al*. (2011).



Graph 1. - Mechanical composition of cluster

Mass of stems in a cluster. The results of our study (graph 1.) show that the highest mass of stems in a cluster is present in Vranac variety (8.87g) and the lowest is present in Cabernet Sauvignon variety (3.78g). In terms of weight of the stems, the studies of varieties showed highly significant statistical difference.

Only between the varieties of Pinot Noir and Merlot, as well as Cabernet Sauvignon and Merlot there was not any statistically significant difference. The results of our examinations are consistent with results of *Pajović et al*. (2009).

Mass of berries in a cluster. Since from the aspect of the use-value of the varieties it is better if the variety has a higher share of berries in the structure of the cluster, it can be concluded that out of the investigated varieties, Vranac variety had the best results (198.05g) (Table. 1).

The results of the mass of berries of the cluster in our study are consistent with the results of *Pajović et al.* (2009). In terms of mass of the berries in a cluster between Pinot Noir variety and Vranac, as well as Merlot and Vranac there is a statistically very significant difference, but between the other tested varieties there is not any statistically significant difference.

Mechanical composition of berries. Berry consists of an external layer – berry skin, flesh (mesocarp and endocarp) and seeds. The values of the parameters of the mechanical composition of berries in a cluster of tested vine varieties in conditions of Trebinje in 2013 are given in Table 2.

Table 2. - Values of mechanical composition of berries of the tested varieties

Variety	Pinot Noir	Merlot	Vranac	Cabernet Sauvignon	LSD 0.05	LSD 0.01
Mass of 100 berries (g)	120.65	126.32	187.79	100.99	9.97	15.10
Mass of flesh of 100 berries (g)	107.57	95.51	150.41	75.97	11.46	17.36
Mass of berry skin of 100 berries (g)	15.16	24.21	28.51	19.54	2.72	4.12
Mass of seeds of 100 berries (g)	5.09	5.59	8.87	5.48	1.71	2.82

Mass of 100 berries. The study results showed that Vranac variety had the highest mass of 100 berries (187.79g) and Cabernet Sauvignon had the lowest (100.99g). Analysis of the significance of differences of masses of 100 berries in tested varieties shows that there is a significant difference between the tested varieties. Only between varieties Pinot Noir and Merlot there are no statistically significant differences. The data obtained for the studied varieties is consistent with the results of *Pajović et al*. (2009).

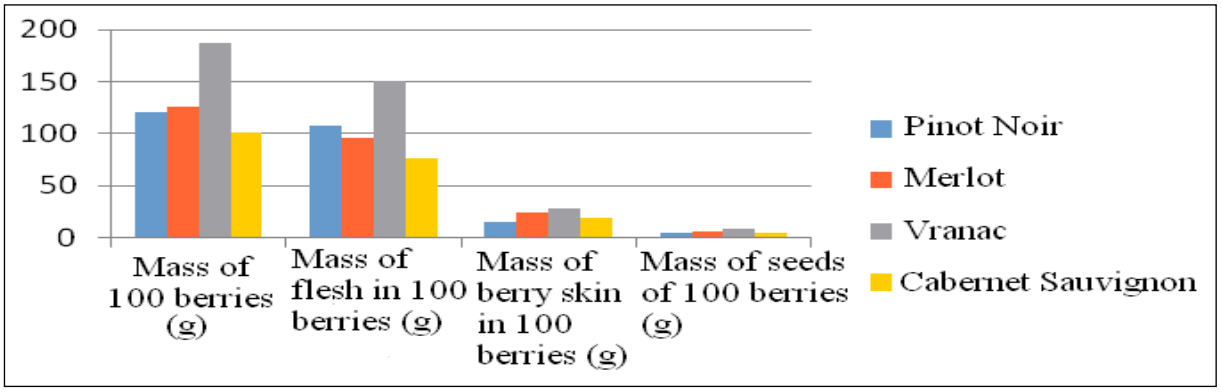
Mass of flesh in 100 berries. Fleshy part of berries (mesocarp) makes most of the berries. The results of the study of the flesh mass in 100 berries show that Vranac variety had the highest mass of flesh (150.41g) and Cabernet Sauvignon had the lowest (75.97g).

In terms of the flesh mass in 100 berries there is statistically highly significant difference among the tested varieties. Only between varieties Pinot Noir and Merlot the difference was statistically significant. Our findings are consistent with the values specified by *Pajović et al*. (2009).

Mass of berry skin in 100 berries. The thickness and elasticity of the skin depends on the variety and growing conditions. Vranac variety had the highest mass of berry skin in 100 berries (28.51g) variety Pinot Noir had the lowest mass (15.16 g) (table 2.). Analysis of the significance of differences in mass of berry skin in 100 berries of tested varieties shows that there is a statistically highly significant difference.

Mass of seeds in 100 berries. The study results showed that Vranac variety had the highest mass of seeds in 100 berries (8.87g) and Pinot Noir had the lowest (5.09g). A highly statistically significant difference can be seen between varieties Pinot Noir and Vranac, Merlot and Vranac and Cabernet Sauvignon and Vranac, while among other varieties there

were no statistically significant differences. The values for the mass of seeds in 100 berries cited by *Pajović et al*. (2009) are consistent with the results of our research.



Graph 2. - Mechanical composition of berries

Chemical composition of the stum is very complex. It varies dramatically, depending on the variety, environmental conditions, applied agricultural technology, degree of ripeness of the grapes, health status, etc. Out of parameters that are included in the chemical composition of the stum, in our study we included: sugar content, acid content and pH. The results of our study of the chemical composition of the stum in tested varieties are shown in Table 3.

Table 3. - Chemical composition of the stum in tested varieties

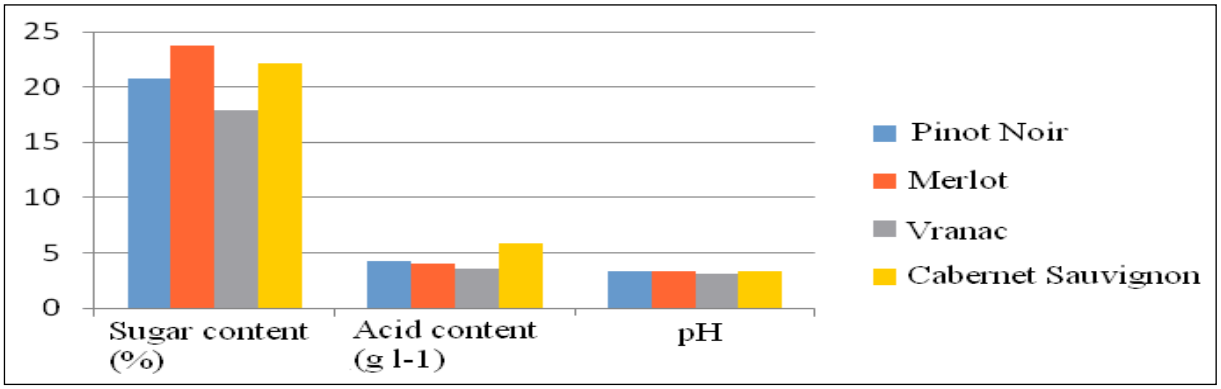
Variety	Pinot Noir	Merlot	Vranac	Cabernet Sauvignon
Sugar content (%)	20.80	23.70	17.90	22.20
Acid content (g l^{-1})	4.30	4.00	3.60	5.90
pH	3.35	3.37	3.08	3.29

The total amount of sugar in the stum varies and depends on the influence of variety, weather conditions during the ripening of grapes and applied agricultural technology. In most cases the sugar content of grape stum from noble vines of *Vitis vinifera* L. ranges between 160 and 250 g l-1 (16-25%). The results show that variety Merlot, had the highest sugar content in stum (23.7%), Pinot Noir had slightly lower sugar content (20.8%) and Cabernet Sauvignon (22.2%), and Vranac had the lowest sugar content out of all of them (17.9%). Our findings are consistent with the results of the author (*Cvetković et al*., 2000; *Mijović et al*., 2004; *Mijatović et al*., 2009; *Bešlić and Todić*, 2010), while *Stanković et al*., 2000, *Avramov et al*. 2003, *Vukosavljević et al*., 2011, *Popović et al*., 2013, report lower or higher values. In terms of sugar content in grape stum, we can see a significant impact of weather conditions and agricultural techniques applied to the tested varieties.

The amount of acid in ripe grapes varies in a very wide range, from 3 to 12 g l^{-1}, mostly 5-8 g l^{-1}, depending on the variety, environmental conditions, degree of ripeness of the grapes, etc. (*Nikolić*, 2012). The grapes which ripen in warmer climates will have less acid than those which ripen in colder climates.

The results of our study (Table 3) showed that the highest content of acid in stum had the Cabernet Sauvignon variety (5.9 g l^{-1}) and Vranac variety had the lowest (3.6 g l^{-1}). The obtained values are significantly lower compared to the results of other authors (*Avramov et al*., 2003; *Mijović et al*., 2004; *Mijatović et al*., 2009; *Bešlić and Todić*, 2010; *Vukosavljević et al*., 2011; *Popović et al*. 2013). The differences in values for a given feature can be interpreted

through the influence of different weather conditions during the ripening of grapes and applied agricultural technology.



Graph 3. – Chemical composition of the stum

The pH value of the must and wine mainly ranges between 2.7 and 3.9 (*Katalinić et al*. 2010). More acidic wines have a value below 3.5, while in the insufficiently acidic wines it moves up to 4. Vranac variety had the lowest pH value (3.08) (graph 3.) and Merlot had the highest (3.37). The pH value of the tested varieties is slightly lower compared to the results of *Pajović et al*. (2009) in Podgorica vineyards. However, it is in accordance with the values specified by the same authors in Skopje vineyards. Our findings are consistent with the results of *Bešlić and Todić* (2010) and *Yuste et al*. (2013).

Conclusions

1. Vranac veriety had the highest mass of cluster, and Cabernet Sauvignon had the lowest. Also, Vranac showed the best qualities regardin the mass of stems and berries in a cluster, while Cabernet Sauvignon had the lowest results for these qualities.
2. Mass of berries and mass of berry flesh in 100 berries was the highest in Vranac variety and it was the lowest in Cabernet Sauvignon variety. Vranac had the highest mass of berry skin and mass of seeds, and Pinot Noir had the lowest.
3. Sugar content in stum varied from 17,9% (Vranac) to 23,7% (Merlot). Vranac variety had the lowest content of acids, and Cabernet Sauvignon had the highest. Vranac had the lowest pH value and Merlot had the highest.

Abstract

Seed aging is one of the main causes of reducing vigor, germination and emergence of Birdsfoot trefoil's seed. In this study, the vigor of domestic birdsfoot trefoil genotypes tested in field conditions. Seeds collected from the local population of 20 genotypes; 10 genotypes from 5 till 6 years old and 10 genotypes seed from 15-16 years old was examined. The seeds were stored in paper packaging in storage conditions. The viability of seeds represents a potential for formation of a new plant. The aim of this study is to determine the seed germination under field conditions and to obtain new plants capable for reproduction. Based on the results of field trials, can be concluded that germination for genotypes of seed from 15 till 16 years old has the high degree of variation (7-48%), while the genotypes of seed from 5-6 years old, interval of variation was lower (71-92%). Age of seeds had no effect on the production of green mass and seed yield. On the basis of the examination of the seed germination of local genotypes *Lotus corniculatus* L., it can be concluded that this plant species belongs to the group of plants with macrobiotic seed.

Keywords: *seed vigor, seed age, germination, sprouting.*

Introduction

The viability of seeds of birdsfoot trefoil is very important for the establishment of crop plants. Seeds of those genotypes with high vigor are recommended for sowing (*Artola et. al.,* 2003). In the opinion of numerous authors, *Lotus corniculatus* L. originates from the Mediterranean, but it is transmitted and widespread to South and North America, Australia and New Zealand. The greatest divergence of *Lotus corniculatus* L. appears in the region of Mediterranean (*Grant,* 1991), and includes the territory of Serbia and Bosnia and Herzegovina. Significance of birdsfoot trefoil for livestock development in mountainous regions is huge. The possibility of expanding *Lotus corniculatus* L., especially when mixed with herbs, is extremely high. One of the conditions for faster expansion of this kind is constantly improving existing varieties, the introduction of new breeding materials.

Mc Graw *et al*., (1986) are investigated the influence of latitude on the interaction of genotype - conditions in terms of seed yield *Lotus corniculatus* L. Investigations were carried out in three US states (Minnesota, Wisconsin and Missouri). The results indicate the powerful effects of abiotic environmental factors, among these three locations, which is why the authors recommend the selection of *Lotus corniculatus* L. variety and selection activities for each area. Winch *et al*., (1985) notes that the huge losses in yield due to seed dispersal.

Rincker (1980) examined the effect of keeping the seeds of legumes at low temperatures and their impact on the yield of green mass. Seeds of birdsfoot trefoil, alfalfa, red clover and alfalfa hybrids 15 years old, stored from the time of harvest at a temperature of -15 ° C and a relative humidity of 60 % have been sown. The green mass yield did not show significant differences between 15 years old seeds and fresh seeds, which means that at low temperatures, the seeds can be stored for many years. The condition is that the seed has good germination after harvest.

Smith *et al.*, (2009) and Beuselinck *et al*., (2005) are investigated the effect of seed origin from geographical and environmental distant populations due to the phenotype and genotype. They found regional differences in the size of the plants, growth, sexual maturity, the sheet size and fertility.

Ujević - Kovačević (1972) concluded that seed germination depends on a number of hereditary and external factors. The same authors found that the mass of 1000 seeds, plant development, environmental conditions, etc., as an important indicator of the quality of seeds depends on variety. Previous studies in breeding programs of birdsfoot trefoil emphasize the advantage of local populations in relation to supplies from other regions, the fact that acclimated ecotypes achieve better production results compared to the introduced populations and varieties (*Steiner et al*., 2001; *Sareen*, 2004; *Radic et al*., 2014).

There is a large number of population's birdsfoot trefoil that possesses considerable genetic variability in the agro-ecological conditions of Bosnia and Herzegovina (*Radić*, 2010). Vučković *et al.* (2007) tested in an experiment the ten populations birdsfoot trefoil from Serbia and Bosnia and Herzegovina on the basis of morphological, ecogeographically and chemical characteristics, have determined according to a number of morphological and chemical properties, that this population can serve as a valuable material for selection

Lotus corniculatus L., is the most important plant species of the genus *Lotus*, which has a high nutritional value and does not cause bloating at nutrition stock in the green state (*Beuselinck and Grant*, 1995).

The aim of this study is to determine germination of different ages of birdsfoot trefoil in field conditions and to obtain new plants capable for reproduction.

Materials and Methods

During the selection at pollinated plants a part of the seed is left in reserve to preserve a certain genotype. The longevity of seeds is different in different plant species, and depends on the genotype and the manner of storage. We need to distinguish terms of viable and vital seed for tests on seed germination. A viable means seed where the germ live and in which place life processes and vital seed is that which germinate in natural conditions.

In order to reduce the cost of seed multiplication is very important to know what the length of life of seeds, in order to preserve valuable selection material. To test was used seeds stored in storage conditions in the paper package. From seed left in the reserve during the preceding breeding cycle and taken the seed of those promising genotypes that showed a number of positive production traits. It is 20 genotypes of domestic origin of *Lotus corniculatus* L. obtained in a previous cycle of selection in natural populations from different locations throughout Bosnia and Herzegovina. The seeds of local genotypes 20 of birdsfoot trefoil are between 5 and 16 years old stored at room temperature sown in *Jeffi* containers filled with substrate. Testing germination was conducted in two groups. The first group consisted of ten genotypes seed from 15 till 16 years old end second group of ten seed from 5 till6 years old. The sowing was carried in containers with four replications of 100 seeds. The seed was planted in the substrate, and after sowing, the containers placed in the greenhouse. Water spraying is done every day. Number of emerged plants was determined after 10, 17 and 24 days. Counting of emerged seed was conducted in the same time periods, growth saplings are monitored per day and atypical plants were removed from each genotype. The plants are replaced in open space due to tempering after thirty days. Seedling growth was slow in the initial period of tempering but all the plants were vital and continued growth. When the plants have reached a height of 10 cm transplant was performed on experimental plots. Data on germination and formation of young plants were statistically analyzed and graphically presented. From each genotype data were taken, all the repetitions and represented as mean values , and then compared with each other. Correlations were identified as Pearson

correlation coefficients. Correlations were found between duration of storage of seed and germination, as well as between the time terms for determining germination.

Results and Discussion

The viability of seeds involves the possibility of formation of a new plant. It is conditioned by the amount of embryos and reserve materials. If embryo is well developed and fulfilled, it is the main condition for obtaining a strong saplings and normally developed plants (*Milošević,* 1987).

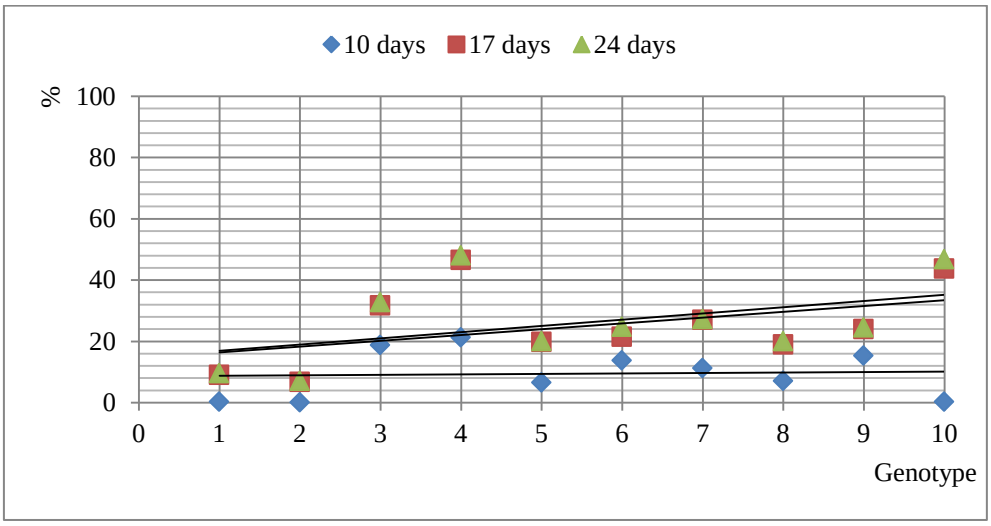

Figure 1. Germination seeds of genotypes of birdfoot trefoil from 15 till 16 years old.

Figure 1 shows the results of germination genotypes of Birdsfoot trefoil of 15-16 years old. Germination was in the interval from 0 to 21%, (in average of 10 %) in the first count after ten days from sowing In determining germination after 17 and 24 days were found small differences in germination in tested genotypes Observing the line of mean values of these tests can be concluded that they almost match. This fact leads us to the conclusion that most seeds germinate after 17 days. The total lowest germination after testing of these genotypes had genotype two (7 %) and the highest genotype four (48%). The average germination was 26% of genotypes of 15-16 years old.

For tested genotypes is determined the degree of multiple correlations between germination in three periods count (r = 0.55). The coefficient of partial correlation was the lowest among the first and third counting ($r_{1,3}$=0,50), and the highest between the second and third counting ($r_{2,3}$=0,99).

By observing the figure 2 in which the data are presented to germinate of seeds of ten local genotypes birdsfoot trefoil age 5-6 years old, it can be concluded that all have a high percentage of germination. Total germination ranged from 71 to 92%. These indicators tell us that the seeds birdsfoot trefoil kept in storage conditions can be used for productive purposes and up to six years after the harvest.

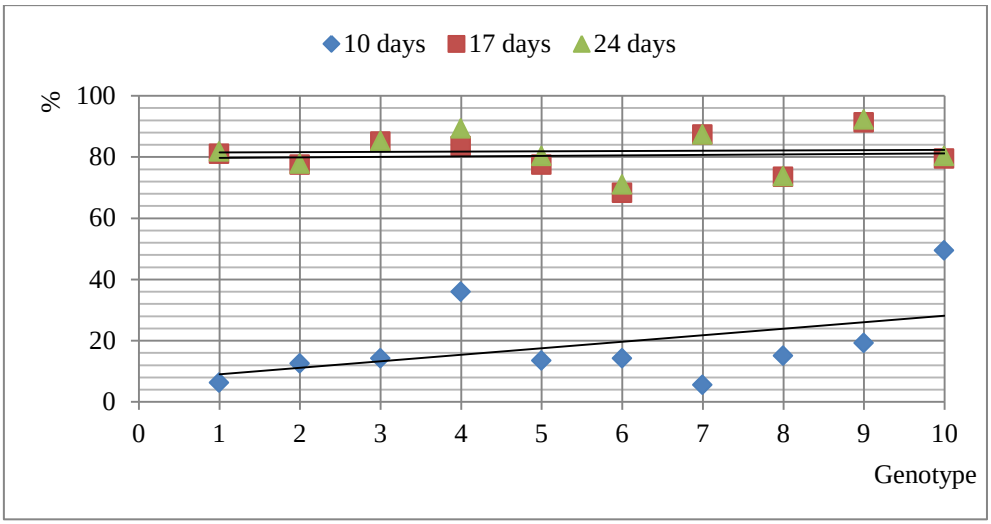

Figure 2. Germination of genotypes of birdsfoot trefoil from 5 till 6 years old.

The lower degree of correlations (r=0,38) is determined in relation to the seed which has been longer stored (r=0,55). Correlation was less between the first and third counting ($r_{1,3}$=0,13), while the correlation between the second and third counting ($r_{2,3}$=0,96) showed a high degree of interdependence as well as the first group of plants.

Observing germination at intervals of counting, shows that the much smaller difference in the first counting the genotypes of 15 to 16 and 5 to 6 years old whereas the difference in the second count was dramatically higher. Observing the seed depending on the age of seeds can be seen that in genotypes seed 15-16 years old have a wide degree of variation (7-48%), while genotypes whose seed was age 5-6 years old, variation interval was less (71-92%). The difference in germination after 17 and 24 days a small, the same as in the first ten genotypes in which the seed longer guarded. The biggest difference between the first and second counts in seed germination in seven genotype was found. In the third counting period, there is no significant difference in the percentage of germination in relation to the second count.

The seed that had a longer period of conservation has kept the germination of 7% (genotype 2) up to 48 % (genotype 4), and the seeds of genotypes 5-6 years old germinated from 71 % (genotype 2) to 92 % (genotype 9). Similar results obtained Artola *et al*. (2003). This indicator is very important from several aspects such as: biological, ecological, economic, and genetic and others. Seed viability of this plant species is a good predisposition for further work in the selection. Seeds of birdsfoot trefoil can be stored for many years at room temperature and will maintain the level of commercial viability standard. This means that the seed birdsfoot trefoil be marketed through six years of age, but it is necessary before sowing to carry out control germination.

Seed age had no influence on the formation of vegetative and generative organs (figure 3). By visual examination of saplings is not noticed an increased number of atypical plants. Morphometric parameters studied lines not showed differences that can be brought in connection with the age of the seed. Age of seed has no effect on seed production of green mass and seeds, it is important to keep the seed germination longer period of time, to be used in various purposes has been concluded. Similar results obtained Rincker (1980) when he sowed the seeds of birdsfoot trefoil, alfalfa, red clover and hybrid of 15 years old, but a precondition is good germination to seed after harvesting, must have a high germination.

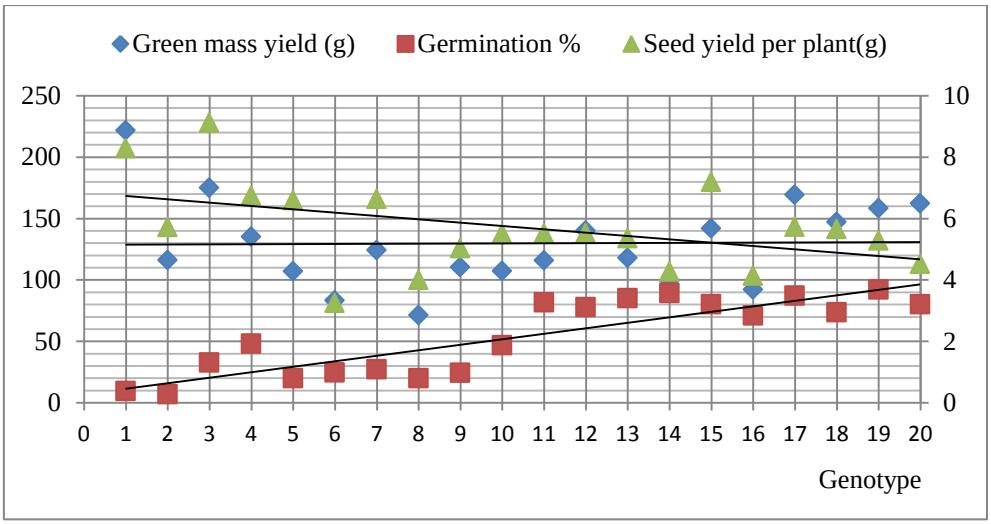

Figure 3. Interactional relationships between seed germination of the genotypes with the seeds production and biomass.

Based on the results of germination can be seen that longevity of seed of *Lotus corniculatus* L. belongs to the group of macrobiotic seeds (Milošević i Ćirović, 1994). Seed dormancy of *Lotus corniculatus* L. is quite high up 90% (McDonald, 1957), but age seed reduces the proportion of hard seed was found. On the basis of these studies we can conclude that with age seed, the percentage of dormant seeds decreases. At all lines of seed germination was good although he could not determine the number of hard seed. In laboratory conditions, hard seeds are counted in germinated seeds.

Conclusions

Seeds of genotypes with longer conservation of 15 to 16 years old kept the germination from 7% till 48%, and seed genotypes of 5 to 6 years old from 71% till 92%.

These results show that the seed of examined local genotypes of birdsfoot trefoil has a high germination, and about five years of age may be marketed.

Based on results of germination, the seeds longevity of *Lotus corniculatus* L. belongs to the group of plants with macrobiotic seed.

Age seeds of the examined genotypes of birdsfoot trefoil had no influence on the amount of green mass and seeds.

Abstract

In this paper the total phenols content and antioxidative activity of milled red (sweet and hot) pepper were determined. For extraction (90-95°C for 15 min), distilled water and methanol/water (30%) were used as solvents. The aim was to determine the total phenol content and antioxidant activity in sweet and hot pepper red spicy peppers using methanol and distilled water extracts.

The total phenols (TP) content (n=20), was determined spectrophotemetrically using Folin-Ciocalteu reagent at 600nm, and antioxidant activity by PFRAP method (with color reaction at 700nm).

The obtained data shows that highest (TP) content was found in sweet pepper 626.71 (in distilled water extract) and 368,27mg GA/100 of DW in 30% methanol extract. The average content of antioxidant activity of sweet spice pepper extract (distilled water) is 52.31mgGA /100g, while the value of hot pepper is 47.25mgGA /100g. The methanol extract mild red pepper is 9.18 mgGA/100g, while hot pepper is slightly higher (17.29 mgGA /100g).

It can be concluded that TP and the antioxidant activity of pepper was not affected by kinds of peppers (sweet or hot), but were affected by the solvent. The LSD test indicated that the difference in the antioxidant activity was significant, using two solvents (water and methanol/water). It showed that antioxidative activity was in correlation with total phenols content.

Key words: Red *pepper, phenol content, antioxidative activity, distilled water, methanol*

Introduction

Pepper (Capsicum annuum L.) is one of the most important vegetable crops in the world. There are many varieties of peppers that vary in colour, shape, size, flavour and degree of spiciness. Red pepper is used in all the kitchens around the world to improving the sensory properties of food, as a natural dye. It is rich in biologically active compounds including significant the phenol compounds, which are believed to have a positive effect on human health and are powerful antioxidants.

Phenol compounds are plant secondary metabolites and they possess a wide range of physiological functions as antioxidants: active anticancer, anti-inflammatory, anti-allergic, anti-microbial, and protect the cardiovascular system.

Phenolic acids make up about one third of the phenolic compounds present in plants, but they are present in free or bound form. In nature it is rarely found in free form, most often come in the conjugated forms and as esters (Macheix et al., 1990). Depending on the form of phenolic acids present, it is necessary to choose the extraction conditions that result in the least possible degree of degradation (Ross et al., 2009).

The antioxidant may be a substance present in low concentrations, which delays or prevents oxidation (Halliwell and Gutteridge, 1999). Because of the proven antioxidant activity peppers attributed to the presence of phenolic compounds, it has become a subject of research, and a very interesting for food industry. The level of antioxidants is different between the

cultivated species, mostly hot peppers are richer in antioxidants than fresh, and some writers claim that sweet peppers have a higher amount of phenolic compounds, and therefore higher antioxidant activity (Perucka and Materska, 2007). Pepper is rich in flavonoids, phenolic acids and carotenoids (Lee et al., 1995; Hasler, 1998). Since polyphenols are the most common: hydroxycinnamates, flavonols and flavones (Marin et al., 2004). Sweet peppers contain volatile components, fatty acids, carotenoids (5.8 g/g fresh weight), vitamins, proteins, fibers, minerals (Bosland and Votava, 2000; Materska and Perucka, 2005).
Due to the favourable impact of the consumption of peppers on human health, the goal of this work is to extract and determine the total phenol content and antioxidant activity in sweet and hot pepper red spicy peppers.

Materials and methods

Packages of sweet and hot red spice pepper were used for research. A total of 10 packages of sweet spice pepper and 10 packages of hot. Packages were purchased in shopping centers in Sarajevo Canton, Bosnia and Herzegovina. Samples were stored in dry, dark and cool places before analysis.

• Extraction with distilled water: Samples were homogenized in fine powder and about 2 g of the powder was extracted with 40 ml of hot distilled water at 90-95°C for 15 min (using reflux). The resulting extract was filtered into a volumetric flask of 50 ml ,with the addition of distilled water to the mark.

• Extraction with 30% methanol: Sample of pepper (2g), added with 40 mL of (30:70) of methanol preheated to 50 ° C. The homogenized sample was transferred to a flask, with reflux condenser, wherein the extraction is carried out for 15 minutes at a temperature of about 90°C the extract was filtered in a 50 ml flask. The flask was amended solvent to stamps.

Determination of total phenols content

The total phenols content was measured using the Folin Ciocalteu reagens (FC), by a method based on colored reaction of phenols with FC (Ough and Amerine,1988), with slight modification. The absorbance of resulting blue color was measured at 600 nm (Shimadzu 2200 UV-VIS spectrophotometer). Quantification was done with respect to the standard curve of gallic acid (300 mg/L). The results were expressed as gallic acid (GA) miligram per 100g of dry weight (DW).

Determination of antioxidant activity (pFRAP method)

Determination of antioxidant activity was performed by spectrophotometry using pFRAP (potassium ferric antioxidant power) method according Meng et al., (2011) and Jayaprakasha et al., (2003), with slight modigications. Components with antioxidant activity react with $K_3[Fe(CN)_{6]}$ and translate it into a form of $K_4[Fe(CN)_6]$. Reaction with $FeCl_3$, is resulted by production of blue colored complex with maximum absorbance at 700 nm. The antioxidant activity is expressed as mgGA/100g.
All measurements were performed in triplicate. The results were evaluated statistically in excel by two–way analysis of variance (ANOVA). To compare the average value LSD test was used.

Results and discussion

Data on total phenol content and antioxidant activity in sweet and hot pepper spicy pepper, obtained by laboratory research are presented in the tables1 and 2.
It was found that the total phenol content of spice pepper no significant impact (sweet, hot) ($F_{calc.} = 0.004245 < F_{crit} = 4.493998$), but is affected by the influence of the type of solvent that was used in preparing the extract (distilled water / methanol: water) ($F_{calc.} = 8.357656 > F_{crit} = 4.493998$), while a significant impact of their interaction has not been determined (F_{calc}=

0.316276 <F_{crit} = 4.493998). The extract of sweet pepper (n=5), which is the solvent distilled water containing significantly higher average amount of total phenols (626.7048), the extract from which the solvent is 30% methanol (368.2711 mgGA /100 g).
Greatest amount of phenol in the distilled water extract was in the sample P_{13} (835.1847), while the least amount of phenol had a P_{12} (463.3256 mgGA/100g). The extracts of the samples with 30% methanol is recorded twice reduced the average amount of total phenols, so that the highest concentration of total phenolic compounds contained in the sample an amount was 729.8395 (P_5), while the minimum amount of phenol was observed in the P_4 (196, 3762 mgGA /100g).
The results showed that in the fresh spice pepper greater extraction capacity is achieved by using distilled water. Compared to distilled water, 30% methanol solution proved to be less efficient in the solvent extraction of total phenols. The results of total phenols in hot spicy red pepper have shown that there are significant differences between the content of total phenols in the spice pepper extracts obtained by methanol extract according to distilled water

		P8		18,3723	0,0463			P18		55,4646	0,0657
		P9		18,0466	0,0226			P19		44,8658	0,0636
		P10		21,3890	0,0651			P20		45,0421	0,0457

The average total phenols in the water extracts (n=5) was higher (589.4942) in relation to the methanol (n=5) extract (415.2334 mgGA/100g). The maximum total phenols content was in spicy pepper with using of distilled water as solvent 760.2379 mgGA/100g (P_{16}), while the minimum content was observed in the sample P_{17} to the value of 319.4117 mgGA/100g. At least registered concentration at 30% methanol extraction is reached with the sample P_8 (247.5392), and the largest concentration of phenol was observed in the sample P_7 (538.2125 mgGA /100g). In hot spicy peppers, better extraction capacity is achieved using distilled water; it was evident that the extraction with distilled water greater proportion of total phenols in comparison to a methanol extract was determined.

The average value of antioxidant activity of the extract in distilled water was greater in sweet peppers (52.30522), and lower in hot pepper (47.25156 mgGA/100g). In spicy peppers harvested with 30% methanol, the antioxidant activity was hot pepper with an average value (17.29646), while the sweet pepper contained lower average antioxidant activity were 9.18226 mgGA /100g. It was determined that there are no significant differences in types of pepper (sweet and hot), but there are species with a solvent (distilled water / methanol). Materska and Perucka (2005*)* were showed that antioxidative activity of pepper extract was depended mainly on phenolic compounds.

It has been shown that total phenolic compounds varies between periods of production of pepper, so that the measured values of 675 and 136 mgGA /100g, depending on the time of sowing and harvesting. Studies have shown that the highest average total phenol content was recorded in paprika produced in the month of November (1360 mgGA / 100g), while the Indian peppers recorded the total amount of phenol in the value of 500mgGA / 100g (Tripathi and Mishra, 2009). Flamingo peppers contain a total amount of phenol, about 852 mgGA / 100g (Deepa et al., 2007).

The total amount of phenol in the hot Mexican peppers was (20-782 mgGA /100g), according to Lee et al., (1995), and Menichini et al., (2009).

According to Kumar et al., (2010) the content total phenols in fresh pepper was 266mg/g fresh weighs.

Conclusions

Results, statistical analysis showed that the impact of antioxidant activityand total phenols is not significant species pepper (sweet, hot), but is determined by the influence of the type of solvent that was used in preparing the extract (distilled water / methanol: water). The average antioxidant activity of sweet spice pepper extract in distilled water is 52.30522, while the value of spicy pepper is 47.25156 mgGA/100g. The average antioxidant activity of the methanol extract with mild red pepper is 9.18226, with hot pepper is slightly higher at 17.29646 mgGA /100g.

EFFECT OF THE DATE OF APPLICATION OF HERBICIDES ON THE PRODUCTIVITY OF COMMON WINTER WHEAT

Emil PENCHEV, Zornitsa PETROVA

Dobrudzha Agricultural Institute – General Toshevo 9520, Bulgaria
*Corresponding author: emo_ap@mail.bg

Abstract

The effect of the herbicides Derby Super VG, Granstar 75 DF, Lintur 70 VG, Secator OD, Mustang 306.25 SK, Palace 75 VG and Husar Max OD, applied at different phenophases, on the productivity of two major common winter wheat varieties (Enola and Aglika) was investigated. Five-factor dispersion analysis was used to evaluate the effect of the factors genotype, climatic conditions, sowing date, herbicides and phenophase of treatment. As a result from the investigations carried out on the date of treatment with the herbicides and its influence on the productivity of common winter wheat it was found out that best results were obtained after using the herbicides at tillering stage. Regardless of the cultivar or the sowing date, lowest losses of wheat were observed after treatment with the preparations Derby Super VG and Secator OD.

The application of the herbicides at the end of tillering allowed wheat to realized its highest productivity regardless of the sowing date or the cultivar used. The application of the herbicides at phenophase first-third node was related to lower efficiency of some of them as Granstar 75DF, Palace 75WG and Husar Max OD. After the use of Derby super VG and Secator OD at this phenophase, no significant decrease was found neither in the efficiency against weeds nor in wheat productivity. The use of herbicides at phenophase emergence of flag leaf was accompanied with further decrease of wheat productivity. On the one hand, this was due to the growth of weeds and the lower efficiency of the used herbicides, and on the other – to increasing of toxicity on wheat caused by some herbicides. Due to the higher toxicity of the herbicides Lintur 70VG and Mustang 306.25 CK on wheat, greatest yield decrease was registered after using them at this phenophase.

The influence of factors “phase of treatment“ and “climatic conditions” was proved with the highest statistical significance, and the factor “date of sowing” - with the lowest one.

Key words: winter wheat , herbicides , productivity

Introduction

A main method for control of weeds in the cereal crops on a whole area is the chemical method, or the use of herbicides. Barros et al., (2007) reported that Akurat 60VG (3.0 %) and Grodil ultra VG (0. 6%) were used against annual broad-leaved weeds: *Galium aparine (L.)(* cleavers), *Anagallis arvensis (L.)*(scarlet pimpernel), *Lactuca seriolla (L.)*(prickly lettuce), *Daucus carota (L.)*(wild carrot), *Lamium amplexicaule (L.)* (henbit dead-nettle), *Scandix pectin- veneris (L.)*(shepherd`s needle). After later application of the herbicides (phenophase of weeds 5^{th} – 6^{th} pair of leaves and phenophase of the crop booting), lower yields were measured. Akurat 60VG (3.0 %) provided satisfactory control when applied at booting stage for control of weeds, without decreasing yield.

The investigation showed that after treatment at stage end of booting of wheat, best results were obtained from Banvel K, which increasing yield with 19.0 %, followed by 2,4DP with 17.9%. Lowest was the increase after 2,4D - 10.1% . The active substance dicamba in the composition of the herbicide Lintur 70VG decreased the yield from barley with an average of

5.0 %, when applied at stage end of tillering, and at later treatment at stage visible 1st and 2nd node – with averagely 32.0 % .
The use of Palace 75WG and Husar Max VG at phenophase tillering lead to higher yields in comparison to the application of the herbicides against broad-leaved weeds Derby super VG, Weedmaster 464SL and Laren 60VP. High yield from wheat was obtained after treatment with Derby super 175СК (5 ml/da) and Puma super 7,5EV(100ml/da) at phenophase full tillering of the crop .
The aim of the research was to determine the effect of the date of application of a set of herbicides on the productivity of common winter wheat cultivars Aglika and Enola.

Material and methods

The research was carried out during 2012 – 2014 at Dobrudzha Agricultural Institute – General Toshevo (Bulgaria). The field experiment was designed according to the block method in four replications, with size of the experimental plot 15 m^2. Two check variants were involved: K_1 – weed-free check manually weeded till phenophase heading of wheat, and K_2 – check weeded till the end of the crop's growing season.
The following herbicides were used: Derby super VG (florasulam+aminopyralid- potassium) – 3.3 g/ha, Granstar 75DF (tribenuron-metil) - 15 g/ha, Lintur 70VG (triasulfuron+dicamba) - 150g/ha, Secator OD (amidosulfuron+iodosulfuron) - 100 ml/ha, Mustang 306.25СК (florasulam+2.4-D ester) - 800ml/ha, Palace 75WG+oil (pyroxulam) - 250+1000 g/ml/ha and Husar Max OD (mesosulfuron+iodosulfuron+antidot) - 1000 ml/ha, The preparations were applied at three stages of common winter wheat cultivars Aglika and Enola (end of tillering, first – third node, emergence of flag leaf: stages 29, 32 and 37 according to Zadoks et al., (1974)).
Before planning of wheat, artificial weed infection background was created with the most widely distributed weeds in the region of Dobrudzha Agricultural Institute – General Toshevo. These were the annual broad-leaved weeds ivy-leaved speedwell, wild mustard, cleavers, chamomile types, field chamomile, royal knight's spur, and the perennial broad-leaved weeds creeping thistle and field bindweed.
Weed density was determined per unit area quantitatively by species from ¼ of a sampling frame, in four replications prior to the application of the herbicides.
The herbicide efficiency was determined 25-30 days after the use of the preparations for each species by qualtity and by weight from ¼ of a sampling frame, the weeds being in dry condition. The effect was evaluated according to a 9-degree scale of the EUROPIAN WEED RESEARCH SOCIETY for reading of the herbicidal activity and selectivity, 1 corresponding to 100 % herbicidal effect without symptoms of phytotoxicity on the cultural plants, and 9 – to 29.9 % - 0 % effect of the herbicide and total perishing of the plants.
Five-factor dispersion analysis was applied to determine the effect of the factor date of herbicide application on the productivity, the absolute and the test weight. Data were analyzed by the statistical package SPSS 19.0.

Results and discussion

The application of the herbicides at the end of tillering allowed wheat to realized its highest productivity regardless of the sowing date or the cultivar used. Averaged for the period of testing, the highest yield of 648.5 kg/da was obtained from the weed-free check at the optimal sowing date for wheat. The use of herbicides at this date allowed the realization of a yield within the range 93.2 – 96.0 % from the clean check. This was due to the crop, cultivated free from weeds. According to the weeded check (K_2), there was exceeding of 133.3 to 137.2% for the respective herbicides.

The sowing delay reduced wheat productivity of wheat. A yield of 608.2 kg/da was obtained, with 40.3 kg/da lower, than the yield obtained after sowing within the optimal dates of a weed-free crop. The application of the herbicides contributed to exceeding of yield of 131.1 to 134.4% from the yield obtained from the weeded check.

The application of the herbicides at phenophase first-third node was related to lower efficiency of some of them (Granstar 75DF, Palace 75WG and Husar Max OD). Concerning others (Mustang 306.25CK and especially Lintur 70VG), 28 to 56 days after their use, symptoms of phytotoxicity were found on the wheat plants in the form of anthocyanine coloration. The occurrence of phytotoxicity was more expressed after the use of Lintur 70VG. After the use of Derby super VG and Secator OD at this phenophase, no significant decrease was found neither in the efficiency against weeds nor in wheat productivity.

The use of herbicides at phenophase emergence of flag leaf was accompanied with further decrease of wheat productivity. On the one hand, this was due to the growth of weeds and the lower efficiency of the used herbicides, and on the other – to increasing of toxicity on wheat caused by some herbicides.

Regardless of the sowing date, highest yield from cultivar Aglika was obtained after the use of Derby super VG and Secator. The exceeding of the yield according to the weeded check varied from 124.8 to 125.5% after sowing within the optimal dates and from 134.0 to 134.7% after late sowing. It is necessary to point out that at this phenophase, incomplete destruction was also observed after the use of the above two products. The lower efficiency of Granstar 75 DF, Palace 75WG and Husar Max OD at this phenophase was better expressed than the efficiency at phenophase 1^{st} – 3^{rd} node. This reflected on yield. After both sowing dates, higher yield was obtained according to the weeded check, which varied from 110.2 to 115.6 % after the optimal sowing date and from 121.4 to 122.3 % after the late sowing date.

Due to the higher toxicity of the herbicides Lintur 70VG and Mustang 306.25 CK on wheat, greatest yield decrease was registered after using them at this phenophase. Regardless of the sowing date of cultivar Aglika, yield was obtained with 93.6 to 94.4% lower than the yield from the weeded check after the application of Lintur 70VG.

The means of squares of indices yield, absolute weight and test weight are pointed in table 1, also the interactions between the studied factors. By the index “yield” was proved with statistical significance p = 0.001, the influence of the factors “phases of treatment” and “climatic conditions “. The conditions during the years was the factor with highest part of the variation (40 %) by this character. The sowing date was with lowest (10%).

The statistical significance of the factors “herbicides” and “genotypes” were proved with p=0.01, also the interaction between the factors “genotypes” and “climatic conditions”. By the character “absolute weight” with highest statistical significance were proved the factors “phase of treatment“, “ecological conditions” and “genotypes“. By the index test weight all four factors were proved with statistical significance p=0.001 except the factor “date of sowing “.

Table 1. Mean of squares of studied factors .

Indices	Yield	Absolute weight	Test weight	df

In table 2 are presented the results of the five factors ANOVA for the structural elements of the “yield”. The index “plant’s height” for both varieties was estimated with highest values after the treatment in phenophase “end of tillering” of the crop. With the progress in this phenophase of the wheat, the values of this character decreased and the reason was the stronger influence of the weeds. The differences between the variants of treatments were not essential. According the character “plant’s height”, the following factors-“phenophases of treatment” , “herbicides” and “climatic conditions” were proved with statistical significance p=0.001. The indices “spike’s length” and “spikelets number” were genetically connected. The action of the herbicides by these characters was not essential. They ranged within narrow borders of both varieties. It was established, that the influence of the factor “ecological conditions” was the highest statistical significant one among the characters “spike’s length “and “spikelets number “.

The indices “spikelets number” and “grain’s weight” were the most variable. They decreased with delay in the term of herbicides application. The most essential decreasing of these indices was obtained by using of Lintur 70 BG and Mustang 306.25CK in phenophases “1st – 3rd node” and „emergence of flag leaf ”. This was due to the presence of sterility spikes, because of herbicides Lintur 70BG and Mustang 306.25.CK influence.

Table 2 . Means of squares of the structural elements.

Indices	Plant’s height	Spike‘s lenght	Spikelets number	Grain‘s number		Grain‘s weight	df

H – herbicides, F – phase D – date of sowing, Y – yields , G – genotypes

Conclusions

The applying of herbicides at the phenophase “end of tillering” permitted the wheat varieties to realize the highest productivity irrespective of the used variety or the term of sowing.

The influence of factors “phase of treatment“ and “climatic conditions” was proved with the highest statistical significance, and the factor “date of sowing” - with the lowest one.

The interaction of the factors “genotypes” and “climatic conditions” was statistical significant for all studied indices.

RESEARCH ON SOME GRAIN QUALITY CHARACTERISTICS OF TURKISH AND ITALIAN RICE VARIETIES GROWN IN BULGARIA

Ivanka TOROMANOVA, Tonya GEORGIEVA*

Agricultural University, 4000 Plovdiv, Bulgaria
*Corresponding author: tonia@au-plovdiv.bg

Abstract

A field experiment was carried out in the Saedinenie region, Plovdiv municipality, Bulgaria in the period 2013-2014. The basic grain quality characteristics of rice were studied within two Turkish (Osmanchik 97 – standard for Bulgaria, and Gala) and four Italian (Lince, Puma, Cameo and Brio) rice varieties. The following indicators were recorded: mass of 1000 grains, hectoliter mass and some biochemical indicators such as: starch content, crude protein and crude fats – in % of absolute dry substance. The sowing took place in the period 13-16 May involving the split plot design in four repetitions over an area of 14,85 m^2 at a sowing rate of 600 k.s./m^2. Rice was previously grown in the same area. The applied fertilization rate was $N_7P_{18.}$ The experiment was performed in conformity with an approved Bulgarian growing technology – the flooding irrigation regime. The statistical processing of experimental data was carried out via SPSS V.9.0 for Microsoft Windows.

On the average, it was defined that varieties Cameo – 37,11 g/1000 grains and Osmanchik 97 – 34,35g/1000 grains were outlined for largest grains within the stated period. The smallest grain size was observed with the Brio variety. The grain hectoliter mass of the tested varieties showed close values – between 43,25 kg (Cameo) and 44,60 kg (Brio). Only the Puma variety stood out with higher mass (48,88 kg).

For the period, the Turkish varieties Gala (8,80%) and Osmanchik 97 (8,30%) registered highest protein content on the average under Bulgarian conditions, followed by the Italian varieties Cameo (8,39%) and Lince (8,28%). Osmanchik 97 accumulated highest quantity of starch – 78,98%, followed by Brio – 76,70% and Linche – 76,69%. Crude fats stayed within the range from 3,42 (Brio) to 3,87% (Osmanchik 97).

Keywords: *rice, protein, starch, fats, grain quality characteristics*

Introduction

Rice quality is not always that easy to define as it depends on the consumers and its final envisaged application. It is the only cereal with whole edible grain thus making its quality much more important than that of any other cereal (Hossain *et al.*, 2009).

Traditionally, rice breeders concentrate on high yield and disease resistance. However, based on the recent research of 11 major rice-producing countries, authors such as Juliano and Duff (1991) have come to the conclusion that breeding is being redirected towards searching for quality characteristics targeted at increasing grain nutritional value.

Protein and starch content are the two dominant factors defining rice quality. Rice is an important source for protein, providing more than 50% of the total protein consumption in some countries. Most factors for its variation are related to the growing conditions (sun radiation and temperature in the grain-maturity period), as well as to the growing technology (stem density, nitrogen fertilization norm and time limit, irrigation regime and weed control). Negative correlation exists between protein content and rice yield, which is usually weak and depends rather on the growing conditions than on the genotype (Gomez, 1979).

Bulgarian rice producers have oriented their efforts towards the search for high-production potential varieties, fast adapting to the conditions in Bulgaria, and yet, with high-quality grain

relevant to the taste preferences of the Bulgarian consumer. The varieties produced in the Northern Mediterranean Region, for example Italian varieties, are considered to be of interest for being more adaptive and with high-production potential. The research carried out by Angelova, S. (1999), for example, defined that the Italian varieties Alfa and Artiglio stand out with higher yield and higher crude protein content in comparison with the Russian Krasnodarski 424 variety (used earlier as standard). In other studies carried out by Bulgarian authors, biochemical characteristics of introduced varieties was performed as well (Tosheva and Kamishev, 2013; Todorov and Angelova, 1998). Italian varieties are subject to other researchers in the Balkan Peninsula Region (Ilieva *at al*., 2000; 2013)

The aim of the present survey is to study the genotype influence on some physical and biochemical grain qualities of rice grown under the conditions of South Bulgaria.

Materials and Methods

A two-factor field experiment involving the split plot design was carried out in the Saedinenie region, Plovdiv municipality, Bulgaria in the period 2013-2014. The genotype was the basic studied factor (of the whole plots) in the experiment. Six induced varieties were tested – 2 Turkish and 4 Italian, using the Osmanchik 97 Turkish variety as standard. The experiment was performed after rice as a forerunner, in 4 repetitions with reported yield plot area of 14,85 m^2.

The 1000 grain mass was determined by the adopted technology in conformity with the Bulgarian State Standards (BDS). It was reported via mass measuring (g) of two samples of 500 grains (paddy rice) for each variety, from each repetition and for each experimental year.

The hectoliter mass (kg/100 l grain (paddy rice) was measured according to the adopted technology, in conformity with BDS.

The lab analyses were carried out in the Central Laboratory for Research at Agricultural University – Plovdiv. The analysis regarding the presence of raw protein was implemented under BDS 13490, for fats – under BDS 3412 established for wheat cultivars. The amount of starch content was measured with the polygraphic method.

The statistical processing of the tested data was performed via SPSS V.9.0 for Microsoft Windows. The proof for differences was reflected at significance level P 5% (Fowler and Cohen, 1992).

The experiment was carried out on fluvisol with humus content under 2,5%. The total cumulative nitrogen for both experimental years was between 10,81 and 11,50 mg/ 1000 g soil, which qualified the soil as poor, whereas with reference to cumulative phosphorus and potassium content, the soil was well supplied. The reported pH qualified the soil as acid (PH 5,81 to 5,18).

On the whole, the reported weather conditions for the vegetation year 2013 were favourable for rice growing (Fig. 1 and 2). Critical deviations from the basic climate affecting factors were not indicated during each crop development phenophase. The high after-sowing temperatures set up prerequisites for fast germination and intensive increase of plant height. The average temperatures from May to October were from +0,2°C to +3,8°C higher compared with the long-term period. This contributed to: accelerating the plant growth and development; forming a greater number of productive panicle elements; shortening the vegetation period.

The rainfall during the almost entire vegetation in 2013 was lower compared with the long-term period (Fig. 2). In August, during the flowering time, the rainfall was 32,7 mm lower than the long-term period, whilst normal pollination requires moderate and equally allocated showers.

The conditions in 2014 extremely differed from those in 2013. The average twenty-four-hour temperature results for the first two months of the vegetation period (May – June) showed that

at this stage rice was in more adverse conditions compared with the previous year. In May temperatures were considerably lower (by 2.7°C) than those in the long-term period and caused a negative effect on the germination length and preliminary development. Comparatively close temperature levels to those in the long-term period were measured from tillering to full-maturity, but they were between 0.5°C and 1.2°C lower in comparison with 2013.

The average monthly rainfall during the whole vegetation period in 2014 was drastically higher compared with the long-term period (Fig.2) and 2013. The registered heavy rainfall was an unfavourable prerequisite for rice growth as it changed the regulated water regime and cell microclimate. The amount of rainfall was lower only in August with registered temperature of 35.6°C, which did not favors normal rice flowering.

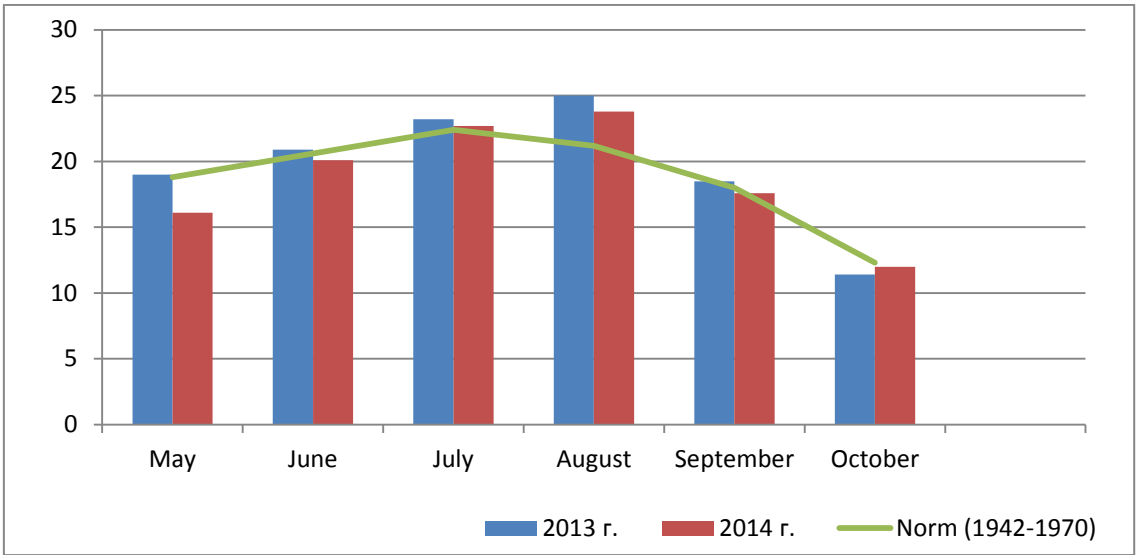

Figure 1. Average monthly temperatures (°C) for the research period, 2013-2014

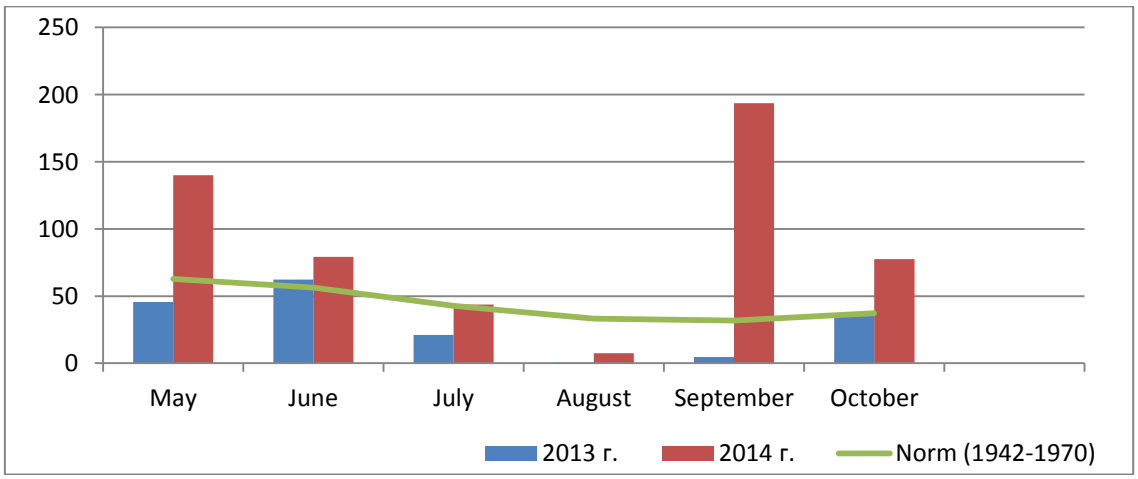

Figure 2. Total sum of rainfall (mm) for the research period 2013-2014

Results and Discussion

The 1000 grain mass is an indicator influenced by vegetation factors and the applied agrotechnics in rice growing. The tested varieties particularly differ by this indicator under the conditions of the performed experiment in 2013. The Cameo variety stands out with largest grain, overweighing the standard (Osmanchik 97) by 14,26%. It forms 37,90 g/1000 grain mass which statistically overweighs the indicators of the other varieties. Next comes Osmanchik 97, Gala and Puma with minimum difference – of about 2% and grain mass from 32,96 to 33,67 g. The Lince variety accumulates 32,52 g 1000 grain mass which is about 2% below standard. The Brio variety has got proven lowest indicator value of 29,31 g.

The 1000 grain mass of the tested genotypes in 2014 showed close values, fluctuating between 30,25 g for Brio to 36,32 g for Cameo. Osmanchik 97 also formed large grain - 35,52 g which drew it closer to Cameo while all the rest were with 32-33 g 1000 grain mass.

The summarized tendencies of the research for both years indicate that the Italian Cameo variety stood out with highest proven values by this indicator (mean 37,11 g). Its 1000 grain mass overweighed the Turkish Osmanchik 97 variety by 8%, adopted as Bulgarian standard. On the average, Brio was with smallest grain for the period and ranked 13,3% below standard. The other varieties showed values close to that of Osmanchik 97.

Table 1. 1000 grain mass of rice (paddy), g, 2013-2014

Variety	1000 grain mass - paddy, g					
	2013		2014		Mean	
	g*	%	g*	%	g	%
Osmanchik 97	33,17 bc	100,0	35,52 a	100,0	34,35	100,0
Gala	33,67 b	101,5	32,78 c	92,3	33,23	96,7
Lince	32,52 c	98,0	33,04 bc	93,0	32,78	95,4
Cameo	37,90 a	114,3	36,32 a	108,4	37,11	108.0
Puma	32,96 bc	99,4	33,45 b	94,2	33,21	96,7
Brio	29,31 d	88,4	30,25 d	85,2	29,78	86,7
Mean	33,26		33,56		33,41	

**Data in the same column and heading followed by the same letter are not statistically different (P<0,05) by Duncan's multiple range test.*

The hectolitre mass data of the grains are presented in table 2. Considerable differences among varieties by this indicator have been observed. The Puma variety stands out with highest proven values - 48,48 kg, which is 10,5% above standard. The Cameo variety shows lowest hectolitre mass - 42,03 kg. This value is 6,45 kg less than Puma and demonstrates distinction both from Puma and all the other varieties, including the experimental ones. Gala, Lince, Brio and Osmanchik 97 demonstrate close values by this indicator – from 43,25 to 43,90 kg and statistically do not differ among themselves.

The reported results in 2014 were about 1 kg higher on the average. This indicator was influenced by a number of factors including the 1000 grain mass which, although insignificantly, was also higher during the second year. The hectoliter mass was highest with the Puma variety - 49,28 kg thus confirming the tendency in 2013. The hectoliter mass for Brio and Gala was 45,95 and 45,13 kg respectively, while all the others stayed within the range from 43,97 kg (Osmanchik 97) to 44,47 kg (Cameo).

The mean hectoliter mass of the tested varieties for the period was between 43,25 and 48,88 kg. All genotypes performed close to the standard values (± 1,5%), except for the Puma variety (48,88 kg), overweighing Osmanchik 97 by 11,3%.

Table 2. Rice grain hectoliter mass (paddy), kg, 2013-2014

Variety	Hectolitre mass, kg					
	2013		2014		Mean	
	kg*	%	kg*	%	kg	%
Osmanchik97	43,86 b	100,0	43,97 d	100,0	43,92	100,0
Gala	43,90 b	100,1	45,13 bc	102,6	44,52	101,4
Lince	43,79 b	99,8	44,36 cd	100,9	44,08	100,4
Cameo	42,03 c	95,8	44,47 bc	101,1	43,25	98,5
Puma	48,48 a	110,5	49,28 a	112,1	48,88	111,3
Brio	43,25 b	98,6	45,95 b	104,5	44,60	101,5
Mean	44,27		45,53		44,88	

**Data in the same column and heading followed by the same letter are not statistically different (P<0,05) by Duncan's multiple range test.*

The data from the biochemical analysis of the rice grain point to the existence of variety dependence for the following indicators: content of crude protein, starch and fats (Table 3). For the period, the protein content in the grain (brown rice) was about 8% on the average. The Turkish variety Gala stood out with highest % of crude protein under the two-year testing conditions (8,89%), followed by the Italian Cameo (8,39%). The tested varieties accumulated about 1% more protein in 2014 which was related to the less favourable conditions for both productiveness formation and the negative correlation between yield and protein content quoted by many authors (Gomez, 1979).

On average, starch content fluctuated in different varieties from 75,17% (Puma) to 78,98% (Osmanchik 97). In accordance with the reported results, the Osmanchik 97 standard variety performed highest and comparatively steady starch content in the two consecutive years.

The tested varieties accumulated comparatively close fat content in the two consecutive years - 3,73% (2013) and 3,57% (2014) on average. The highest reported amount was with the Turkish variety Osmanchik 97 (3,87%) and the Italian Lince variety (3,80%).

Table 3. Biochemical analysis of rice grain (brown), 2013-2014

Variety	Protein %			Starch %			Fats %		
	2013	2014	Mean	2013	2014	Mean	2013	2014	Mean
Osmanchik 97	8,48	8,12	8,30	78,99	78,96	78,98	4,08	3,65	3,87
Gala	8,02	9,58	8,80	78,76	73,10	75,93	3,78	3,62	3,70
Lince	7,72	8,84	8,28	75,77	77,60	76,69	3,72	3,88	3,80

Brio	7,50	8,37	7,94	75,77	77,62	76,70	3,44	3,39	3,42
Mean	7,79	8,73	8,26	77,61	75,46	76,54	3,73	3,57	3,65

Conclusions

The tested Italian (Lince, Cameo and Puma) and Turkish (Osmanchik 97 and Gala) rice varieties have accumulated 1000 grain mass above 32g. It is the Cameo variety (37,11 g/1000 grains) that stands out for the period by 8% above standard. The Brio variety demonstrates smallest grain-size - 29,78 g/1000 grains on average.

The mean grain hectoliter mass of the tested varieties for the period is 44,88 kg. The highest proven value for this indicator (11% above standard) belongs to Puma - 48,88 kg. All the other genotypes perform close values (±1,5% compared to the standard).

The Turkish variety Gala shows highest protein content – 8,80% toward brown rice dry substance. The other varieties perform protein content from 7,85 to 8,30%. The mean starch content for all tested variants is 76,54%, whereas Osmanchik 97 is the only considerably outlined variety for its starch content - 78,98%. The accumulated fats in the grain are from 3,42 (Brio) to 3,87% (Osmanchik 97).

Abstract

The normal growth of most crops ensures in an average annual rainfall 600-800mm. The average annual rainfall in the studied area was 830 mm (with a confidence interval 804-856 mm), and was sufficient to provide the necessary moisture for vegetation for the crops with deep root system. For other crops was necessary to provide irrigation. The terrain is located in the area of Elena town and was in erosive danger. Crop irrigation by gravity way can lead to the intensity of the erosion process and disinterment of the topsoil humus-elluvial layer of the rows. The established values of the indicator pH in the studied plots were significant restriction for the growth of the proposed crops for cultivation. For creation of better conditions for crops growth needs liming on the plots with identified soil acidity. The exceedances of the established concentrations of the easily-mobile exchangeable aluminium and hydrogen, toward conventional limit for toxicity were minor and determine low level of acid toxicity of the soil for the plants. The average content of exchangeable manganese, found in the subsoil horizon exceeds the registered content for the cultivated layer. There is not a tendency of biological accumulation of manganese in the topsoil horizons.

Key words: *soil, fertilization rates, berries, medical plants*

Introduction

Bulgaria has a relatively rich soil and climatic resources, which allow the growth of different plant species. For the properly solve of a number of production problems associated with the effective use of agricultural lands is necessary to know the physiographic features of the area, where are situated soil and climate and in many cases microclimates conditions of the plots, determining the different growth and specific qualities of the growing crop.

Dealing with indicators such as average monthly temperatures during the vegetation period, average dates of sustainable establishment of average day air temperatures above or below a certain limit, temperature amounts for the period with average air temperatures over a certain limit, duration of these periods and of the period without frost, indicators for characterization the conditions of moisture would contribute for the proper and timely implementation of various agronomic practices, ensuring production efficiency (Leeuwen et al., 2004).

The aim of this study was to make the soil and climatic characteristics of the land in the area of Elena town and to assess their suitability for creation and growth of berries and medicinal plants.

Materials and methods

The object of the study is located in the area of Elena town, Elena municipality, Veliko Tarnovo region. The size of the investigated area was 20 ha. In the course of this study was accepted a model to take soil samples, where each sample was taken from the terrain with a soil probe, as sample points are located within the borders of the terrain in a square grid (BDS ISO 10381-2:2002). In two depths 0-25 and 25-50 cm were taken 26 samples points in 4 repetitions. After standard preparation, soil samples were analyzed to establish the indicators: soil texture with fotosedimentograf (Trendafilov and Popova, 2007), Hydrological

characteristics of the soil (Trendafilov and Popova, 2007), Bulk density of the soil by paraffin method, Relative density - pycnometrically, pH - potentiometric in KCl (Arinushkina, 1970); easily mobile exchangeable Al^{3+} and H^{+} titrimetrically by Sokolov (1939); easily mobile exchangeable Mn^{2+} in extract with 1m KCl as the preparation of the extract is performed by the laboratory system for liming by (Palaveev and Totev 1970), (LSVPT-64), and the determination of Mn^{2+} in the extract by AAS (BDS11047, 1995); easily mobile exchangeable Ca^{2+} and Mg^{2+} complexometric by method of Mazaeva, Neugodova and Hovanskaya (Palaveev and Totev, 1970), humus content by Turin method (Trendafilov and Popova, 2007), water-soluble salts (BDS ISO 11265:2002), content of easily absorbable iron, total nitrogen in the soil (BDS ISO 11261: 2002), mobile forms of phosphorus and potassium (GOST 26209-91/01.07.93). Based on the obtained results from the preliminary study was determined harmful acidity and the degree of saturation of soil bases and is proposed plan for melioration of the problem areas and recommended fertilization rates.

Results and discussion

Climatic characteristics

In climatic attitude the studied objects belongs to European continental climatic region, humid continental climatic sub region and before mountainous climatic region. The average altitude of the area is 331m. The average annual rainfall is 830 mm. The rainfall amount during the month with minimum rainfall is 28,75 mm and maximum 125,29 mm. The average annual air temperature is 10,48°C and vary from 9,14 to 11,83 ^{o}C. The winter is cold and summer is cool. For characterization of the climate elements for the studied terrain in the land of Elena town are used data from 10 years period of observation, registered at the nearest meteorological station Elena (Subev, 1959). The average monthly temperature in January vary from -2,88°C to 0,16°C and in July from 19,7°C to 20,6°C (Kichukova, 1983). The average of the absolute minimum air temperature in December is -12,6°C, January -15,7°C and February -13,8°C.

The average temperature amount of biologically active temperatures was 3183°C with a confidence interval from 3066 to 3301°C. Figure 1 shown the probability for recruitment of temperature amounts in the region.

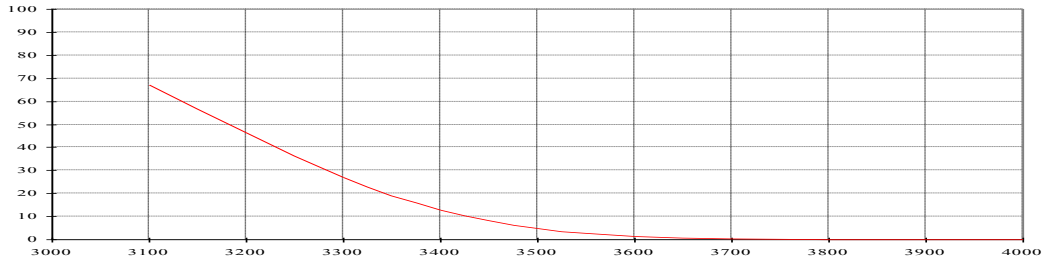

Figure 1. Probability for recruitment (%) of temperature amounts

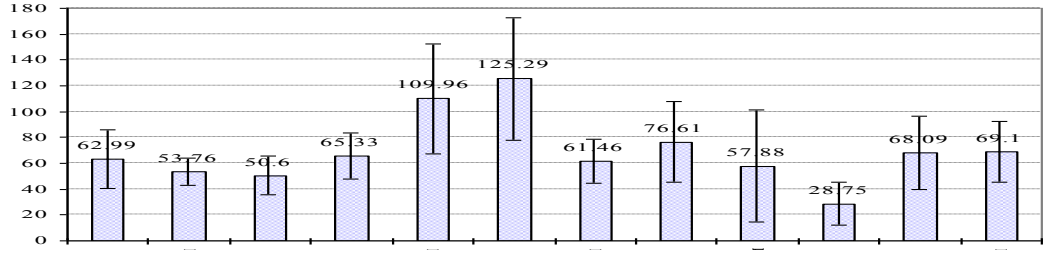

Figure 2. Average monthly rainfall (mm) amounts with intervals of variation (from January to December)

Figure 1 shown, that the probability for recruitment of temperature amount of 3100°C was 67%. The probability for recruitment of temperature amount of 3500°C was 5% and the probability for recruitment of temperature amount higher than 3700°C was 0%. The temperature amount with 75% probability, on the basis of which should make economic calculations about the suitability of the area for growth of berries and medicinal plants in different directions was 3060 °C.

Figure 2 shown the average monthly rainfall amounts with the intervals of their variation.

The normal growth of most crops ensures in an average annual rainfall 600-800mm. The average annual rainfall in the studied area was 830 mm (with a confidence interval from 804 to 856 mm) and was sufficient to provide the necessary moisture for the vegetation for the crops with deep root system, but for the rest crops is necessary to provide irrigation. There is an average annual deficit from -56 to -4 mm. Rainfall amount during the vegetation period (April 1 to September 30) was average 496,53 mm, as the established need was 400-500mm. The average hydrothermal coefficient for April, May, June, July, August September and October shown in Figure 3 (Selyaninov, 1958).

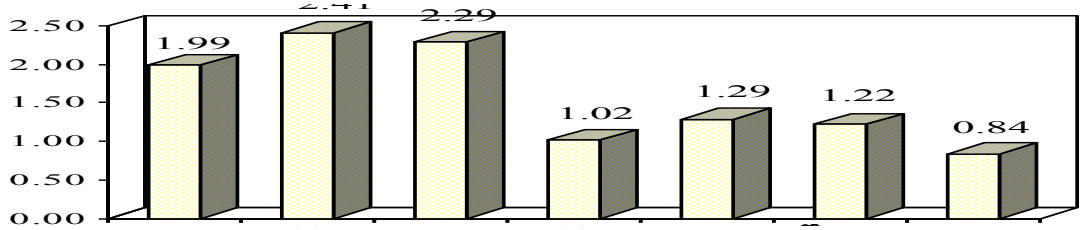

Figure 3. Average values of hydrothermal coefficient by Months (April to October)

General characteristics of the soil

The main soil difference distributed within the studied objects is Haplic luvisols. The soil is formed on sandstones, under the influence of pseudopodzolic process of soil formation. Big role for the formation of Haplic luvisols has the top soil waterlogged. During the wet season iron and manganese compounds are reduced and move into the lower horizons, where in dry conditions formed spots and nodules.

Morphological characteristics

The soils in the studied objects are deep, as the depth of the soil profile is more than 75 cm. Humus-elluvial horizon in not eroded and slightly eroded areas is with depth 20 and over 20 cm. In heavily eroded terrain (Plot 7) humus-elluvial horizon is strongly reduced or absent altogether. In the most heavily eroded sections illuvial horizon is on the top and as a result of which on the terrain is observed red spots.

Morphological description of the soil profile:

A_1 0-25cm. light gray with a yellowish tint, fresh, loose, sandy clay loam, single grained structure, contains iron and manganese nodules, not effervesce from HCl, sharp transition.

B_1 25-50cm. gray-brown, with rust and gray spots, fresh, dense, sandy clay, contains iron and manganese concretions, not effervesce from HCl, gradual transition.

B_2 50-75cm. dark brown, with rust and gray spots, dense, sandy clay, contains manganese and iron concretions, not effervesce from HCl, gradual transition.

The terrain is under erosive danger. Crop irrigation by gravity way can lead to the intensity of the erosion process and to disinterment of the topsoil humus-elluvial horizon of the rows.

Soil texture and physical properties of the soil

The average content of physical clay in the topsoil horizon determined the soil as sandy clay loam. In 25-50cm layer the soil is clay. In both studied depths prevailing the fraction of particles <0,001 mm as the relative part in depth 25-50cm is higher (Table 1). The differentiation of the soil profile is strongly expressed. The average value of the texture coefficient is 2,31. The illuvial horizon is dense, which is a limiting factor in the growth of

shrub crops (raspberry, blackcurrant, blackberry, blueberry). In eventually growth of shrub plants is necessary to perform proper tillage of the soil. It is appropriate periodic soil tillage to 40cm depth or perform of deep melioration loosening. The soil is tilled during the dry period of the year, which provides maximum effect.

Table 1. Average values of the physical indicators of the soil by depths

Indicators	Depth (cm)		
	0-25	25-50	Average
Particles <0,001mm(%)	19,39	44,61	32,00
Physical clay (%)	28,80	61,30	45,05
Texture coefficient	2,31		2,31
Saturation (%)	21,85	20,21	21,03
Porosity %	46,60	45,83	46,21
Bulk density at saturation	1,44	1,46	1,45
Specific density g/cm3	2,7	2,7	2,7

The average values of bulk density did not differ significantly in both studied depths. The data shown a substantial dense of the cultivated soil layer, which should be taken into account in the growth of the proposed crops. The average values of the specific density shown high content of the mineral components in the soil and respectively low organic matter content. The established average specific density did not differ in both studied depths of the soil profile. The total porosity of the soil was low in both, the cultivated soil layer and the subsoil. The average porosity for both studied depths was respectively 46,60 and 45,83%.

Humus content

The average content of organic matter in the soil for all studied plots was 1,00% with a confidence interval from 0,92 to 1,08%. The organic matter slowly decrease in the depth of the soil profile (Figure 4). The established humus content for the cultivated layer did not exceed 1,33%. The humus reserve of the topsoil horizon assessed as low. The average value for all studied objects was 20,9 t/ha and vary in confidence interval from 12,6 to 29,2 t/ha.

The organic matter content in the studied objects can not satisfy the requirements of the crops. The apply of manure in the soil will increase the organic matter content and also is expected to improve the total physical properties of the soil. The rate for apply of manure should be no lower than 30t/ha.

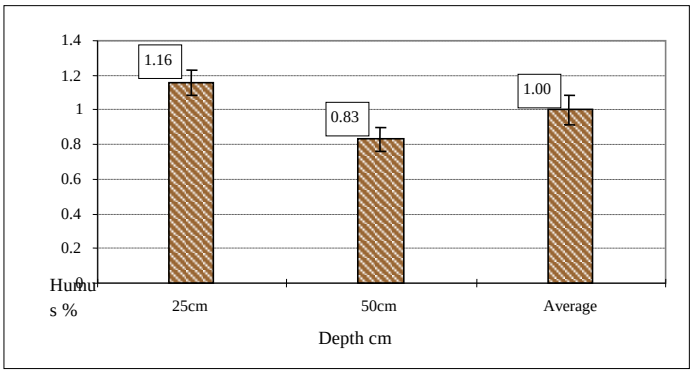

Figure 4. Average humus content in the soil profile depth

Content of water-soluble salts

The content of water-soluble salts in the soil profile depth average for all studied plots was low and did not constitute a restriction for the growth of the selected crops.

Soil pH

The average pH values for the cultivated layer ranged from 3,80 to 5,35. They were higher in the plots, where lime was applied (Plots 1,2,3 and 4). The soil reaction of the cultivated layer

is defined as very strongly acidic to weakly acidic. The pH of the subsoil horizon had lower values compared to the topsoil layer and were in the range of 3,60 to 4,50. The soil reaction of the subsoil horizon was very strongly and strongly acidic (Table 2).

Table 2. Average pH values by depths and plots

pH в KCl	**Depth (cm)**		
Plot	**0-25**	**25-50**	**Average**
Plot 8	4,55	4,50	4,53
Plot 5	5,30	4,50	4,90
Plot 6	5,35	4,10	4,73
Plot 7	4,60	4,00	4,30
Plot 3	4,50	3,95	4,23
Plot 4	3,90	3,80	3,85
Plot 9	3,87	3,83	3,85
Plot 1	3,80	3,60	3,70
Plot 10	4,90	3,80	4,35
Average	4,43	4,06	4,24

The established values of the indicator pH in the studied plots were significant limitation for the growth of the proposed crops. To create better conditions for the growth of the crops on the plots with established harmful soil acidity need liming. On the plots № 1, 4 and 5 is appropriate the growth of blueberries, which grow well in soil solution pH 4,3 to 4,8.

Content of easily mobile exchangeable hydrogen and aluminum

The average content of easily mobile exchangeable Al^{3+} and H^{+} by plots and depths shown in Figure 5.

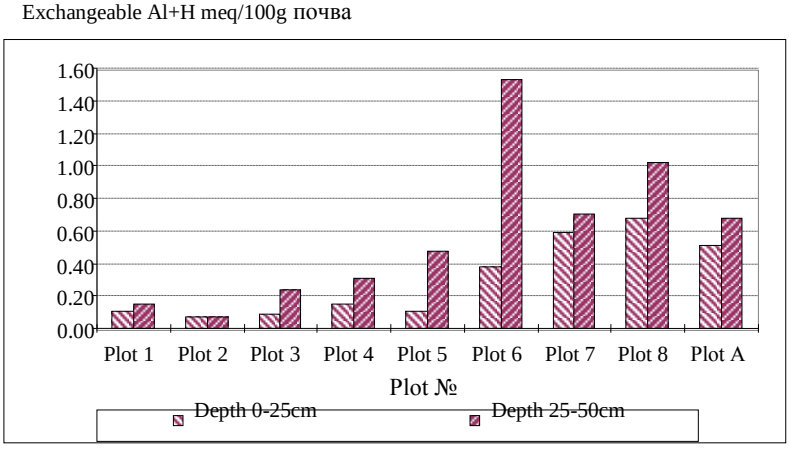

Figure 5. Average content of exchangeable Al + H by plots and depths

The contents of easily mobile exchangeable ions of Al^{3+} and H^{+} increased in the depth of the soil profile, as the excess was most significant in plot №6. The average values of the exchangeable Al^{3+} and H^{+}, found for the depth 25-50cm in plot №6 exceed the registered for the topsoil layer with 4,09 times. This is because of significantly higher sorption capacity of the clay illuvial-metamorphic B horizons. The content of easily mobile exchangeable Al^{3+} and H^{+} for the whole studied soil layer (0-50cm) in the plots was from 0,068 to 0,952 meq/100g soil. The values were lowest in plot №2, where was performed liming. The average value of Al^{3+} and H^{+} for the cultivated layer, found for all studied objects was 0,313 meq/100g soil with a confidence interval from 0,110 to 0,378 meq/100g. The amount of hydrogen + aluminium for the subsoil horizon was average 0,529 meq/100g (confidence interval 0,208 - 0,714 meq/100g), and for the whole analyzed soil layer (0-50cm) - respectively 0,421 meq/100g with a confidence interval from 0,206 to 0,499 meq/100g. The exceedances of the established concentrations of the easily mobile exchangeable aluminium and hydrogen,

toward conventional accepted limit for toxicity were minor and determine low degree of acid soil toxicity for the plants (Figure 5).

Content of easily mobile exchangeable manganese

The average content of exchangeable manganese, found in the subsoil horizon exceeds the registered content for the cultivated layer (Table 3). There is not tendency of biological accumulation of manganese in the topsoil horizons. The data shown, that in the topsoil horizon were created relatively good conditions of aeration and bigger part of manganese is segregated in the form of concretions. In regard to the sensitive crops, the indicated ratio is main criteria for the presence of manganese phytotoxicity of acidic soils. Values greater than the limit numbers according to BDS 17.4.4.07-1997 were found in all studied plots (Table 4). Those plots needs liming to prevent the risk of manganese intoxication.

Table 3. Average content of easily mobile exchangeable Mn by plots and depths

Mn meq/100g	**Depth (cm)**		
Plot	**0-25**	**25-50**	**Average**

Content of easily mobile exchangeable calcium and magnesium

The content of easily mobile calcium and magnesium in most plots was higher in the subsoil horizon compared to the topsoil (Table 5). This distribution is logical because the soil layer 25-50cm is saturated to a greater degree with clay soil colloids.

Table 5. Average content of easily mobile exchangeable Ca+Mg by plots and depths

Ca+Mg meq/100g	**Depth (cm)**		
Plot	**0-25**	**25-50**	**Average**

Degree of soil saturation with bases and rates for liming

Depends on the obtained values of the indicator V3% was determined the need of liming at plots №6 and 7. For the rest plots the lime rates were defined by the necessary to prevent soil manganese toxicity. The balance lime rates were given in kilograms CaO per hectare. When apply lime meliorants they should be recalculated based on the content of calcium oxide in the meliorant. The rates for some of the most often applied meliorants for chemical melioration of acid soils shown in Table 6. After the last passage of the lime spread aggregate on the field performed shallow tilling - disking, cultivation or milling (for smaller areas). After that the soil was ploughed at a depth of 20-25 cm.

Table 6. Rates for application of lime meliorants in the soil

Average	12210	22210	24410	30510

Content of nutrient macro elements

The soil reserve with assimilable forms of nitrogen and potassium were low. The content of assimilable phosphorus was assessed as an average (Table 7). The necessary nutrient macro elements in organic agriculture are applied into the soil, by the use of appropriate fertilizers. Nitrogen is provided by application of manure and potassium by the application of plant ash. By the use of precipitate fertilizer is carried out the liming of areas and simultaneously phosphorus application in the soil.

Table 7. Content of nutrient macro elements

NH_4 mg/kg soil	NO_3 mg/kg soil	Total nitrogen mg/kg soil	P_2O_5 mg/100g soil	K_2O mg/100g soil
28,90	7,88	36,78	14,00	6,00

Conclusions

The soil-climatic conditions of the studied area were suitable for growth of berries and medicinal plants and based on the soil indicators are recommended the following fertilization rates.

Fertilization of raspberry - The main fertilization is in autumn before planting. Application: 50 t/ha manure; 230 kg/ha P_2O_5 or 1150 kg/ha precipitate fertilizer, 180 kg/ha K_2O. The rate of potassium fertilizer in nature is 1800 kg/ha, when used plant ash from coniferous species. Fertilizers must ploughed into the soil to a depth of 25 cm. Those fertilization rates must applied periodically, after establishment of the content of nutrient macro elements in the soil.

Fertilization of blackberry - The main fertilization is with 50 t/ha manure, 290 kg/ha P_2O_5 and 230 kg/ha K_2O. The rates in nature of phosphorus and potassium fertilizer are respectively 1250 kg/ha precipitate fertilizer and 1800 kg/ha plant ash. The application of the fertilizers must be the same way as on the raspberry.

Fertilization of blackcurrant - The main fertilization is with 50 t/ha manure, 270 kg/ha P_2O_5 and 160 kg/ha K_2O. The rates in nature of phosphorus and potassium fertilizer are

respectively 1350 kg/ha precipitate fertilizer and 1800 kg/ha plant ash. The blackcurrant is sensitive to soil acidity. In order to create suitable conditions for growth, on the areas identified for its growth is necessary to control the soil acidity. When found necessary must apply once more liming.

Fertilization of blueberry - The main fertilization is with 40 t/ha manure, 190 kg/ha P_2O_5 and 140 kg/ha K_2O. The rates in nature of phosphorus and potassium fertilizer are respectively 1120 kg/ha precipitate fertilizer and 1400 kg/ha plant ash.

Fertilization of strawberries - Before planting of the strawberries, must liming to neutralize harmful soil acidity. The fertilization is with 520 kg/ha P_2O_5 applied as precipitate fertilizer and with 2000 kg/ha wood ash of coniferous species. The rate of nitrogen is covered by the application of manure.

Fertilization of Melissa officinalis - The main fertilization is with 40 t/ha manure, 260 kg/ha P_2O_5 and 180 kg/ha K_2O. The rates in nature of phosphorus and potassium fertilizer are respectively 1300 kg/ha precipitate fertilizer and 1800 kg/ha plant ash.

Fertilization of chamomile - With lime application on the areas, for growth of chamomile, must apply 30 t/ha manure. If the previous crop before the chamomile is fertilized with manure, must not apply fertilizer.

Abstract

The objective of this study was the allelic variation at the *Glu-1* locus of selected advanced lines from ten cross-combinations, obtained by crossing synthetic hexaploids (2n=42, $BBA^uA^uD^tD^t$) with bread wheat varieties. In total, 52 genotypes in BC_1F_4 and BC_3 were investigated by SDS-PAGE electrophoresis and grouped in 20 HMW-GS combinations at the three loci of group 1 chromosomes (*Glu-A1*, *Glu-B1* and *Glu-D1)*. At the *Glu-D1* locus, the genetic diversity was relatively high-H=0.63, as calculated by Nei index. Maximum concentration of hereditary material in favorable quality subunits 1Dx5+1Dy10 and 1Dx1.5+1Dy10 was observed. Subunit pair 1Dx1.5 + 1Dy10, coding by *ah* allele, was different from the *T. aestivum* genes. This allele was inherited from *Aegilops tauschii* (2n=14, D^tD^t) through the synthetic wheat and might have a significant effect on the bread-making quality in bread wheat. The average score of the high molecular glutenin combinations was calculated as 6.50. According to its share in the formation of this value, the investigated loci ranked as followed: *Glu-B1>Glu-A1>Glu-D1*. Twelve biotypes showed subunit 1Ax1.1, that is uncommon for the bread wheat, representing a reservoir of expanding allelic diversity for HMW-GS along with the D^t-genome derived genes.

Key words: synthetic hexaploid wheats, *Aegilops tauschii*, *T. aestivum*, SDS-PAGE, HMW-GS

Introduction

In the last century, modern wheat breeding caused a loss of beneficial genes in the newly created *T. aestivum* varieties. Contrasting to this, local landraces and wild wheats possessed a diversity of alleles, which are important for resistance to biotic and abiotic stresses and grain quality in wheat. Many synthetic amphiploids and nearly isogenic lines have been developed as bridges to transfer valuable traits in common wheat (Jauhar and Peterson, 2006; Plamenov and Spetsov, 2011; Hu et al., 2013).

Aegilops tauschii (2n=14, DD), the donor of D-genome in wheat (*T. aestivum*, 2n=42, BBA^uA^uDD) has many breeding traits (Gill et al., 1996; Tang et al., 2008; Trethowan and Mujeeb-Kazi, 2008), including seed proteins of significant importance for the end-use quality in wheat (Pena et al., 1995; Tang et al., 2008). *Ae. tauschii* accessions have been crossed to tetraploid *Triticum* species to obtain synthetic hexaploid wheats or directly to bread wheat varieties. The D-genome derived synthetics beard various genes in the Glu-D1 locus for grain quality, which formed interesting combinations with alleles in Glu-A1 and Glu-B1 loci (Peña et al.,1994, 1995; Hsam et al., 2001).

Gluten quality is a target of the modern wheat breeding. It consists of two prolamins - glutenins and gliadins (Atanasova et al., 2009; Rasheed et al., 2012; Hu et al., 2013). Glutenins, including high-molecular-weight and low-molecular-weight glutenin subunits (HMW-GS and LMW-GS), form a long chain of polypeptides, connected in between through disulfide strings to determine exclusively dough viscoelastic properties. HMW-GS subunits are coded by genes at *Glu-A1*, *Glu-B1* and *Glu-D1* and localized in long arms of 1A, 1B and

1D chromosomes. Each single locus is responsible for one x- and y-type subunit. These loci are highly polymorphic in nature without the influence of environment (Payne et al., 1981). The allelic variation at the three loci coding HMW-GS has been used either independently or in combination with other traits to estimate the genetic variation in species, hybrids and populations. The genotypes received Glu-1 скор, which has been used as a criterion for bread making quality (Payne, 1987). Although HMW-GS constitute only 10% of the storage in seed endosperms, about 67% of variation in bread-making quality in *T. aestivum* is due to different allelic variants of glutenins (Payne et al., 1984). Thus, the analysis of HMW-GS is a prerequisite and basic measure in breeding for wheat improvement.

The aim of this study was to characterize the high-molecular-weight glutenin subunits in selected advanced plants from hybrid generations of ten cross-combinations between two synthetic D-genome derived lines (*T. dicoccum*/*Ae. tauschii*) and *T. aestivum* varieties. Establishing the glutenin pattern in single plants at early stage of breeding will be very important for the fast creation of homozygous lines and their immediate involvement in breeding process.

Materials and methods

Materials: Plants in BC_1F_4 and BC_3 generations selected from ten cross-combinations, were included in the investigation (Table 1). First, 5 hybrids between three bread wheat cultivars and two synthetic wheats (*Triticum dicoccum*/*Aegilops tauschii*) were produced. The hybrids were crossed to eight *T. aestivum* varieties to develop 10 cross-combinations which were advanced on the field by selecting different plants on spike colour and shape. Synthetics (AD530 and 532) involved hybrid parent as tetraploid component in crosses to *Ae. tauschii* accessions (Table 2).

Methods: HMW glutenins were extracted according to Singh et al. (1991). The electrophoresis run on vertical apparatus as classical one-dimensional 12% polyacrylamide gel SDS – PAGE (Laemmli, 1970). Arrangement and numbering of HMW-GS in Glu-A1 and Glu-B1 loci in wheat was carried out (Payne and Lawrence, 1983). Alleles in Glu-D1 locus were described according to William et al. (1993). Quality score was calculated (Payne et al.,1980) by summing individual scores of separate high-molecular-weight glutenin subunits. Genetic diversity in a locus was determined by the Nei index (Nei, 1973) by means of: $H = 1-\sum Pi^2$, where *H* and *Pi* designate the index of diversity and frequency of alleles in a locus, respectively. Allelic frequencies were calculated as a sum total of accessions divided by accession number.

Results and discussion

Generally, 406 seeds were investigated, between five and ten grains per selected plant (Table 1). Six cross-combinations generated two and three HMW-GS patterns. Subunit 2* was the most frequent glutenin in Glu-A1 and the index for genetic diversity was comparatively high, H = 0.71. Subunit N was found very rarely (9.6%). Subunits 2* and 1, which displayed high frequency, contributed to bread making quality in wheat. Genotypes with subunit 1.1, originating from the synthetic wheat, should be valuable for wheat improvement, because the allele *x*, coding this glutenin unit, appeared as a new gene for the bread wheat genome. The score of Glu-A1 was estimated as 2.11 without the effect of allele *x*, which score is not calculated yet (Табл. 3).

Three alleles (*b, c, f*) were found in Glu-B1 coded pairs 7+8, 7+9 and 13+16, respectively. Its genetic diversity is H=0.51. The subunit 7+9 had the biggest part 65.4%, the next were 13+16 (23.1%) and 7+8 (11.5%) pairs, which positively influenced the bread quality. The quality score in this locus was 2.35, compared to the maximum value of three (Табл. 3).

In locus Glu-D1, the genetic diversity (H=0.63) was higher than in locus Glu-B1. Three alleles (*d, a* and *ah*) were again determined in this locus, providing 5+10, 2+12 and 1.5+10 pairs, respectively. Allele *ah*, coding 1.5+10 subunits, is a new gene in the glutenin spectrum of 21 advanced *T. aestivum* genotypes. It originated from the diploid *Ae. tauschii* through the synthetic amphiploid, used in crosses to bread wheat varieties. The glutenin-score was calculated as 2.04 from the maximum value of four. The subunits 1.5+10 have no score estimate at present, so it is expected this value to be increased. Some information is available for the positive effect of allele *ah* on bread-making qualities (Peña et al., 1995; Tang et al., 2008). It was proved, that biotypes with 1.5+10 pair in combination with 7+8 in Glu-B1 and subunit 1 in Glu-A1 were better for grain quality than the combination of 5+10 with the same alleles of the two loci (Peña et al., 1995; Tang et al., 2008). Li et al. (2009) stated that 5+10 were the best valuable subunit pair for quality among all others in Glu-D1 locus, while Vaiciulyte-Funk et al. (2015) found 2+12 in combination with Null, 6+8 and HMW-glutenin quantity of 10.3-11.4% being most suitable for ring shaped bread production.

Table 3. Frequency and genetic diversity in HMW-GS among the advanced lines

Locus	Allel	Subunit	Glu-1 score	Selected plants/no	Frequency, %
Glu-A1	c	N	1	5	9.6
H=0.71	a	1	3	17	32.7
Score>2.11 (3.00)	x	1.1	-	12	23.1
	b	2*	3	18	34.6
Glu-B1	b	7+8	3	6	11.5
H=0.51	c	7+9	2	34	65.4

Score-2.35 (3.00)	f	13+16	3	12	23.1
Glu-D1	d	5+10	4	22	42.3
H=0.63	a	2+12	2	9	17.3
Score>2.04 (4.00)	ah	1.5+10	-	21	40.4
Glu-score 6.50 (10.00)					

A final result of all recombination among the subunits in the three loci were twenty HMW-GS patterns (Table 4, Fig. 1). The Glu-1 score varied from 5 до 10, with a medium of 6.50. This value does not include subunits 1.1 (in 12 progenies) and 1.5t+10t, which have no score values at present. According to the share in forming the glu-score, the loci were arranged as following: Glu-B1>Glu-A1>Glu-D1.

The resulted HMW-GS configurations contributed differently to grain quality. Three of them, 2*, 7+9, 5+10; 1, 7+9, 5+10 and 1.1, 7+9, 1.5+10 monitored the basic part (36.5 %) of glutenins. They were connected with high (score 9) and comparatively good (score 7) quality. About 23% of the glutenin potential was under control of four spectrums with frequency of 5.7%. The glu-score of two glutenin compositions was 7 and assigned to good grain quality. The rest 13 HMW-GS patterns, each was found once or twice in the selected lines, controlled 40.2% of glutenins in the plants investigated. We suppose, progenies with 1.5t+10t pair in Glu-D1 and a subunit 1.1 in Glu-A1, should produce grain of good to high quality (Table 4).

Table 4. HMW-GS patterns of selected lines from ten cross-combinations in BC_1F_5 and BC_3F_2 generations

HMW-pattern	Allele	Glu-1 score	Progeny/ no	Frequency, %

Фиг. 1. HMW-GS composition in advanced wheat lines originated from ten cross-combination with participation of two synthetic D-genome derived wheats (12% SDS-PAGE):
1. Bezostaya 1 (check); 2.128-1; 3. AD530-4 (check); 4.128-2; 5.128-3; 6.136-1; 7.Aglika (check); 8.136-2;9. Polena (check); 10.532-2 (check); 11.166-1; 12.166-2; 13.168-1; 14.118-1; 15.168a-1; 16.181-1; 17.110-1; 18.177-1; 19.110-2; 20.167a-1; 21.168-2; 22.166-3; 23.168a-2; 24.110-3; 25.168-3.

Conclusions

1. Analysis of glutenins in 52 plants selected in BC_1F_4 and BC_3 from ten cross-combinations with participation of two synthetic D-genome derived wheats (*T. dicoccum*/*Ae. tauschii*) classified them in twenty HMW-GS different patterns.
2. Twenty one progenies were found to have the subunits 1.5t+10t, originated from the synthetic wheats. One progeny (seeds in BC_3F_2) displayed the spectrum Glu-A1(1)+Glu-B1(7+8)+Glu-D1(1.5t+10t) which seemed to be a combination for high grain quality.
3. Twelve progenies had the subunit 1.1 in the Glu-A1 locus. Allele *x*, coding this glutenin, was considered as a new gene for the wheat genome. Lines were grouped in 5 HMW-GS patterns and could be also regarded as valuable resources for enlargement the genetic diversity in wheat.

INVESTIGATION ON THE RESISTANCE OF COMMON WINTER WHEAT LINES TO NATURAL INFECTION OF P. STRIIFORMIS

Vanya IVANOVA

Dobrudzha Agricultural Institute – General Toshevo, 9520, Bulgaria
*Corresponding author: vkiryakova@yahoo.com

Abstract

Stripe rust is an important disease on wheat which can cause significant yield losses and deteriorate grain quality. The ability of the pathogen to mutate and replicate quickly, as well as to overcome vast spaces airborne makes it threatening to the resistance of the new cultivars. This imposes the necessity to constantly work on the development of new improved cultivars with higher durable resistance.

Our investigation presents the results from the study on the resistance of common winter wheat lines under natural infection of *P. striiformis.*

Fifty-nine common winter wheat lines at adult stage were tested for resistance to a natural population of *P. striiformis* at Dobrudzha Agricultural Institute – General Toshevo, Bulgaria during season 2013 – 2014. A certain degree of resistance was shown by 71 % of the lines. In 8.4 % of the lines there was no attack by stripe rust. High resistance was found in 17 % of the investigated material.

The lines which reacted as resistant were 33.9 %, while moderate resistance was found in 11.8 % of the lines. In a large part of the investigated material the resistance to stripe rust was combined with good field resistance to leaf and stem rust and to powdery mildew, and with other valuable properties such as high bio chemical index of grain determined in our previous investigations. The purposeful use of own and foreign sources of resistance in breeding has lead to the development of initial material combining disease resistance with other valuable economic properties.

Keywords: resistance, common wheat lines, *P. striiformis*, natural infection

Introduction

Stripe rust with cause agent *P. striiformis*is a main disease on wheat worldwide which can cause considerable losses of yield and grain quality (Singh et al., 2004; Long, 2007). Some authors point out that stripe rust is becoming an increasingly serious problem in the last 40 years (Line, 2002; Chen, 2005).

The occurrence of stripe rust in Bulgaria is sporadic. It can be found in regions with more humid and cool climate such as the coastal areas and the high fields in the piedmonts. In the recent years, however, it is observed all over the country due to the climatic changes favoring its development and propagation.

Because of the occurrence of new airborne races and the ability of the pathogen to mutate fast, the genes for resistance are being overcome more frequently (Chen, 2005). This imposes the necessity to work constantly for the development of new improved cultivars with more durable resistance. Therefore the strategy is to use closely related and wild species as new sources of resistance. The studies have shown that especially valuable in this respect are some forms from genera *Triticum, Agropyron, Aegilops* (Riley, 1968; Sears, 1961).

The aim of this study was to investigate the response of common winter wheat lines to natural infection of *P. striiformis* with a view of their most rational usage as sources of resistance in breeding.

Materials and Methods

Fifty-nine common winter wheat lines and their resistance stage to natural infection of stripe rust at adult were subjected to investigation. The studies were carried out at Dobrudzha Agricultural Institute – General Toshevo, Bulgaria, under field conditions during harvest season 2013 – 2014. The lines were derived from 12 crosses. The mother components of the presented lines originated from complex crosses of cultural wheat to wild and synthetic forms. Foreign and Bulgarian cultivars and lines carriers of genes which determine resistance to diseases were also involved. The pedigree of the investigated lines is given in Table 1.

The sowing of the tested lines was done manually, each line being planted in 5 rows 1m long, with 25 cm interspacing. Cultivar Michigan amber was used as a check susceptible to *P. striiformis*. The attacking rate on the check cultivar over the years was 60 %.

The attacking rate of stripe rust was read as percent of infected leaf area according to the modified scale of Cobb (Peterson, 1948).

The level of resistance was calculated by comparing the relative disease severity (DS) of each cultivar to that of the susceptible check M. amber. The relative DS was calculated by the formula as follows:

Average disease severity (DS) of the cultivar / Average disease severity (DS) of M. amber x 100.

The field response of the host plants to stripe rust is presented in Table 2.

Table 2. Field response of host plant to stripe rust

Reaction	Description	Observation	Constant Value
NoDisease	No visible infection	0	0
Resistant	Visible chlorosis or necrosis, No uredia are present	R	0,2
Resistant – Moderately Resistant		R-MR	0,3
Moderately Resistant	Small uredia surrounded by chlorotic/necrotic areas	MR	0,4
Mod. Res. - Mod. Sus.		MR-MS	0,6
Moderately Susceptible	Uredia medium size with no necrotic margins but possibly some distinct chlorosis	MS	0,8
Mod.Sus.- Susceptible		MS-S	0,9
Susceptible	Large uredia without necrosis or chlorosis	S	1

Disease severity and host response data are often combined into a single value called the coefficient of infection (CI) (Table 2). The (CI) is calculated by multiplying the severity times a constant for host response: where immune I=0.0, R=0.2, MR=0.4, MS=0.8, and S=1(Roelfs et al., 1992). The field responses and the constant values are presented in Table 2.
The cultivars were classified into:
Immune – 0; Very resistant (0-5); Resistant (6-25); Moderately Resistant (26-45); Moderately Susceptible (46-65); Susceptible (66-100).

Results and Discussions

The reaction of the investigated common winter wheat lines and their coefficient of infection and rating are presented in Table 3. Among the investigated 59 lines, 71 % demonstrated certain degree of resistance. In 8.4 % of the lines, stripe rust attack was not found. These lines (20-330-2-5, 20-333-1-2, 20-333-2-4, 20-333-4-14 and 20-333-5-5) were registered as immune. Three lines were tested from cross No 20-297- . Line 20-297-1-12 reacted with (CI=3.3), which places it in the group of very resistant lines (VR). Line 20-297-1-1 responded with(CI = 6.6) and also fell in the group of resistant lines (R). The line combines resistance to stripe rust with high resistance to leaf rust and powdery mildew, and demonstrated resistant to moderately resistant response to the cause agent of stem rust (Ivanova et al., 2009). The third line from this cross, 20-297-1-13, reacted as moderately susceptible (MS) with (CI = 53.3).
The pedigree of the lines from this cross involved the combination (Russalka x *Ag. glaucum* x Avrora). It is known that the wheat x couch grass (*Agropyrum repens*) hybrids are characterized with very high multi barrier resistance to stripe rust at adult stage (Malinsky et al., 1984).

Table 3. APR of common winter wheat lines to the cause agent of stripe rust *P. striiformis*

There is data that cultivar Russalka possesses very high multi barrier resistance to stripe rust. Malinsky and Mihova (1985) proved that the resistance in cultivar Russalka to race 41 E136 is controlled by one dominant gene and one recessive gene.

Savov and Donchev (1982) presented researches on the resistance at adult stage of cultivar Russalka to leaf rust and powdery mildew. Cultivars Nadadores 63, TPR 354, Sonora 64 tend to be varieties with durable and horizontal resistance to *Puccinia graminis tritici* and this resistance

has remained invariable for more than 20 years (Karjin, 2002). The involvement of all these cultivars in the cross explains the complex character of resistance in the above lines.

From the cross with breeding number 20-300-, a total of 6 lines were tested. Five of them (20-300-2-2 awned, 20-300-2-6, 20-300-2-18, 20-300-3-5 and 20-300-3-16) responded as very resistant (CI = 1.6) and one (20-300-2-2) as resistant (CI = 6.6) (Table 3). The high resistance of these lines to stripe rust was combined with expressed full resistance to all pathotypes of leaf rust at young stage and high field resistance to leaf and stem rust and powdery mildew (Ivanova et al., 2009; Ivanova et al., 2015). The mother component of the cross involved the combination (M. amber x 73/557).

Line 73/557 is a cross between the amphidiploid (*T. timopheevi var. typica* x *Ae. squarrosa var. strangullata*) and cultivar Avrora. It is possible that the high resistance to stripe rust demonstrated by these two lines came from genes transferred from the wild species or from

cultivar Dobrudzha 1, for which there is data that carries partial resistance to stripe rust (Karjin et al., 1994). The lines from the cross 20-303- are rather diverse with regard to their response to *P. striiformis.* Line 20-303-4-18 belonged to the group of resistant lines (CI=20.0). Three of the lines had moderate resistance (20-303-1-3, 20-303-2-5, 20-303-4-12), two were with moderately susceptible reaction (20-303-2-4 and 20-303-2-15) and one (20-303-1-12) fell in the group of the highly susceptible lines. Cultivar Dobrudzha 1 and line 73/557 were also involved in the mother component of the lines from this cross, but the father component in this case was the combination (11-8 x Trayana), which is in fact the new cultivar Lider recently developed at Dobrudzha Agricultural Institute. In a previous investigation (Ivanova, 2015) it was found that cultivar Lider responded with a resistant reaction to natural infection of *P. striiformis.* Seven lines were tested from the cross 20-306-. Only one of the lines in this cross reacted as moderately susceptible. The rest demonstrated degree of resistance within the range from moderate to high (Table 3). Lines 20-306-5-2, 20-306-5-3, 20-306-5-5 and 20-306-5-11 showed resistant reaction to stripe rust. Line 20-306-5-2 combined resistance to stripe rust with high resistance to leaf rust and powdery mildew (Ivanova, 2015). Lines 20-306-5-3, 20-306-5-5 and 20-306-5-11 combined resistant reaction to stripe rust with high resistance to leaf and stem rust. Line 306-6-2 (awned form) had expressed high resistance to stripe rust also combined with high resistance to the other two types of rust (Ivanova, 2015). The complex character of resistance in these two lines was mainly due to the cultivars with durable resistance included in them, such as Sonora 64, Wisconsin 245, Nadadores 63, San Pastore, TPR 354, the combination (Russalka x *Ag. glaucum* x Avrora) and the line 73/557.

Ten lines were tested from the cross 20-309-. Three of them demonstrated moderate and high susceptibility. The rest reacted as resistant, and one of them, 20-309-5-1, demonstrated high resistance. The high resistance to stripe rust in this line was combined with high resistance to leaf rust and powdery mildew and with high to moderate resistance to stem rust (Ivanova, 2009). Three lines were tested from the cross 20-318-. Two of them reacted as resistant, and one of them demonstrated high resistance. The resistance to stripe rust of line 20-318-1-6 was combined with high resistance to leaf rust and powdery mildew, and with high to moderate resistance to black rust. Line 20-318-3-5 combined resistance to stripe rust with high resistance to powdery mildew and with high to moderate resistance to brown and stem rust (Ivanova, 2015).

Line 20-318-4-16 was with expressed high resistance to stripe rust combined with high resistance to powdery mildew and was very resistant to resistant to leaf and stem rust (Ivanova, 2015). These lines also involved cultivars with durable resistance such as cultivar Vratsa, which carried horizontal resistance to stripe rust (Karjin, 2003).

One line was tested from the cross 20-324-, which also exhibited resistant reaction (CI = 6.6) to the natural population of stripe rust. The resistance to stripe rust in this line was combined with high resistance to brown rust and powdery mildew (Ivanova, 2009). Two lines were tested from the cross 20-327-. One of them reacted as very susceptible (CI = 130.0), while the other demonstrated resistant reaction. Two lines were tested from the cross 20-330-. In one of them no attacking rate was registered, i.e. it behaved as immune, while the other one responded as very resistant (CI = 3.3). Four lines from the cross 20-333- were tested. None of the lines from this cross was attacked by stripe rust, i.e. they demonstrated immune reaction.

The investigations of Mihova showed that the resistance at adult stage was typical of wheat with regard to stripe rust; she pointed out that the Bulgarian cultivars Ogosta, Tundzha and Vratsa were carriers of such resistance (Karjin et al., 1994). The presence of these cultivars in the investigated lines from crosses 20-318, 20-324-, 20-327-, 20-330- and 20-333- was probably the reason for the exhibited resistance to stripe rust.

Thirteen lines were tested from the cross 20-336-. The responses of these lines were rather versatile ranging from resistant to very susceptible (R-VS). Six of the lines demonstrated certain degree of resistance, three of them responding as resistant and three as moderately resistant. The mother component of the lines from the cross 20-339- involved cultivar Erythrospermum 19-16. Mihova found high level of horizontal resistance to stripe rust in this cultivar (Karjin et al., 1994). We, however, tested only one line from this cross and it showed susceptible reaction.

Conclusion

Among the tested 59 common winter wheat lines at adult stage for resistance to the natural population of *P. striiformis*, 71 % demonstrated certain degree of resistance. 8.4 % were registered as immune. The resistance to stripe rust in the greater part of these lines was combined with resistance to the other economically important diseases on wheat, as well as with other invaluable properties such as high bio chemical index determined in our previous researches. The high and complex resistance makes these lines especially valuable for breeding. They are important initial material containing original resistance which has been efficient for more than 30 years now.

NEW COMMON WINTER WHEAT LINES WITH RESISTANCE TO LEAF RUST (P. TRITICINA)

Vanya IVANOVA

Dobrudzha Agricultural Institute – General Toshevo 9520, Bulgaria
*Corresponding author: vkiryakova@yahoo.com

Abstract

Wheat is the most important cereal crop in global agricultural economy and cultivated in diverse agroclimatic regions of the world. Breeding for disease resistance is the most economically and environmentally safe method to reduce crop losses. The long term success of breeding for disease resistance depends on the nature of the pathogen and virulence spectra in the pathogen population, the availability, diversity and type of genetic resistance in the host and the methodology for screening and selection for resistance.

During 2010-2012, under the conditions of the infection field of Dobrudzha Agricultural Institute – General Toshevo, Bulgaria, 800 common winter wheat lines were tested to a population of races of the cause agent of leaf rust *P. triticina*. Forty-eight of the lines, which demonstrated resistance under field conditions, were tested to individual pathotypes of the pathogen at seedling stage under controlled conditions. The tested lines, which exhibited a certain degree of resistance at seedling and adult stages, carried both race specific and race nonspecific resistance. The combination of various mechanisms of resistance is highly significant for the durability of resistance. In this relation, the investigated 48 lines can be considered efficient sources of resistance which can be used in the breeding programs.

Key words: *wheat, P. triticina, sources of resistance, race specific resistance, race nonspecific resistance*

Introduction

Leaf rust caused by *Puccinia triticina* Eriks is one of the most common diseases with highest economic importance among the diseases on wheat both in Europe and worldwide. In Bulgaria, the agro climatic conditions are favorable for its development; therefore it occurs annually and influences the yields from wheat. The harmfulness of the disease is expressed mainly in smaller assimilation leaf surface leading to higher transpiration and disturbed hydro balance, which, on its part, leads to premature decay of the leaf mass. The plants damaged by leaf rust typically have low winter resistance and low drought resistance indices. The spikes of the attacked plants form lower amount of grain, which is of poor quality and is the main reason for the lower yields. According to Kolmer et al. (2005), the losses caused by leaf rust can vary from insignificant level to 20 % depending on the growth stage of the crop and the mean resistance or susceptibility of the cultivar. Caldwell et al. (1934) pointed out that the yield decrease in the susceptible cultivars varied within 15-28%, and the losses were mainly due to the reduced number of grains per spike and their lower weight. According to Gospodinova (1979), the losses after early occurrence of the disease can reach 30–40%.

The proper way of solving the problem with leaf rust is developing resistant cultivars and the efforts in this respect are primarily directed to the search and the suitable choice of sources of resistance. The resistance is often neutralized by the occurrence of new pathogen pathotypes. The resistance of the cultivars grown in Bulgaria to *P. triticina* is not sufficient to protect wheat from this pathogen’s attacks for a longer period of time and therefore it is necessary to include new sources of resistance in the breeding programs (Karjin, Stefcheva, 2004).

The aim of this investigation was to study the response of new common winter wheat lines recently developed at Dobrudzha Agricultural Institute – General Toshevo (DAI) to the cause

agent of *P.triticina* at both young and adult stages, and to involve the best of these lines in the breeding for new common winter wheat cultivars.

Materials and methods

During 2010 – 2012, 800 new common winter wheat varieties were screened for resistance to the cause agent of leaf rust *P.triticina* under infection field conditions at DAI. Forty-eight lines were selected out of them, which responded with a certain degree of resistance (moderate MR to high VR) in the infection field, and which demonstrated resistant reaction to some of the leaf rust pathotypes at young stage under greenhouse conditions.

The investigation was carried out under conditions of maximum infection background of *P. triticina.* The full set of pathogen pathotypes of leaf rust identified for the respective year was transferred to field. The lines were sown manually in 1.5 m rows with 25 cm interspacing. Cultivar *Michigan amber* was used as a multiplier of the cause agent of brown rust. The artificial inoculation with the cause agent was done according to a methodology adopted at the Plant Pathology Laboratory of DAI (Ivanova, 2012). The infection type and the attacking rate were read according to Cobb's scale modified by Peterson (Peterson et al., 1948) at stage milk maturity. The mean coefficient of infection (CI) was calculated, or the so called corrected attacking rate, by introducing a coefficient with the following values of the respective infection types: R-0.2; MR-0.4; M-0.6; MS-0.8; S-1. Depending on the values of (CI), the investigated lines were divided into several groups: immune I (CI=0); very resistant VR (CI=0-5.99); resistant R (CI= 6-25.99); moderately resistant MR (CI=26-45.99); moderately susceptible MS (CI=46-65.99), and susceptible to very susceptible S–VS (CI= 66-100). The lines with susceptible reaction (from moderately to very susceptible) were of no interest to us.

The forty-eight lines selected against high infection background which demonstrated a certain degree of resistance, were tested to 9 *P. triticina* pathotypes of various virulence under controlled climatic conditions according to standard procedures (Browder, 1971). The pathotypes were identified on the basis of 15 monogenic lines (*Lr1, Lr2a, Lr2b, Lr2c, Lr3, Lr9, Lr11, Lr15, Lr17, Lr19, Lr21, Lr23, Lr24, Lr26* and *Lr28*) and coded by the method of Limpert and Muller (1994). To improve the formation of spores, all plants were treated with solution Maleic hydrazide 97% (1g in 3 l water). On the 9^{th}- 12^{th} day after inoculation, the type of infection was read according to the scale of Stakmen et al. (1962).

Results and discussion

The data from the testing of the investigated lines to 9 pathotypes at young stage are presented in Table 1. The lines demonstrated various degrees of resistance or susceptibility to the pathotypes with different virulence. Line 01/A-169-72 exhibited resistant reaction to all used pathotypes. According to data of (Ivanova, in press), isogenic lines carriers of genes *Lr22a, Lr22b, Lr43* demonstrated complete resistance to all pathotypes at young stage during the three years of the investigation, and only in 2012 genes *Lr9* and *Lr28* also exhibited complete resistance to all pathotypes.

The line indicated above may contain some of these genes but this is a subject of additional genetic and breeding studies. This line responded with high resistance under field conditions during the three years of the investigation (Table 2) which is an indication that it carries race specific resistance.

Table.1 Reaction of common winter wheat lines to 9 pathotypes of *P. triticina* in seedling stage

Line 1/169-87 responded with resistant reaction to 8 of the used pathotypes. It demonstrated susceptible reaction only to pathotype 12773. Line 99/45-83 also responded with susceptible reaction to two of the pathotypes (12773 and 62572). The data from Table 2 shows that in 2010 this line reacted as highly resistant to a population of races under field conditions, while in 2011 and 2012 it responded as resistant. Resistant reaction to six of the pathotypes involved in the investigation was demonstrated by lines 9720-150, 6A/19-3 and 20/96. Line 9720-150 reacted as highly resistant under field conditions in all three years of the investigation. The other two lines reacted as resistant in two of the years and as highly resistant in one year. Lines 94/266-3-6, 9792-115, 01/A-3, 01/A-19-75 and 20/100-5 exhibited at young stage resistance to 5 of the used pathotypes. Line 01/A-19-75 demonstrated stable reaction in the three years of the investigation under field conditions reacting as highly resistant. The response of the other four lines to a population of races was within the range very resistance – resistance (Table 2).

Another group of eight lines (99-10-5-71, 93/86-9, 9792-123, 9792-124, 10337-108, 01/A-13, 01/A-166-73and 20/143) exhibited resistant reaction at young stage to four pathotypes of different virulence. Lines 10337-108, 01/A-13 and 01/A-166-73 showed stable highly resistant reaction under field conditions. Stable resistant reaction during the investigated period was demonstrated by lines 93/86-9 and 20/143 (Table 2). The following lines showed resistant reaction at young stage to two or three pathotypes: 99-10-5-72, 3451-1-3, 3506-1-1, 20/28, 20/93-1, 2534-6-3-4, 01/A-20 and 01/A-175-77. Lines 01/A-20 and 20/28 demonstrated high resistant reaction under field conditions, and lines 3506-1-1 and 20/93-1 reacted as resistant. Nine of the studied lines responded with resistant reaction to one pathotype at testing under greenhouse conditions: 99/151-9-83, 9793-126, 01/A-25-73, 20/18-82, 20/27, 20-104-71, 20-130-2-71, 20/185-74 and 1/28-84. All tested lines responded with resistant reaction to one or several pathotypes at seedling stage, and those which demonstrated very resistant and resistant reaction to a population of races under field conditions were carriers of race specific resistance. Further breeding and genetic studies are necessary to find out which genes determine their resistance.

Typical adult or field resistance was exhibited by lines 2669-3-1, 3059-1-2, 3540-4-1, 8112-77-11, 01/A-29-73, 01/A-32-71, 01/A-75, 01/A-177-72, 20/26, 20/69, 20/158-77 and 1/35-85. All these lines responded with susceptible reaction to all pathotypes used at young stage, while demonstrating resistant to very resistant reaction in field. The resistance these lines carry is race-nonspecific.

Conclusion

All tested lines responded with resistant reaction to one or several pathotypes at seedling stage, and those with very resistant and resistant reaction to a population of races under field conditions were carriers of race specific resistance. Line 01/A-169-72 demonstrated complete resistance to all pathotypes used at young stage. This line could carry genes *Lr22a, Lr22b, Lr43, Lr9* or *Lr28* since these isogenic lines responded with resistant reaction to the used pathotypes; further genetic and breeding investigations are however necessary to confirm this.
A part of the lines, 2669-3-1, 3059-1-2, 3540-4-1, 8112-77-11, 01/A-29-73, 01/A-32-71, 01/A-75, 01/A-177-72, 20/26, 20/69, 20/158-77 and 1/35-85, carried race nonspecific resistance.
Every breeding strategy should include a rich set of sources with different types and mechanisms of resistance to allow both genetic variability and alternatives for correction of the “erosion of race specific genes” phenomenon. On the other hand, the combination of resistant genes at young stage with APR genes expresses a high level of durable rust resistance. In this sense the investigation carried out can assist breeding and the presented lines can be involved in the breeding programs.

Abstract

Drought is the most important environmental factor that adversely affects plant stands. Application of growth regulators, we can achieve a partial elimination of the impacts of environmental stress. The aim of this study was to determine the impact of growth regulators on the physiological parameters, grain yield and quality of winter wheat under drought stress simulated by experimental rain-out shelters. We hypothesized that growth regulators can contribute to mitigating the impact of drought on water use efficiency, yield formation and grain quality of winter wheat production. The experiment was conducted in a field experimental station in Žabčice (49°00'41.3"N) on winter wheat variety Matylda in 2013/2014. The experimental station is located in a warm area with prevailing continental climate (average annual rainfall 482 mm and temperature 9.3°C). Within this experiment following growth regulators and fungicide with growth regulation effect were used: Retacel extra R68 (chlormequat chloride 720 g/l), Moddus (trinexapac-ethyl 250 g/l), Cerone (ethephon 480 g/l), Amistar (azoxystrobin 250 g/l). These growth regulators were applied at growth stages between BBCH 31 and BBCH 49. Application of growth regulators partly eliminated negative impact of drought on chlorophyll fluorescence, chlorophyll and flavonol content and grain yield particularly for azoxystrobin, chlormequat chloride and trinexapac-ethyl applications. Growth regulators also reduced the negative impact of drought on grain quality. Results of field experiments can contribute to mitigating the impact of drought on yield formation of winter wheat production in the realization of biological potential of wheat genotypes.

Introduction

Wheat is one of the most important crops all over the world. Worldwide production of wheat increasing every year, and the increase is a result of higher yields and slightly larger area of all crops, which may reach 222.3 million hectares. Drought stress in winter wheat is evidently more significant in the Central Europe than in other countries, it is also supposed that according to the model of climate prediction periods of drought are going to be more often. Drought decreases the growth of plants, influences various physiological and biochemical processes such as photosynthesis, respiration, metabolism of nutrients and growth stimulators. Drought is one of the most common environmental stresses that affect growth and development of plants.Tolerance to water stress is a complicated parameter in which crops performance can be influenced by several characteristics (Ingram and Bartels, 1996). Tolerance can be divided into two parts including drought avoidance and dehydration tolerance (Kramer et al., 1995). Drought avoidance includes root depth, reasonable use of available water by plants, and changes in plants' lifestyle to use rainfall. Dehydration tolerance consists of plants' capability to partially dehydrate and grow again when rainfall continues (Salekdeh et al., 2002). Adaption of plants to drought stress is a vital issue to develop new improve methods for increasing stress tolerant plants (Rizhsky et al., 2002).

Many factors can affect plants' responses to drought stress such as plant genotype, growth stage, severity and duration of stress, physiological process of growth (Chaves et al., 2003), different patterns of genes expression (Denby et al., 2005), different patterns of the activity of respiration(Ribas-Carbo et al., 2005), activity of photosynthesis machinery (Flexas et al., 2004), and environmental factors (McDonald, 1996). Physiological responses include closure of stomata, decrease in the activity of photosynthesis, development of oxidative stress, alteration in the integrity of cell wall, production of metabolites which are toxic and cause plants' death (Bray, 2002), signal recognition of roots, turgor loss and adjustment of osmosis, reduction in water potential of leaf, decrease in stomata conductance to CO2, reduction of internal CO2 concentration, and reduction of growth rates.Photosynthesis is an essential process to maintain crop growth and development, and it is well known that photosynthetic systems in higher plants are most sensitive to drought stress (Falk et al., 1996). The effect of water stress on photosynthesis has been a subject of controversy among plant physiologists for many years, and conflicting results have been reported depending on the plant material, and the experimental procedures used for investigations (Comic and Massacci, 1996). However, it has not been well established that where and how the chloroplasts are damaged underdrought stress, and how the damages can be detected and evaluated easily. In response to water stress, a decrease in net CO, assimilation is generally observed. This effect can result from different events, such as an inhibition of electron transport activity limiting the generation of reducing power or a limitation in the metabolic activity (Guo and Al-Khatib, 2003). Classical methods, based on CO, and water exchange measurements, provide information concerning net photosynthetic activity; however, these informations are not sufficient, and additional techniques are required to determine without ambiguity the effects of water stress on photosynthesis. It was reported that the approach for measuring photosynthetic traits such as chlorophyll content and chlorophyll fluorescence parameters might estimate influence of the environmental stress on growth and yield, since these traits were closely correlated with the rate of carbon exchange (Guo and Li, 2000; Araus et al., 1998; Fracheboud et al., 2004). So these parameters can be used as reliable indicators to evaluate the energetic/metabolic imbalance of photosynthesis and yield performance across genotypes under water deficit (Araus and Hogan 1994; Araus er al. 1998). Unfortunately, little is known about changes of these traits such as chlorophyll content and chlorophyll fluorescence parameters under drought stress in wheat. In this study, dry and wet varietes differing in drought tolerance were selected to compare chlorophyll and flavonolcontent and chlorophyll fluorescence parameters under drought stress. The relationship between these traits and drought tolerance is discussed in this study.

Material and methods

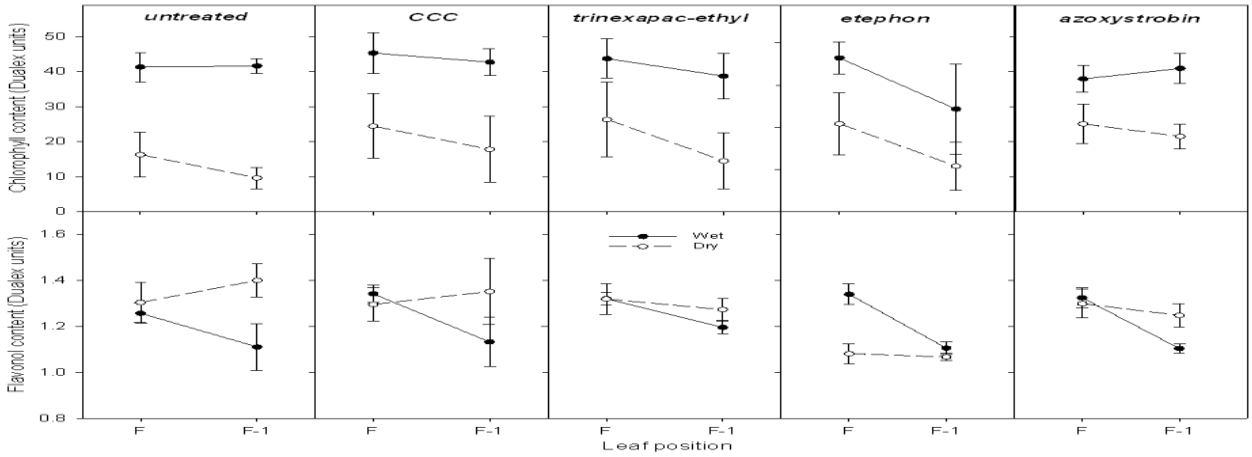
The experiment was carried out at the field experimental station in Žabčice with winter wheat variety Matylda. The experimental station is situated in Southern Moravia (the Czech Republic). Moderate soils are dominant type in this region. The location is considered to be one of the hottest areas in the Czech Republic. Sowing of the variety Matylda was carried out on October 15th, 2013 in three replications randomly distributed on selected plot with sowing rate of 4 million growing seeds/ha. Variety Matylda belongs to the set of early varieties. The variety has a medium plant height with an average resistance to lodging. Variety Matylda has a very high yield potential. During the growth phase by the end of stem elongation period BBCH 39 there were over the half of the experimental area built short-termed rain out shelters providing induction of drought stress. Measuring of physiological parameters (water use efficiency, CO_2 assimilation rate and the chlorophyll content in leaves was done in the middle of drought stress (May 26th, 2014), and at the end of drought stress effect.After wheat ripening evaluation of yield and yield structure has been done. For evaluation of CO_2 assimilation rate,

transpiration and stomatal conductivity gas exchange system LI 6400 XT with an assimilation chamber equipped with LED light source has been used. The measurement took place at constant temperature, relative air humidity, CO_2 concentration and at saturation light intensity. The observed parameters allowed calculation of water use efficiency (WUE) and indirect parameter of water use efficiency A/Gs.As an additional parameter for evaluation of primary phase of photosynthesis measuring of chlorophyll fluorescence by the apparatus FluorPen has been done. Parameters of the maximal and actual quantum yield PS II were evaluated. The content of chlorophyll and flavonols was determined in vivo by the method of transmittance and UV screening of chlorophyll fluorescence by the instrument Dualex4 FLAV.

Results and discussion

Chlorophyll and flavonol content

Drought stress led to a general decline in chlorophyll content in both upper leaves (F and F-1) (Graph 1). All growth regulators used in the experiment reduced this decline, particularly in the flag leaf. The highest mitigating effect on drought caused decline in chlorophyll content was observed for active ingredient azoxystrobin. Active ingredient etephon reduced negative effect of drought on chlorophyll content, but also led to a decrease in chlorophyll content in lower leaf (F-1) (Graph 1), both in the treatment well watered and drought stressed. Conversely, the flavonoid content in leaves of plants exposed to drought stress increased particularly in the lower leaf (F-1). Growth regulators generally reduce this effect, while the most significant effect was found for application of etephon where flavonoid content in drought stressed plants dropped below a level of well watered plants.

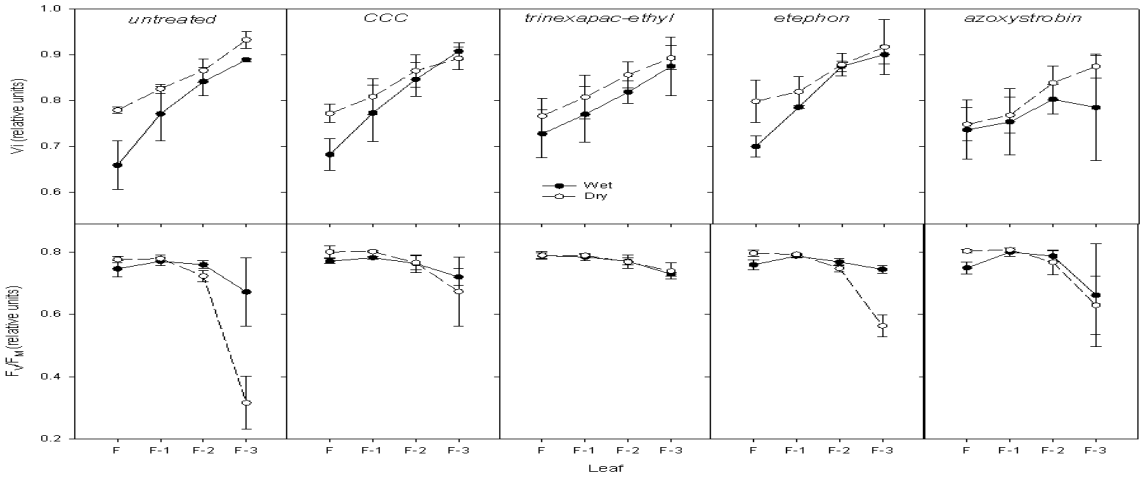


Graph 1: Chlorophyll and flavonol content

Chlorophyll fluorescence

In the term of measurements, chlorophyll fluorescence parameters V_i and F_V / F_M were affected differently within the vertical canopy profile. V_i parameter shows response to drought stress in virtually all leaves within the vertical canopy profile, while the values increased in direction to the lower leaves. Conversely, a parameter F_V/F_M was significantly affected by drought stress only in the lowest leaf (F-3) (Graph 2). The positive effect of growth regulators on partametr V_i occurred only in the lower leaves, particularly for growth regulators CCC and etephon. Conversely, the positive effect of regulators reducing the impact

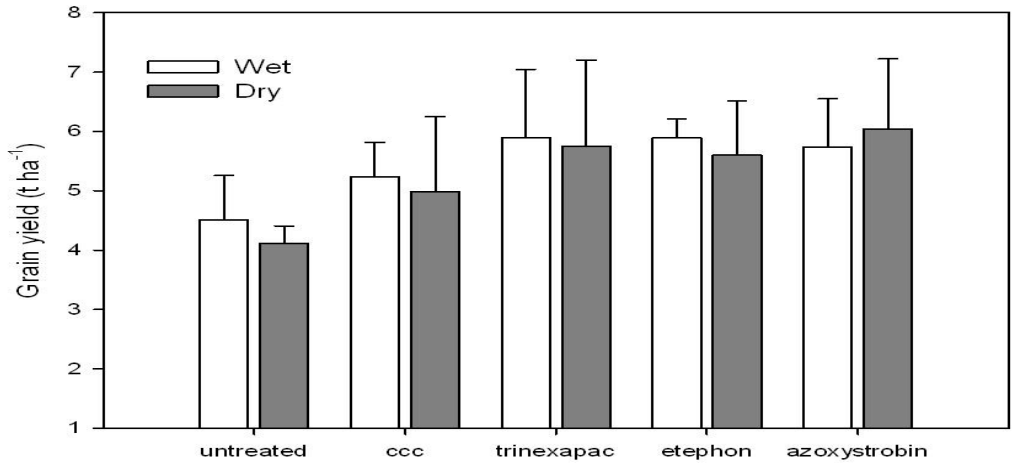
of drought on the parameter F_V/F_M was seen in all growth regulator treatments with the most significant effect of the active ingredience trinexapac-ethyl.



Graph 2: Chlorophyll fluorescence

Grain yield

Yield results showed a positive effect of all applications of growth regulators, with the highest impact of the trinexapac-ethyl, etephon and azoxystrobin. All three treatments also reduced the negative impact of drought on yield....Graph 3



Graph 3: Grain yield

Conclusions

In this study, we monitored the values of chlorophyll and flavonol content, Fo, FV/Fo and FV/F, under watered and drought stress condition.The highest mitigating effect on drought caused decline in chlorophyll content was observed for active ingredient azoxystrobin.Conversely, the flavonoid content in leaves of plants exposed to drought stress increased particularly in the lower leaf (F-1). Growth regulators generally reduce this effect, while the most significant effect was found for application of etephon where flavonoid content in drought stressed plants dropped below a level of well watered plants.Conversely, the positive effect of regulators reducing the impact of drought on the parameter F_V/F_M was seen in all growth regulator treatments with the most significant effect of the active ingredience trinexapac-ethyl.It is evident from the measurements that all the regulators increased the yield and which it itself proves the positive effect during the drought because it

was a very dry year and the canopy did not lodge. Furthermore, the biggest reduction of drought stress effect on yield was evident in strobilurin and partially at trinexapac-ethyl application as well.Therefore, these photosynthetic traits could be good indicators of adaptation of wheat to drought stress. Since the measurement for these traits and using plant growth regulators is fast and reliable, the approach is quite attractive.

EFFECT OF SOME CITRUS ROOTSTOCKS ON YIELD AND FRUIT QUALITY OF TWO MANDARIN VARIETIES

Sobhy Mohamed KHALIFA*, Ashraf Ezzat HAMDY

Hort. Dept, Faculty of Agric, Al-Azhar University, Cairo, Egypt
*Corresponding author: Sobhy_khalefa@yahoo.com

Abstract

The present study was carried out during the two successive seasons of 2013 and 2014 to investigate the effect of volkameriana lemon (VL) and sour orange (SO) rootstocks on yield and fruit quality of Balady and Fremont mandarin cultivars. Generally rootstocks were found to have significant effects on yield, and fruit quality of both varieties. Balady and Fremont mandarin trees budded on VL rootstock showed higher fruit yield/ tree (kg) fruit weight(g), volume(cm^3), height, diameter (cm), fruit pulp weight (g), fruit peel weight (g) and peel thickness (cm), juice volume of fruit (ml), number & weight of seeds/ tree and fruit firmness than those dudded on SO rootstock. On the other hand, trees budded on SO rootstock had the highest of TSS%, total acidity of fruits juice and vitamin C compared with those budded on VL rootstock. Oppositely, the effect of the rootstocks on TSS/acid ratio of two scion cultivars was found to be insignificant. Fremont mandarin cultivar was the higher in yield/ tree, fruit weight, pulp weight, fruit juice, acidity and vitamin C than Balady one, Balady cv. was superior to Fremont mandarin regarding the other characteristics. Therefore, it was found that VL is a suitable rootstock for Balady and Fremont mandarin cultivars compared with SO.
Key words: Citrus, mandarin, rootstock, yield and fruit quality.

Introduction

Citrus is the first fruit crop in Egypt whereas, it is covering an area of 395731feddan with annual production of 2786397tons (**FAO, 2012**). Mandarin occupies the second planted citrus species after orange with 27.2 % of citrus cultivated area and 21.7 % of total citrus production (**The Management of Central Horticulture, 2011**).Rootstocks have had a substantial role in the development of the citrus industry in the world. Rootstock utilization has gain value for solving both limiting and restricting factors of citrus production (soil, climate and pests, etc.) and conditioning the market demands on productivity, short juvenility period and high-fruit quality **(Tuzcu et al., 1992).**Factors like cultivar characteristics, rootstocks employed, growing conditions along with cultural managements, type of flowers, and the fruit drops can affect citrus cultivars yield and quality performance **(Demirkeser et al., 2003).**The rootstock may influence several aspects of citrus growth and development, including yield, fruit quality, and tolerance to stress caused by biotic and abiotic factors **(Filho et al., 2007).** In the Mediterranean region, all citrus cultivars are mainly budded on Sour orange, due to its resistance to gummosis fungi, high adaptability to wide range of soil conditions and the ability to produce high fruits quality (**Castle, 2010**).However, the Sour orange rootstock has shown to have some serious problems such as susceptibility to be attacked by citrus tristeza virus, poor compatibility with some citrus cultivars and in some cases produce low fruit yields compared with other rootstocks (**Castle, 2010 and Georgiou, and Gregoriou, 1999**).Volkameriana lemon which appears to be one of the most promising rootstocks because its tolerance to tristeza (**Shafieizargar et al., 2012**).Balady and Fremont mandarin cultivars are growing in new reclaimed soils and suffering from the aforementioned problems. Accordingly, this experiment was conducted to elucidate the effect of two rootstocks on yield and fruit quality of two mandarin cultivars.

Materials and methods

The present study was carried out in the two successive seasons of 2013 and 2014 where trees of Balady and Fremont mandarin (***Citrus reticulate Blanco***) of eight years old budded on Sour orange (SO) (***C. aurantium*** L.) and Volkamer lemon (VL) (***Citrus volkameriana*** **Ten. and Pasq.**), rootstocks. The trees were planted at 3x5 meters apart for Balady and 1.5x5 for Fremont mandarin trees and grown in a private orchard located at Alsalehia Algadeeda, Alsharkia Governorate, Egypt, were used. The trees were grown in sandy soil, irrigated using drip irrigation system. Fifteen trees of each rootstock and Mandarin cultivar were selected nearly similar in growth, healthy and subjected to the same cultural practices, where it divided into three replicates, with five trees per each replicate. Ninety fruits from each cultivar budded on every rootstock were harvested at fruit at maturity stage, where 6 fruits of each tree were used. The collected fruits were divided into three replicates for each rootstock and Mandarin cultivar.

Measurements:

Yield: Harvesting was achieved on 10thFebruaryand 15th December of Balady and Fremont cvs. respectively and fruits per tree were collected and separately weighed so that the yield per tree (kg) could be calculated in both studied mandarin cultivars and in two studied seasons.

Fruit physical and biochemical characteristics: Samples of 90 fruits were collected at maturity stage from 15 trees such that 6 fruits per tree. The harvested fruits were divided into three replicates in each mandarin cultivar budded on either SO or VL rootstocks to determine some fruit physical and biochemical characteristics.

Physical characteristics such as fruit weight (g), fruit volume (cm^3), fruit pulp weight (g), fruit peel weight (g) and peel thickness (cm) juice volume of fruit (ml), number and weight of seeds/fruit were recorded. Fruit firmness expressed as Newton (N) was measured using pressure tester (digital force-Gouge ModelIGV-O.SA to FGV-100A.Shimpo instruments).

Fruit biochemical characteristics. The following characteristics were recorded as follows:

Total soluble solids (TSS %) was determined by using a digital refractometer.

Total acidity (TA) was determined by titration and expressed as citric acid according to **A.O.A.C., 2000**.

Total soluble solids/acid ratio was calculated from the values of total soluble solids divided by values of total acids. Also, **Ascorbic acid (VitaminC)** was estimated by titrating juice sample with 2, 6 dichlorophenol indophenol dye according to **A.O.A.C., 2000**.

Statistical Analysis: A complete randomized block design was followed and the analysis of variance (ANOVA) was performed using two ways ANOVA Co-stat software according to **Stern (1991),** and the means were differentiated using Duncan multiple range test at 5% level **(Duncan, 1955).**

Results and discussions

The yield

Yield was affected by the kind of rootstock in both scion cultivars, in the two studied seasons (Fig.1). Trees of the two cultivars budded on VL possessed yield significantly higher than those budded on SO in the two studied seasons. Data also revealed that Fremont cultivar gained fruit yield/tree significantly higher than those of Balady cv. which possessed the least values in the two tested seasons.

The present results are in agreement with that previously obtained by **Hifny et al., (2013)** on Valencia orange, **Shafieizargar, et al., (2012)** on Queen orange and **EI-Sayed et al., (2007)** on Washington navel who found that orange trees budded on VL produced fruit yield (kg/tree) higher than those budded on SO rootstock. Further, **Filho et al., (2007)** mentioned that fruit yield of ‘Fallglo’ and ‘Sunburst’ mandarin trees was not affected by the rootstock. These

results indicated the inconsistency in yield differences as affected by rootstocks, which could be attributed to differences in scion cultivars, tree age, climatic conditions, and soil characteristics, etc.**(Yildiz1 et al.,2013).**The lower yield efficiency on sour orange and ‘Carrizo’ is probably caused by the bigger canopy size induced by these rootstocks. The higher yield efficiencies were also reported for trees reduced in size by rootstocks **(Auler et al., 2008).**Yield difference among rootstocks and their interactions with different citrus cultivars could be attributed to differences in morphology and physiology of rootstocks, which are reflected as tree growth vigour, size and depth of roots, water and nutrients uptake capability, carbohydrate synthesis, and also their adaptation to climatic and soil conditions, good compatibility between rootstock and cultivar and the possibility of fruiting potential of a cultivar on certain rootstocks **(Continella et al., 1998)**. The compatibility between rootstock and scion is very important to achieve sufficient yield. These various characteristics of rootstocks can affect growth, fruiting, and fruit quality of the scion cultivar. VL rootstock usually supplies the scion with an extreme vigor, great tree size, and cause large fruit. VL rootstock vigority may be attributed to its ability to generate a more extensive root that would absorb more water and nutrients **(Reuther et al., 1967).**Sour orange, the most common citrus rootstock, produced high quality fruits but smaller sized fruits out of marketable grade. In contrast, the ‘Volkamer’ lemon produced good quality marketable sized moderate number of fruits and proved as a reliable rootstock for ‘Queen’ orange**(Shafieizargar, et al., 2012)**.

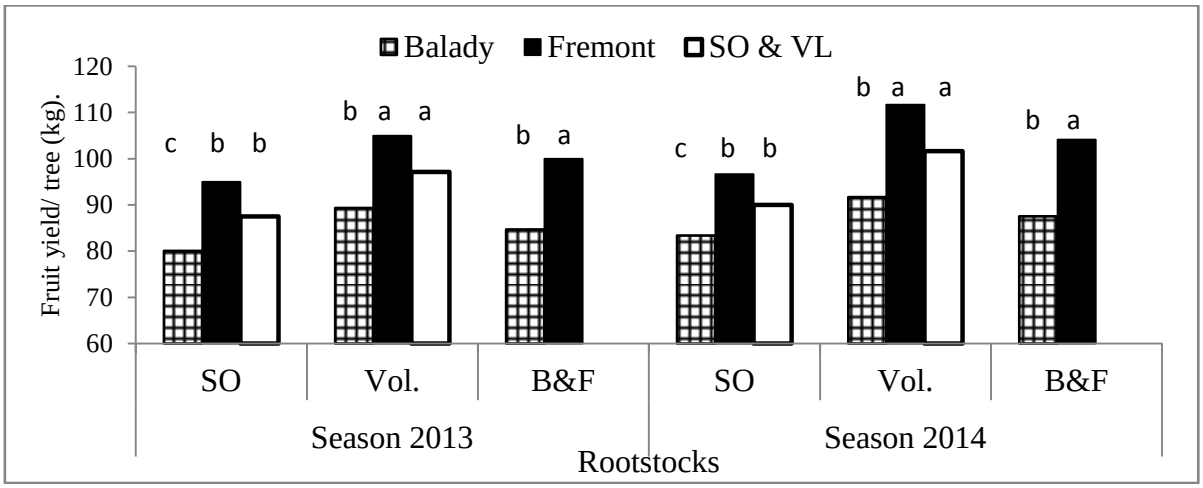

Fig.1. Effect of citrus rootstocks on the yield of Balady and Fremont mandarin cultivars 2013 and 2014in seasons.

Fruit physical characteristics.

Data in Table (2) showed the effect of Sour orange (SO) and Volkamer lemon (VL) citrus rootstocks on fruit weight (g), volume (cm^3), peel weight (g),pulp weight (g),fruit height(cm), diameter(cm) , Peel thickness (cm), juice volume (cm^3), number of segments/ fruit, number of seeds/ fruit, weight of seeds/ fruit and firmness of both Balady and Fremont mandarin cultivars in the two studied seasons.

Regarding the effect of rootstock kind on fruit weight and fruit volume of Balady and Fremont mandarin, fruits the results in table (2) showed that fruit weight, fruit volume (cm^3), fruit peel weight (g) and fruit pulp weight (g) of both Balady and Fremont mandarin cvs. budded on VL was significantly bigger than those budded on SO. in two studied seasons. Fremont cv. had the higher fruit weight, fruit volume and fruit pulp weight than Balady one while Balady cv. gained the highest fruit peel weight in two studied seasons.

The results are in agreement with those of **Hifny et al., (2013)**who found that fruit weight of Valencia cv. budded on VL was greater than those budded on SO. **Al-Jaleel and Zekri (2002)**

found that fruit weight of Olinda Valencia budded on VL was higher than those budded on SO rootstocks. On the other hand, **Filho et al. (2007)** on Fallglo and Sunburst mandarins reported that fruit weight was not affected by the rootstocks. **Shafieizargaret al., (2012)**suggested that the fruit size of Queen orange was highly affected by many growth factors such as nutrients and water availability and extensive rooting system, it could have contributed to the bigger fruits of trees on VL and other vigorous rootstocks.

Concerning the effect of rootstock kind on fruit height, fruit diameter and fruit Peel thickness (cm) data in table (2) showed significant increase in fruit height, diameter and Peel thickness (cm) of Balady and Fremont mandarin trees budded on VL compared with those budded on SO rootstocks. Data in table (2) also illustrated no a real significant difference between both studied cvs. was noticed regarding fruit height and diameter while significant difference between them was noticed regarding fruit peel where Balady cv. Possessed higher fruit Peel thickness (cm) than Fremont one in the two studied season.

The results are in agreement with those of **Yildiz1 et al., (2013)** reported that higher values of fruit diameter were verified in fruits of Rhode Red Valencia orange trees on Carrizo and Troyer rootstocks; however Valencia Late on Carrizo rootstock had the least fruit diameter. The highest rind thickness was also obtained in fruits of Rhode Red Valencia on Troyer and those of Valencia Late on Carrizo and Troyer rootstocks. **Incesu et al.,(2013)** found that maximum fruit length of Moro blood orange was highest obtained from fruit on Yuzu and the lowest one on Troyer citrange.

Regarding the effect of kind of rootstock on fruit juice volume, data in table (2) showed significant increase in fruit juice volume (cm^3) of Balady and Fremont mandarin trees budded on VL compared with those budded on SO rootstocks. Balady cv. had the higher fruit juice volume (cm^3) than Fremont cv., in the two studied season.

These findings are in harmony with those of **Incesu et al.,(2013)** found significant difference between the effect of rootstocks on fruit Juice of Moro blood oranges. **Ahmad et al., (2007)** on Kinnow mandarin found that the highest juice content was with VL rootstock. On the other hand of **Yildiz1 et al., (2013)**mentioned that no significant difference between the effect of tested rootstocks on fruit Juice of Rhode Red Valencia and Valencia Late orange.

Data in table (2) indicated that number and weight of seeds significantly increased of Balady and Fremont mandarin fruits when budded on VL compared with those budded on SO rootstocks. Balady cv. gained the highest number and weight seeds / fruit compared with Fremont cv., which possessed the least values in the two studied season.

The results are in agreement with those of **Demirkeser et al., (2009)** who found that the number of seeds was significantly influenced by the rootstocks in Nova and Robinson fruits where the trees were grafted on SO rootstock higher than which was grafted on Troyer rootstock. However, seed number did not reach commercially unacceptable levels. On the contrary **Ghnaim and Al-Muhtaseb, (2006)** working on Washington Navel found that no significant differences for seed number were observed among the four rootstocks.

Regarding the effect of kind of rootstock on Pulp Firmness (N), data in Table (2) showed significant increase in pulp firmness of Balady and Fremont mandarin fruits budded on VL compared with those budded on SO rootstocks. Balady cv. had the higher Pulp Firmness than those of Fremont cv., in the two studied season.

The results are in agreement with those of **Hifny et al., (2012)**who found that pulp firmness of Valencia cv. budded on VL was higher than those budded on SO. Similar results were gained by **Wutscher and Bistline(1988**) who stated that the little percentage of fruit juice caused by budding on VL rootstock has the responsible for the higher pulp firmness compared with that on SO rootstock.

Fruit biochemical characteristics.
Data in Table (3) showed the effect sour orange (SO) and Volkamer lemon (VL) citrus rootstocks on the percentages of total acidity, TSS , TSS/ Acid ratio and Vitamin C (Ascorbic Acid) of Balady and Fremont mandarin fruits in the two studied seasons.
Total Soluble Solids (TSS %). Data in Table (3) cleared that total soluble solid of fruits from trees budded on SO rootstock had higher TSS % compared with those budded on VL rootstocks. Balady cv. possessed higher TSS % values than Fremont cv., in the two studied season. The results are in agreement with those of **Al-Jaleel et al.,(2005)**who found an increase in TSS% in fruit juice of Allen Eureka lemon scions budded on VL rootstock compared with SO rootstock. **Kaplankiran et al., (2005)** working on Okitsu Satsuma mandarin reported that the highest TSS was obtained from fruits on sour orange. Generally, some vigorous rootstocks such as VL and rough lemon, which normally have an extensive rooting system, are able to absorb more water and produce heavy crop loads with higher juice content but this is sometimes coupled with low TSS. Some other rootstocks such as Sour orange and 'Cleopatra' mandarin produce fruits with lower juice content but with high TSS **(Reuther et al., 1967).**
Total Acidity. Data in Table (3) indicated that the lowest total acid percentage was gained in fruits budded on SO rootstock with significant differences than VL rootstock. Fremont cv. had the higher total acidity percentage than Balady cv., in the two studied season. The results are in agreement with those of **Hifny et al., (2013)** who noticed an increase in total acidity in fruit juice of Valencia scions budded on SO rootstock compared with those budded on VL rootstock. Oppositely **Incesu et al.,(2013)** on Moro blood oranges reported that the effects of the rootstocks on fruit juice acidity were insignificant.
TSS/Acid Ratio. Data in Table (3) indicated that TSS/Acid ratio of fruit juice did not show a significant difference between the effects of two studied rootstocks. While Balady cv. had the higher TSS/Acid ratio in fruit juice than Fremont cv., in the two studied season. The maximum values of TSS/Acid ratio in fruit juice was recorded in fruits budded on SO rootstock compared with those budded on VL rootstock. The flavor and palatability of citrus fruit is a function of relative levels of TSS%, acids and the presence or absence of various aromatic or bitter juice constituents **(Davies and Albrigo, 1994).** The results are in agreement with those of **Incesu et al.,(2013)** on Moro blood oranges who found that the TSS/TA ratio, is generally defined as the fruit maturity index in citriculture, was not affected by rootstocks. Oppositely **Hifny et al., (2013)** found an increase in TSS/Acid ratio in fruit juice of Valencia scions budded on VL rootstock compared with those budded on SO rootstock.
Vitamin C (Ascorbic Acid). Data in Table (3) cleared that fruits from trees budded on SO rootstock showed an increase in Vitamin C content significantly higher than those on VL rootstock. Fremont cv. had the higher of vitamin C in fruits juice than Balady cv., in the two studied season. The results were in harmony with those obtained by with **Hifny et al., (2013)** who reported that the ascorbic acid (V.C.) of Valencia orange fruit trees budded on SO rootstock was superior to those budded on VL rootstock. On the contrary **EI-Sayed et al. (2007)** found that Washington navel orange budded on VL, produced fruits with highest juice acidity and ascorbic acid but presented lower TSS and TSS/acid ratio at harvest time in both seasons. The increase in Ascorbic acid (V.C. mg/100ml of fruit juice) as well as Titratable acidity percentage in fruit juice at harvest time could be attributed to the increase in fruit weight and size and to the increase in shoot growth and leaf area caused by N application **(Chen et al., 1999).** According to several researches, citrus trees grafted on Sour orange rootstock can be expected to produce medium-sized to large fruit with high Total Soluble Solids (TSS %) and high juice acidity **(Ramin and Alirezanezhad, 2005; and Zekri and Al-Jaleel, 2004)**. On the other hand, Citrus trees grafted on lemon rootstocks are usually expected to produce larger fruits with poor fruit quality; thick rinds, low total soluble solids

and low juice acidity **(Zekri and Al-Jaleel, 2004) .**

Conclusion

The study revealed that rootstocks produced marked effects on most of the parameters measured; suggesting that tree size, yield, and fruit quality of both Balady and Fremont mandarin cvs. can be controlled by proper selection of rootstock. Trees budded on VL rootstock showed the highest fruit yield/ tree (kg) fruit weight, volume, height, diameter, fruit pulp weight, fruit peel weight and peel thickness, juice volume of fruit (ml), number & weight of seeds/ tree and fruit firmness compared with the trees duded on SO rootstock. While trees budded on SO rootstock had the highest TSS%, total acidity of fruits juice and vitamin C. Therefore, it was found that VL is a suitable rootstock for both Balady and Fremont mandarin cultivars.

Abstract

Water deficit is the most severe limitation factor of plant growth and development, while plant genotypes may express different water stress hardiness. In the present study, *Lotus corniculatus* seedlings of two different populations (Kilkis and Taxiarchis; northern Greece) were used to evaluate the effect of water deficit on growth characteristics. Plants from the two populations were transplanted to pots and following a two-month establishment period, they were subjected to two water regimes: a) irrigation up to field capacity and b) limited irrigation in order to maintain water deficit conditions in the soil. Stem weight (SW), leaf weight (LW) and leaf area (LA) were measured during the growing season at four different phenological stages. The allometric indices of specific leaf area (SLA), leaf area ratio (LAR) and leaf water content (LWC) were estimated. Our findings suggest that plant origin (population) is a significant predictor of SW, LW, LA, SLA, LAR and LWC, while the irrigation treatment significantly affected only the growth parameters SW, LW and LA. The allometric indices SLA, LAR and LWC varied independently of irrigation. Nonetheless, lower values of SW, LW, LA and higher values of SLA, LAR and LWC were recorded on plants obtained from the area of Taxiarchis.

Keywords: *Leaf area, Leaf weight, Leaf Assimilation Rate, Specific Leaf Area*.

Introduction

Plants under natural and agricultural conditions are often exposed to various environmental stresses. In Mediterranean basin water deficit is one of the most important factors that curtail plant growth and crop productivity (Zlatev and Lidon, 2012; Cobb *et al.*, 2013). Changes in precipitation patterns, the increase of mean air temperature and the expansion of waterlogging or drought are expected to be intensified in the future due to global climate change (Xoconstle-Cazares *et al.*, 2010; IPCC, 2011). However, for plants grown in dry environments, both a high potential growth rate and efficient use of available water are desirable. The rates of growth and water use are both influenced by the allocation of biomass to the different organs. The allocation pattern that maximizes growth and/or water use efficiency depends on the availability of water. The influence of physiological traits on water use efficiency depends on the balance between the effects on growth and on water use (Zlatev and Lidon, 2012). Plants can adapt to water deficit conditions using physiological, morphological and biochemical mechanisms (Cattivelli *et al.*, 2008; Ghassemi-Golezani *et al.*, 2013). However, the adaptation mechanisms may differ among plant species and genotypes. Breeding of drought-resistant plants can be an advantageous strategy to avoid drought-induced damage to agriculture (Blum, 2011; Zlatev and Lidon, 2012).

Lotus corniculatus L., which grows under a wide range of environmental conditions, is the most important and widely distributed crop from the *Lotus* genus. It is a perennial legume native to the Mediterranean basin and, North Africa and has been widely used in Southern Europe, New Zealand, North and South America (Kirkbride, 1999; Inostroza *et al.*, 2015). It is a drought tolerant species with high nutritive value. However, there is limited published information concerning the physiological mechanisms that cause drought tolerance, as well as, the effects of drought stress on its growth parameters and specifically for populations obtained from different geographical areas (Carter *et al.*, 1997; Acuña *et al.*, 2012; Escaray *et al.*, 2012; Inostroza et al. 2015).

In the present study, *L. corniculatus* seedlings of two different origins (Kilkis and Taxiarchis; northern Greece) were used to evaluate the effect of water deficit on growth characteristics.

Materials and Methods

The experiment was conducted in the farm of the Aristotle University of Thessaloniki, Northern Greece (longitude: 40°31' 91", latitude: 23°59'58"), at an altitude of 6m a.s.l., during the spring of 2013. The climate of the area could be characterized as Mediterranean semiarid with dry summers. The mean annual precipitation is approximately 400mm and the mean annual air temperature is 15.5 °C. Microclimatic conditions in the experimental area, such as air temperature (T), photosynthetic photon flux density (PPFD) and vapor pressure deficit (VPD), were acquired using a microclimatic sensor (Novasima MS1, Novatron Scientific Ltd, Horsham, UK) and are presented in Table 1.

Table 1. Microclimatic conditions of the experimental area during the experimental period of 2013.

Phenological stages	Temperature (°C)	PPFD (μmol $m^{-2}s^{-1}$)	VPD (kPa)
Early vegetative	32.6	872	4.24
Vegetative	27.7	941	2.98
Flowering	24.3	1304	2.02
Fruit formation	30.6	822	2.70

Lotus corniculatus seedlings were sampled from two semi-arid areas of central Macedonia, Greece, namely Kilkis (K, temperature 12.2 ºC; precipitation 585mm; altitude 570m a.s.l.) and Taxiarchis (Tax, temperature 11.1 ºC; precipitation 767mm; altitude 645m a.s.l.) in September and October of 2012 and transplanted in small pots. At the beginning of March 2013, 32 plants from each origin were transplanted –one plant per pot– in larger pots (16cm diameter and 45cm height), filled with medium texture soil collected from the farm. After a two month establishment period, a transparent shelter was placed upon plants in order to prevent rainfall intervention. Two drip irrigation regimes were applied: a) irrigation up to field capacity (FI) and b) limited irrigation (LI) (40% water of that received by FI) in order to maintain water deficit conditions in the soil. The pots were placed in a completely randomized design with four replicates. Measurements were taken on four different dates corresponding to four phenological stages: early vegetative (5/21), vegetative (5/26), flowering (6/2) and start of fruit formation (6/25). In each phenological stage four plants were cut in order to measure the leaf area (LA) and the fresh weight of shoots, stems and leaves.Leaf area was measured using the portable leaf area measurement system Li-3000A (LiCor Lincoln, Nebraska, USA). Then the samples (leaves and stems) were placed in the oven for 48 hours at 70°C to

determine their dry weight. Specific leaf area (leaf area/leaf weight: SLA), leaf area ratio (leaf area/total shoot dry weight: LAR) and leaf water content (leaf fresh weight – leaf dry weight) / leaf fresh weight: LWC) were calculated (Cornelissen *et al.*, 2003).

Analysis of variance (ANOVA) was used to determine the effects of origin, irrigation treatment and plant phenological stage ($P < 0.05$) for all measured parameters (Steel and Torrie, 1980). Independent t-test was used to compare two means. Statistical analysis was performed using the statistical package SPSS (SPSS for Windows, release 22.0; SPSS, Inc., Chicago, USA).

Results and Discussion

The analysis of variance revealed that the plant origin (population) is a significant predictor ($p<0.05$) of SW, LW, LA, SLA, LAR and LWC, while the irrigation treatment significantly affected only the growth parameters SW, LW, LA. The allometric indices SLA, LAR and LWC varied independently of the irrigation regime ($p\geq0.05$). The time of the season (phenological stage) had significant effects ($p<0.05$) on all recorded parameters. The interaction between population and water treatment was not significant ($p\geq0.05$), indicating that there was no difference in the response of the two populations throughout the growing season at the two water regimes. On the other hand, the interaction between population and phenological stage was significant ($p<0.05$) for SW, LW, SLA, and LAR. Both water treatment and plant phenological stage affected stem and leaf dry weights and LA of *L. corniculatus* regardless of the origin. Mean values of dry leaf weight, SW and LA were reduced under water-limited conditions in both origins (Table 2).

Table 2. Average values (± SE) of growth parameters of *Lotus corniculatus* obtained from two origins (Kilkis, Taxiarchis) and subjected to two irrigation treatments in the experimental setting (n=16).

	Kilkis		**Taxiarchis**	
	Irrigation (FI)	Limited Irrigation (LI)	Irrigation (FI)	Limited Irrigation (LI)
Stem weight	11.36±1.55	6.41±0.37	5.59±1.46	2.72±0.58
Leaf weight	7.58±0.81	3.80±0.30	2.45±0.65	1.73±0.47
Leaf area	1664.07±157.43	919.16±122.99	565.53±130.71	359.18±68.35
SLA	231.85±15.84	240.84±31.99	409.22±103.68	304.03±45.11
LAR	95.82±7.84	90.36±12.82	141.28±34.33	133.85±22.27
LWC	0.81±0.010	0.81±0.007	0.85±0.01	0.84±0.02

The dry leaf weight (Fig. 1a) had an increasing trend in the full irrigation treatment while it remained rather stable in the LI treatment in both tested populations. Kilkis population presented the higher values in both irrigation regimes (Table 2, Fig. 1a) compared to Taxiarchis. However, throughout the growing season plants from Kilkis under FI had significantly higher LW compared to plants of the same origin subjected to LI. Only in the early vegetative stage, both populations presented the same LW regardless of the irrigation treatments. One reason may be that the short period of irrigation treatment could not influence

LW at these early stages. In addition, the early phenological stages coincide very often with sufficient rainfall and lower atmospheric temperatures, leading to lower VPD, lower transpirational losses and consequently with less stress in plants; perhaps this was another reason that we did not detect differences in leaf weight between the two irrigation treatments in these stages (Blum, 2011).

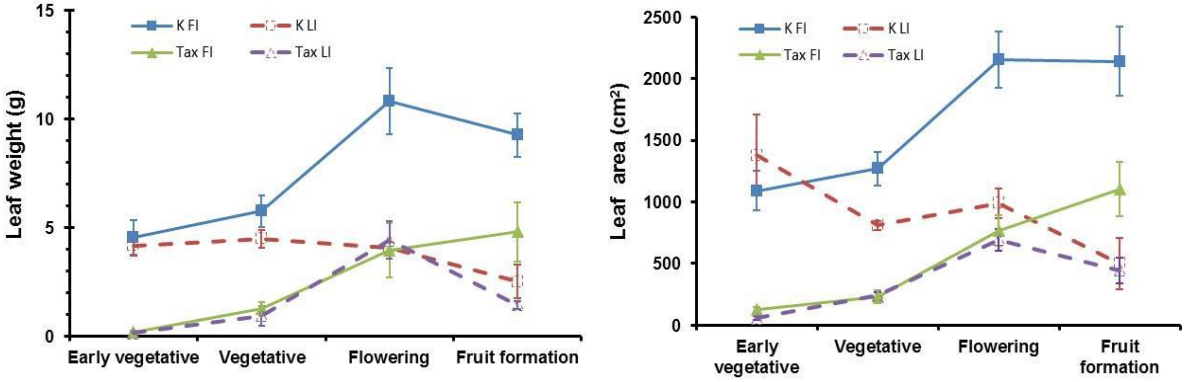

Figure 1. Changes of a) dry leaf weight and b) leaf area at different phenological stages of Kilkis (K) and Taxiarchis (Tax) populations of *Lotus corniculatus*, under full irrigation (FI) and limited irrigation (LI). Values present means ± SE (n=4).

The LA of both populations followed an increasing trend in FI treatment. In the LI treatment though, plants from Kilkis expressed a decreasing while those from Taxiarchis an increasing trend (up to flowering) in LA in response to season progress (Fig 1b). Flowering and fruit formation are recognized as the most drought sensitive plant growth phenological stages. Shrestha et al. (2006) demonstrated that water shortage during the grain filling stage reduced LA in lentils. The decrease of LA may represent a rapid response and a morphological adaptation to reduce water loss and rearrange resources under drought conditions (Zokaee-Khosroshahi *et al.*, 2014). It is well demonstrated that under water deficit conditions plants develop morphological mechanisms, such as decrease in plant dry weight and leaf area to reduce water consumption and continue to sustain life during the dry period of the season (Karatassiou *et al.*, 2014). Not only the pattern of biomass allocation, but also differences in the rates of uptake and loss of CO_2 and H_2O of the different plant organs are expected to contribute to variation in growth and water use efficiency (Zlatev and Lidon, 2012). Under limited irrigation the transpiration rate of Kilkis population was found to be not closely related to stomatal conductance, suggesting a stronger connection to environmental factors such as temperature and VPD changes (Karatassiou et al., 2015) Consequently, in order to understand the influence of limited irrigation on growth and allometric parameters we need to take into consideration the transpiration rate, the assimilation rate and water uptake of the plants.

From the changes of SLA (Table 1, Fig. 2a) during the growing season it becomes obvious that in each origin of *L. corniculatus* plants expressed similar mean values of SLA both under FI and LI. The same trend was recorded for LAR and LWC. Specific leaf area is considered an important attribute of plants to maintain survival in the Mediterranean climate, since it is associated with relative growth rate and plant capacity to use environmental poor resources (Karatassiou et al. 2014). The higher values for SLA were recorded in the first phenological stage for both origins and irrigation treatments. However, plants from Taxiarchis presented higher values of SLA, LAR and LWC (Table 1, Figure 2).

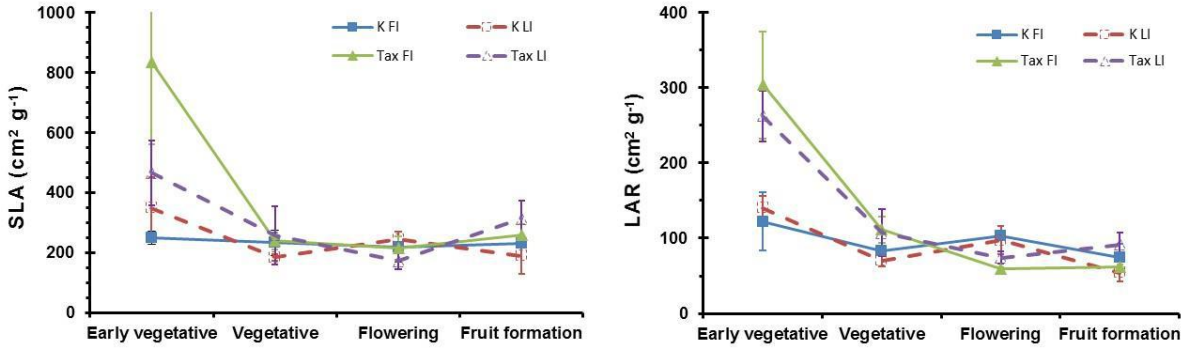

Figure 2. Changes of a) specific Leaf Area (SLA) and b) leaf area ratio (LAR) at different phenological stages of Kilkis (K) and Taxiarchis (Tax) populations of *Lotus corniculatus*, under full irrigation (FI) and limited irrigation (LI). Values present means ± SE (n=4).

The comparable values of SLA, LAR and RWC of both origins of *L. corniculatus* could be probably due to adaptation to poor environments (Li et *al.*, 2005). The above results showed that the two populations of *L. corniculatus* exhibited different responses to water deficit condition as far as growth characteristics are regarded.

Conclusion

Lotus corniculatus populations obtained from two origins of Northern Greece exhibited different growth parameters in response to water stress. The limited irrigation significantly reduced the growth parameters SW, LW and LA but did not affect the allometric ones, SLA, LAR and LWC of both populations.

DOUBLED HAPLOID LINE PRODUCTION IN DURUM WHEAT: PRESENT STATUS AND FUTURE PROSPECTS

Theano B. LAZARIDOU*, Ioannis N. XYNIAS

Abstract

Doubled haploid plant production is a very effective tool in shortening the time needed to develop new varieties. Of the various methods proposed to produce haploid plants anther culture is the most convenient and popular. However, this androgenic response depends on culture medium, on cold or heat pre-treatment, and mainly on the genotype of the donor plants. Although anther culture has been successfully employed in producing haploids in many crop plants, including hexaploid wheat, durum wheat is very recalcitrant to anther-culture, extremely few plants are produced and most of them are albinos. Efforts to produce haploid plants from durum wheat anther culture were attempted by many researchers who evaluated the factors affecting the androgenesis process. They used liquid or solid media, and several medium composition, including the modification of known media, like modified MS, modified W14, C17 etc. The pre-treatment of the anthers with mannitol, PEG, cold or a combined pre-treatment involving mannitol and low temperatures improved green plant regeneration. An alternative approach to obtain durum wheat haploid plants and subsequently doubled haploid lines is the maize technique. Other researchers attempted to cross durum to bread wheat cultivars responding well to anther culture in order to obtain durum wheat haploid plants. A future prospect could be transferring the 1BL.1RS wheat-rye translocation from the bread wheat cultivars to durum wheat and exploit any possible positive effects of the presence of this translocation on durum anther culture.

Introduction

Durum wheat is one widely grown cereal crop in the world and one of the most important ones used for human consumption worldwide. It is cultivated in several European countries including Italy, France, Turkey, Romania, and Ukraine, and in northern Great Plains of Canada and the United States. Genetic improvement to develop new varieties with high yield potential, resistant/tolerant to abiotic and biotic stresses and with acceptable quality is the most viable and environmentally friendly goal in most breeding programs. Isolation of homozygous genotypes through conventional methods requires several cycles of inbreeding and selection, and making this attempt time and money consuming. Doubled haploid plant (DHL) production is a very effective tool in shortening this time, because the homozygosity is achieved in one generation. Of the proposed approaches anther culture is still the most commonly used technique. Although anther culture has been successfully employed in producing doubled-haploids in many crop plants, including hexaploid wheat (*Triticum aestivum* L.) (Kasha and Maluszynski, 2003), this technique has not been proven very successful in durum wheat (Dogramaci-Altuntepe et al., 2001), and extremely few green plants are produced (Cistué et al., 2009). The androgenic response depends on culture medium, on cold or heat pre-treatment, and mainly on the genotype of the donor plants. (Lazaridou et al., 2005). More precisely, in durum wheat the green plant production is greatly genotype dependent. Efforts to produce haploid plants from durum wheat anther culture were attempted by many researchers who evaluated the factors affecting the androgenetic process. They involved the use of liquid or solid media, in several medium composition, including the

modifications of known media, lik e.g. modified MS, modified W14, C17 etc (Saidi et al. 1997). The pre-treatment of the anthers with mannitol (Cistué et al 2006), PEG, cold or a combined pre-treatment involving mannitol and low temperatures (Labbani et al. 2007) improved green plant regeneration. An alternative approach to obtain durum wheat haploid plants and subsequently doubled haploid lines is the maize technique which is less genotype dependent (Jauhar et al. 2009). Finally, Tersi et al. (2005) attempted to improve anther culture response of durum wheat by transferring B genome chromosomes by crossing durum to bread wheat cultivars responding well to anther culture.

In this review, the various efforts to obtain durum wheat DHLs through anther culture, wheat x maize wide crosses, and other alternative methods, as well as the future prospects, are summarized.

DOUBLED HAPLOIDS THROUGH ANTHER AND MICROSPORE CULTURE:

Although the first success in regeneration of bread wheat (*Triticum aestivun*) plants through anther culture was achieved in the early 70's (Ouyang et al., 1973), little progress has been reported in durum wheat. This is because durum wheat is a very recalcitrant to anther-culture crop, few embryos are formed (Foroughi –Wehr and Zeller 1990) and most of the pants produced are albinos (J'Aiti et al., 2000; Labbani et al., 2005; Cistué et al., 2006, 2009). During anther culture, microspores are induced to produce haploid plantlets after going through various developmental stages. This process of haploid production is influenced by physiological factors such as growth conditions of donor plants, developmental stage of microspores, types of pre-treatments and composition of the induction and regeneration media (Liu et al., 2002; Zheng et al., 2003; Cistué et al., 2009; Jauhar, 2003a). Different investigations have been carried out in order to evaluate the effect of these factors in anther culture response and to develop a protocol to regenerate green haploid plantlets from durum wheat anther culture. Several liquid or solid media, and several medium composition and modifications have been applied. Cherkaoui et al. (1997) used three liquid media: BPTG (Chuang et al, 1978), C17 (Wang and Chen,1986), BAC -1 (Marsolais and Masha, 1985), and tested nine Moroccan genotypes for their anther culture response. They reported green plant regeneration from five cultivars and five doubled haploid green plants were produced from BAC-1 medium. Saidi et al. (1997) who also evaluated Moroccan durum wheat genotypes found that pretreating of spikes at 3°C for eight days improved the androgenetic capacity. They used several culture media and found that the C17 medium was consistently the best for embryo induction. However, only two green plants from two cultivars were produced. Jauhar (2003a) reported that the BAD-1 medium (Trottier et al., 1993), is the most suitable induction medium for anther culture of durum wheat. The same medium has been used as a differentiation medium. Among the green regenerants several disomic (2n=28) polyploid and aneuploid plants were recorded. Lazaridou (unpublished data) observed that the use of induction medium W14 (Ouyang et al., 1989), supplemented with 5.0 mg/l 2,4-D + 0.5 mg/l BAP + 20.0 mg/l Ethephon + 50.0 mg/l L-cysteine + 500.0 mg/l myo-inositol (Kiviharju et al., 2005) , and pre-treatment consisting in a combined mannitol 0.7 M and cold for 7 days had a strong effect on the number of embryos produced after durum wheat anther culture. The second approach, microspore culture, is considered as more appropriate for durum DHL production than anther culture. Microspores floating in a medium with high viscosity are developed into embryos with normal morphology (Cistué et al. 2004). Jauhar (2003a) reported that four different induction media have the ability to produce calli from durum wheat microspores e.g.: BAC-1 (Marsolais and Masha, 1985), BAD-1, BAD-3 (Trottier et al., 1993), and M-42 (Kao et al., 1991). Labbani et al. (2007) reported the positive effect on callus formation of liquid CHB3 medium (Chu et al. 1990) after a proper modification. Durum wheat microspore culture was practically ineffective until ovaries were added into the

induction medium. Co culture with ovaries has been tested and found to be beneficial in durum wheat (Cistué et al 2006). Anthers of five cultivars and 20 F_1 crosses were pre-treated in 0.7 M mannitol, and microspores were plated on a C17 induction medium with ovary co-culture. Green plants were regenerated from all genotypes used and most of them were spontaneously doubled haploids. Some haploids and a very few polyploids plants were obtained. The production of many aneuploid plants is another problem in anther culture of durum wheat. Doğramaci-Altuntepe et al. (2001) studied the anther culture response of 10 durum wheat cultivars using three different growth conditions and four culture media and observed several chromosomal abnormalities in the plants produced. Cistué et al (2009**)** using C17 induction medium with ovary co-culture and a supplement of glutathione plus glutamine, 300 g/l Ficoll Type-400, managed to maximize production of green plants per spike from three commercial cultivars and ten F_1 crosses. Many green plants were obtained and no aneuploid plants were obtained.

Osmolality plays an important role in the inward and outward movement of water from plant cells. Depletion of water by osmotic stress is an important signal, or pretreatment, that triggers microspore embryogenesis and directs proper embryo development in various plant species (Wojnarowiez et al. 2004). Various stress pretreatments were applied including cold (Labbani et al., 2005), and osmotic shock (Cistué et al., 2006; Labbani et al., 2007). It was demonstrated by Labbani et al. (2005) that a cold pre-treatment of the microspores at 4° C for five weeks could be promising for green regeneration in durum wheat. Cistué et al. (2006) reported that anthers pre-treated in 0.7M mannitol for 5 days improved green plants regeneration. Labbani et al. (2007) showed that a pre-treatment consisting in a combined mannitol 0.3 M and cold for 7 days had a strong effect on the number of embryos produced and the regeneration of green plants. Ayed et al. (2010), in order to further improve the rate of haploid production through durum wheat microspores culture, have compared different types of stress conditions, including a combined pre-treatment involving mannitol or PEG and low temperatures. They reported that cold treatment for five weeks (4°C) was the most efficient, and that the involvement of PEG4000 1% for 10 days seemed to be a promising pretreatment.

WIDE CROSSES - MAIZE TECHNIQUE

Wide crosses have been utilized for the production of haploids for crop improvement and genetic studies (Baum et al. 1992). Bread wheat DHs are produced by various intergeneric crosses with maize (Inagaki and Tahir 1990; Laurie and Reymondie 1991), and *Hordeum bulbosum* (Barclay 1975). Although the *H. bulbosum* mediated haploid production has been accomplished in bread wheat and has a widespread use in doubled haploidy programs in barley, this method has not been effective in durum wheat (O'Donoughue and Bennett 1994). Crossability of wheat × *H. bulbosum* depends on the wheat allelic composition for the Kr genes responsible for the incompatibility between these two species (Sitch and Snape 1987). The production of haploids by hybridization with maize has been reported in hexaploid wheat (Inagaki 2003, Ushiyama et al. 2007, Xynias et al. 2014) and durum wheat (Almouslem et al. 1998, Jauhar 2003b).

The effect of individual durum wheat (*Triticum turgidum* L.) chromosomes on crossability with maize (*Zea mays* L.) was investigated by Doğramaci-Altuntepe and Jauhar (2001). Doğramaci-Altuntepe and Jauhar (2001) used 14 'Langdon' (LDN) D-genome disomic substitution lines, a LDN Ph mutant (Ph1b ph1b), and normal 'Langdon' line, which were pollinated with maize pollen. Haploid embryos were obtained from all lines but only 14 of the embryos germinated and developed into healthy plants. Different substitution lines exhibited varying degrees of success. These results indicate that the substitution of 5D for 5B confers on durum wheat a greater ability to produce haploids.

Maize - mediated haploidy induction is the method that has helped to produce haploids from several durum cultivars and genetic stocks (Almouslem et al. 1998). Generally in the case of durum wheat x maize zygotes , the maize chromosomes are completely eliminated after the third mitotic. Very rarely however a maize chromosome may be retained in the resulting durum haploid plantlet. Jauhar et al. (2009) observed a durum haploid plant with 15 chromosomes which presumably included a maize chromosome.

An alternative approach to overcome the recalcitrancy of durum wheat (*Triticum turgidum* var. *durum*) to anther culture, was attempted by transferring the responsible genes form bread wheat B-genome to the respective of durum wheat (Tersi et al. 2005). Three durum wheat cultivars were crossed to two bread wheat (*Triticum aestivum* L. em Thell) cultivars and anthers from the resulting F_1 plants and their original cultivars were cultured on potato-2 and W_{14} media. No green plants were produced from the parental durum wheat cultivars. In contrast, green plants were produced from the F_1 plants and the cytogenetic evaluation revealed that they all carried D-genome chromosomes.

Conclusion and perspectives

Haploid plants and haploid–derived homozygous lines are useful in plant breeding programs. Anther culture is a very useful technique for the production of doubled haploids, and thus to the production of DHs through androgenesis, is a proven method to obtain homozygous individuals in a single step. Durum wheat is very recalcitrant to anther-culture, with extremely few plants produced and most of them are albinos. On the other hand maize–induced chromosome elimination approach offers an alternative way in durum haploid plant production. However, the improvement in microspore culture could change this conclusion. A future prospect could be the formation of an improved protocol for anther or microspore culture of durum wheat that involves both cold and osmotic shock. Another prospective could be transferring the 1BL.1RS wheat-rye translocation from the bread wheat cultivars to durum wheat, because it is well known that the presence of 1BL/1RS translocation in bread wheat cultivars improves the embryoid production and green plant regeneration from anther culture. For this, transferring of the 1BL.1RS wheat-rye translocation could improve the anther culture response of durum wheat and consequently any other possible positive effects of the presence of this translocation on durum wheat could be exploited.

INFLUENCE OF DIFFERENT STRAINS OF AGROBACTERIUM RHIZOGENES AND EXPLANTS AGE ON INDUCTION OF HAIRY ROOTS AND PRODUCTION OF HYOSCYAMINE AND SCOPOLAMINE IN HYOSCYAMUS RETICULATUS

Zahra ZEINALI, Bahman HOSSEINI*, Esmaeil REZAEI

Faculty of Agriculture, Urmia University, Iran
*Corresponding author: b.hosseini@urmia.ac.ir

Abstract

Different *Agrobacterium rhizogenes* strains and three various explants age (one week old, two weeks old, four weeks old leaf) were tested to investigate the ability for transformation and production of secondary metabolites in *Hyoscyamus reticulatus*. All the strains of *A. rhizogenes* (A7, 15834, A13 and D7) used in this study produced hairy roots. Furthermore, effects of explants type (Cotyledon, Hypocotyl, two weeks old leaf, two weeks old internode, four weeks old leaf, and four weeks old internode), effects of two inoculation methods (immersion and injection) on hairy roots induction in cotyledon explants, different culture media (MS, 1/2MS, 1/4MS and B5) were investigated. Hyoscyamine and scopolamine production as a main product in *H. reticulatus* were measured by GC/MS. The results show that, induction of hairy roots in *H. reticulatus* was effected by strain and explant type. So, after 19 days, A7 strain and cotyledon explants were the best explants for induction of hairy root in *Hyoscyamus reticulatus*. ANOVA results showed that, the growth of hairy roots was significantly affected by medium type and the highest fresh weight produced in MS and B5 medium. Hyoscyamine (2/6 fold) and scopolamine (7/56 fold) content were increased significantly in Transgenic roots compared with non transgenic roots.

Key words*: Agrobacterium rhizogenes*, Bacteria strain, Hairy root, *Hyoscyamus reticulatus*, stem internode.

Introduction

Hyoscyamus reticulatus is an important medicinal plant, distributed in China, Afghanistan, India, Japan, Korea, South West Asia, North Africa and throughout Europe (Sajeli *et al*., 2006). *H. reticulatus* contains two distinguished tropane alkaloids, Hyoscyamine and scopolamine and both the compounds possess potential acute or chronic toxicity (Vike *et al*., 2008). It has been reported that tropane alkaloids are mostly synthesized in the young root cells and then transported to the aerial parts (Hashimoto *et al*., 1991). Nowadays hairy root cultures from plants are getting considerable attention because of their genetic and biochemical stability, rapid growth rate and ability to synthesize secondary products at levels comparable to the original plants (Srivatava and Srivatava, 2007). In addition, this type of culture is known to produce a spectrum of secondary metabolites that are not present in the parent plant (Reerasham, 2004). During the past two decades considerable efforts have been made to develop an economically feasible *in vitro* production of these compounds. Therefore, in this study the effect of influencing factor including, various explants age, different strains of *A. rhizogenes*, explants type, two inoculation methods and different culture media were investigated.

Materials and methods

Plant Material

Dormancy of seeds was broken by immersing them in 100 ppm GA_3 solution for 24 h. Seeds of *H. reticulatus* were surface-sterilized, Then they were cultured on semi solid hormone-free MS (Murashige and Skoog, 1962) medium and incubated at 25±2°C for a photoperiod of 16 h light.

Bacterial strain

Mono clone of four *A. rhizogenes* strains (A7, 15834, A13 and D7) was grown for 24 h in liquid LB medium with rifampicin 0.50 g/L antibiotic (Sigma Chemical Co.) At 28^{o}C with shaking (180 rpm) in liquid LB medium, to mid-log phase (OD600 = 0.5).

Establishment of hairy root cultures

Leaves of *H. reticulatus* obtained from *in vitro* grown plants at three old types explants (one week old, two weeks old, four weeks old leaf). Excised leaves were dipped into four *A. rhizogenes* strains (A7, 15834, A13 and D7) cultures in liquid inoculation medium for 1 min, blotted dry on sterile filter paper, and incubated in the dark at 25°C on agar-solidified MS medium. After 2 days of co-cultivation, the explant tissues were transferred to a hormone-free medium containing MS salts and vitamins, 30 g/l sucrose, 500 mg/l cefotaxime, and 8 g/l agar. Numerous hairy roots were observed emerging from the wound sites of explants within 10 days.

The hairy roots were separated from the explant tissue and subcultured in the dark at 28°C on agar-solidified MS medium.

Inoculation methods

Leaves obtained from cotyledon explant *in vitro* grown plants were infected by bacterial strain A7 and the effects of two inoculation methods (immersion and injection) were tested. In immersion method explants were pricked with sterile needle dipped in bacterial suspension for 1 min and in injection method bacterial suspension were injected with excel (0/5 mM) to cotyledon explants.

Effect of different cultivation medium

Four commonly used standard plant cell cultivation media viz. MS, B5, 1/2MS, and 1/4MS (Gamborg *et al*., 1968) were tested for their effect on growth and antioxidant activity in hairy root cultures of *H. reticulatus*. The hairy root culture from selected root line was initiated by transferring fresh hairy roots equivalent to 1 g into 250 ml Erlenmeyer flask containing 30 ml of liquid B5 medium. The cultures were incubated on a incubator shaker at 1000 rpm and 28°C. The flasks were harvested after 21 days to analyze DW and antioxidant activity content.

PCR analysis of hairy roots

Genomic DNA was extracted using CTAB method (Khan *et al*., 2007) from each of the hairy root lines as well as from control roots. PCR primers specific for the amplification of the 780 bp fragment of the *rol* B gene were used.

Extraction of alkaloids and GC/MS analysis of hyoscyamine and scopolamine

One gram of dried and powdered roots of *H. reticulatus* was extracted with methanol in a Soxhlet apparatus for 130 min. Then 1 μL of extract was directly injected into the GC/MS. The results were obtained as the mean of 3 separate injections. Antioxidant activity analyses were performed by (Chiuo *et al*., 2007) method.

Results and discussion

Effect of different *A. rhizogenes* strains on hairy root induction

The resulted indicated that interaction effect *A. rhizogenes* strains and explants age were significantly effect on time period requirement for hairy root induction and transformation frequency. All A7, 15834, A13 and D7 strains of *A. rhizogenes* used in this study were able to produce hairy roots at the explants infection site (Figure 1). The highest infection frequency (76/22%) found in A7 strain and one week old explants. The lowest infection frequency (14%) was observed in D7 strain and four weeks old explants. Efficiency of transformation is known to differ with different bacterial strains (Dogan *et al*., 2011). Different strains of *A. rhizogenes*

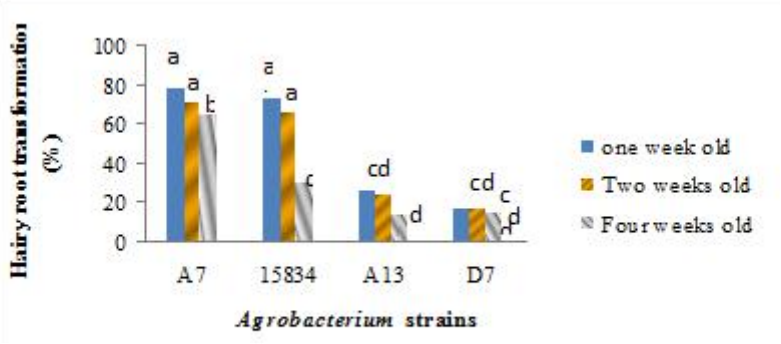

Figure 1. Effect of different strains of *A. rhizogenes* on hairy root induction

Produce different types of opine (Isogai *et al*., 1990). Soil-borne pathogens of genus *Agrobacterium* are able to transfer part of their DNA, the T-DNA carried on a large plasmid, to the genome of a host plant cell. Furthermore, explant age is also an important factor that affects on hairy root induction and growth (Vergauwe *et al*., 1998).

Effect of explants type

Among the different explants tested (Cotyledon, Hypocotyl, two weeks old leaf, two weeks old internode, four weeks old leaf, four weeks old internode) cotyledon explants induced hairy roots at greater percentage (77/66%) whereas the four weeks old internodes segments were less than other explants comparatively (Figure 2). Juvenility and nature of explant influence the *Agrobacterium* mediated transformation process (Trypsteen *et al*., 1991). Nin *et al* (1997) have reported that specificity of *Agrobacterium* transformation is closely connected with the age and hormonal balance of the host tissue. It is quite evident that different explants vary in their wound response, that is, produce the number of competent cells for transformation.

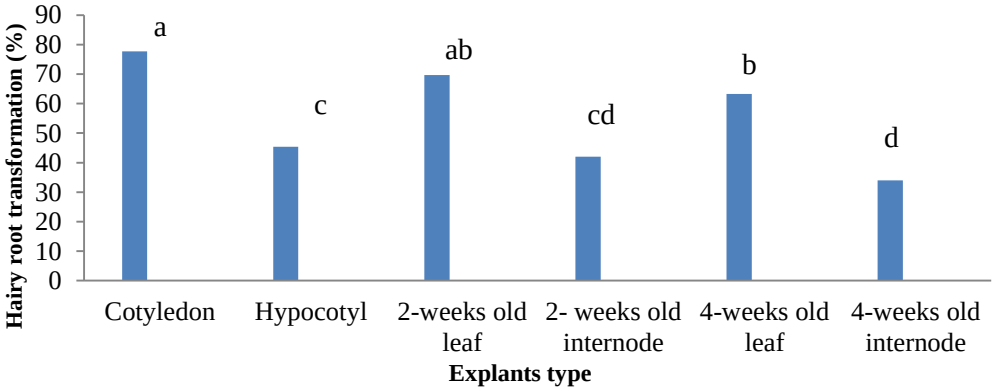

Figure 2. Effects of explants type on transformation frequency.

Effect of different *A. rhizogenes* strains on time period for hairy root induction

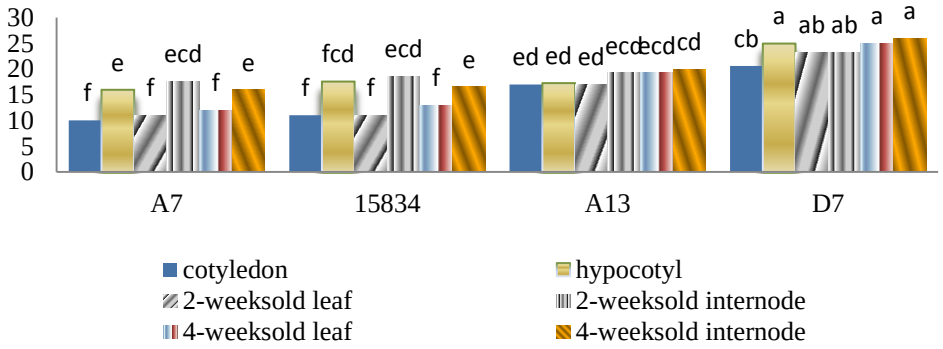

Figure 3. Effect of different strains of *Agrobacterium rhizogenes* and explants type on hairy root appearance

Hairy roots grow rapidly, show plagiotropic growth, and are highly branched on phytohormone free medium. The resulted that hairy roots were induced 10 days after infection with A7 strain and cotyledon explants (Figure 3). The growth rates of transformed roots are known to vary greatly between species, but differences are also observed between different root clones of the same species (Mano *et al*., 1989).

Effect of different cultivation medium

Medium types (MS and B5) and strength (full strength and half strength) displayed significant effect on both fresh and dry weight of *H. reticulatus* hairy roots. B5 and MS medium detected as the best medium for the growth of hairy roots. Fresh and dry weight of hairy roots grown in B5 medium were significantly higher (0.32 gr) than other medium after 21 days (Figure 5).
Media manipulations have been reported to aid in the release of metabolites. Betacyanin release from hairy roots of *Beta vulgaris* was achieved by oxygen starvation (Boitel *et al*., 1996). As the medium strength decreased to half strength, solasodine level in *Solanum mauritianum* hairy roots was lowered but ajmaline and ajmalicine levels in *Pauvolfia micrantha* were increased (Sudha *et al*., 2003).

Molecular identification and quantification of hyoscyamine and scopolamine

PCR results with specific primers showed that all the hairy root lines contained *rolB* gene which was a part of Ri plasmid T-DNA in *A. rhizogenes* (Figure 7).

GC/MS analysis

Hyoscyamine (2/6 fold) and scopolamine (7/56 fold) content were increased significantly in Transgenic roots compared with non transgenic roots (Table 3). Transgenic roots can increase the activation of enzymatic pathways that contribute to the production of secondary metabolites, hence, scopolamine increase in hairy roots, can be due to increase in Hyoscyamine-6-hydroxylase enzyme activity that convert hyoscyamine to scopolamine (Dehgan *et al*., 2012) These results suggest that hairy roots can be used as a new powerful pathway to increase the yield of secondary metabolites in plant biotechnology.

Abstract

This experiment was done as split plot based on randomized complete block design with three replications in Piranshahr-Iran, during growing season of 2011- 2012, to determine the effect of farm slopes on yield and some agronomic traits of wheat under different fertilizer sources. Treatments consisted of farm slope at four levels: (0, 3, 6 and 10 percent) as the main plots and combination of different fertilizer at five levels: [control, application of biofertiliozer (Nitroxin), manure, chemicals (N and P] and integration of biological, manure and chemical as sub plots. Results showed that with rising of farm slope, a significant decrease revealed in the spikelet per spike, number of grains per spike, 1000-grain weight, wheat straw yield, biomass and grain yield. In fact, with increasing the farm slope, the yield components decreased which lead to 52 and 38 percent reduction in grain yield and total biomass of plants located on a slope of 10 percent than the control plants. The applications of integrated fertilizer treatments had the most effect on morphological traits and yield components of wheat that increased 12.58 and 13.58 percent the grain yield and total biomass compared to the control plants. Generally, integrated fertilizer treatments that reduced half of chemical fertilizers application, recommended to development of ecological agriculture in the wheat fields.

Keywords: *Biofertilizer, Integrated nutrition, Manure, Morphological traits, Yield component*

Introduction

The most important issue that is critical to the food security of the world population is food supply such as wheat that increasing its production has been emphasized. Increasing wheat production through the development of acreage due to constraints of resources are impossible, but the only reasonable approach is trying to improve the yield per area.

The crop yield affected by various factors, which is one of the most important, is farm topography (Kravchenko and Bullock, 2000). Land topography effected soil physicochemical characteristics of the soil via erosion (Ebeid *et al.*, 1995), a change in soil organic matter (Kravchenko and Bullock, 2000), the amount of water available in the soil (Verity and Anderson, 1990) and the nutrients. The characteristic of topography in agriculture is important factor in the performance of agricultural products due to a direct effect on the microclimate, soil properties such as temperature and soil moisture (Godwin and Miller, 2003). Farm slope is one of the most important indicators that has a major impact on the nutrient balance and hence reduce soil fertility.

Quantitative and qualitative characteristics of crops are affected by nutrient (Tanaka *et al*., 1997). Supply of nutrients such as nitrogen through the use of chemical fertilizers in the farm with slope, which are prone to washing, is one of the main reasons for pollution of the water cycle in ecosystem. So, replacing it with organic and biological fertilizers plays an important role in the environmental health (Chandrasekar *et al*., 2005).

integrated use of chemical fertilizers and organic fertilizers such as manure and biological fertilizers that called integrated management of nutrient, improve soil fertility and biological

activity of the soil physical properties (Berecz *et al*., 2005) and thus may be more effective than using either of them alone (Montemurro, 2009).
As regards to the most of farm under wheat cultivation in the world has slope, so understanding how the reaction of wheat growth characteristics with changes in the slope of the land is important.
The aim of this study was to evaluate the response of wheat in relation to the slope and use of different sources of fertilizer.

Materials and methods

This field experiments were performed in the research field of Piranshahr, Iran (36°67′ N, 45°21′ E, altitude 1460 m, West Azarbaijan Province) during growing season of 2011- 2012. Some physicochemical characteristics of soil, based on farm slope treatment were given in Table 1.
Treatments were farm slope at four levels: (zero, 3, 6 and 10 %) as main plots and combination of different fertilizer at five levels: (control, application of biofertiliozer (Nitroxin), manure, chemical (N and P) and Integrated (biological +manure +chemical) were considered as sub plots.

There was farm slope as naturally and farm slope determined using the leveling model DSZ-2. The chemical fertilizer were used according to soil physicochemical properties (Table 1) at 100, 120, 140 and 160 kg/ha of urea and 80, 100, 120 and 140 kg/ha triple super phosphate, respectively in plots with a slope of zero, 3, 6 and 10%. Half of urea fertilizer was used at planting and the rest used at stem elongation. In the manure treatment, 10, 15, 20 and 25 t/ha cow manure were used, for farm slopes from zero to 10 percent, respectively. Nitroxin that include *Azotobacter chorococum, Azospirillum lipoferoum* was used as bio-fertilizer treatment.
In the plots with integrated fertilizer treatment, a combination half of the amounts mentioned of chemical fertilizers, manure and biofertilize were used respectively, in plots with a slope of zero, 3, 6 and 10 percent. Totally, there were 20 experimental treatments, 60 experimental plots, and each plot set as ten rows (30 cm inter) with 400 cm long.

Seeds of *Triticum aestivum* L. *cv*. Zarin were sown in December 2011. Environmental conditions of the experimental site, including the highest and lowest temperature, humidity and rainfall, during the study are shown in Table 2.
At plant maturity, the number of spikelets per spike, grains per spike, grain weight, the weight of straw, biomass and grain yield were measured. All measurements in each plot, after the elimination of margins (two rows of both sides and 50 cm from the beginning and the end of rows), was done at the middle row randomly. Analysis of the data was done using SAS software. For mean comparison SNK method was used at the level of five percent.

Results and discussion

Results showed that number of spikelet’s per spike, grains per spike, 1000-grain weight, straw yield, biomass and grain yield of wheat plants affected by treatments and have significant differences compared to mean control value (Table 3).

Table 3. Variance analysis of various traits of wheat under different fertilizer systems and farm slope

Source of Variation	df	Mean square					
		Spikelet’s in spike	Grains in spike	1000-grain weigh	Straw yield	Biomass	grain yield

ns: Non significant, * and **: significant at 0.05 and 0.01 probability level, respectively.

By increasing the slope of the farm, reducing the number of spikelets per spike was observed. So, the highest number of spikelet’s per spike (18.5) and the lowest number (13.5) of it, were observed in plants located in zero and 10% farm slope, respectively (Table 4). In the farm that has high slope, washing minerals and lower soil water holding capacity, leading to a reduction in the growth and development of plants (Kravchenko and Bullock, 2000).

In fertilizer treatments, also the highest number of spikelets per spike (17.6) was observed in the plants that treated with integrated fertilizer that show the role of nutrients diversity in growth and development of plants (Table 5).

Table 4. Mean comparison of wheat traits at different farm slope

Farm slope (%)	Spikelet’s in spike	Grains no. in spike	1000-grain weigh (g)	Straw yield (t/ha)	Biomass (t/ha)	grain yield (t/ha)
0	18.5^{a}	53.15^{a}	47.2^{a}	11.14^{a}	18.8^{a}	7.67^{a}
3	17.1^{b}	45.31^{b}	46.63^{b}	9.88^{b}	16.4^{b}	6.55^{a}
6	15.3^{c}	36.64^{c}	44^{c}	9.13^{c}	14^{c}	4.88^{b}
10	13.5^{d}	28.78^{d}	42.4^{d}	7.88^{d}	11.5^{d}	3.68^{b}

Similar letters in each column indicated no significant difference at 5 % level of probability.

The maximum number of grains per spike (53.1 grain) was obtained in plants located on the slope of zero and the lowest number of grains (28.8 seed) belongs to the wheat plants in 10% of farm slope. As well as, the highest number of grains per spike (48.6) observed in use of integrated fertilizer treatment (Table 5). In fact, the number of grains per spike in the wheat plants that treated with chemical, manure and biofertilizer treatments showed no statistically differences with each other and were in one group (Table 5). Chemical fertilizers and

livestock manure treatment in combination with biological have a rich source of macro and micro nutrients, and use of them in the soil with regards to the gradual release of nutrients, stimulates microbial activity in soil leading to increases plant growth conditions (Ahmad *et al.*, 2007).

Table 5. Mean comparison of wheat traits under different fertilizer treatment

Fertilize treatment	Spikelet's in spike	Grains no. in spike	1000-grain weigh (g)	Straw yield (t/ha)	Biomass (t/ha)	grain yield (t/ha)
Chemical	16.9[a]	44.8[b]	45.8[a]	10.13[a]	16.1[a]	5.94[a]
Bio fertilizer	15.7[b]	37.5[c]	44.5[bc]	9.06[ab]	14.4[c]	5.36[b]
Manure	15.7[b]	38.53[c]	44.7[b]	9.49[a]	15.1[b]	5.67[ab]
Integrated	17.6[a]	48.58[a]	46.2[a]	10.2[a]	16.2[a]	6.12[a]
No fertilizer	14.8[b]	35.39[c]	43.8[c]	8.66[c]	14[c]	5.35[b]

Similar letters in each column indicated no significant difference at 5 % level of probability.

1000-grain weigh of wheat plants that growth from zero to 10% of farm slope, shows a significant decline (Table 4). Also the highest 1000-grain weigh (46.2 g) was obtained in wheat treated with integrated fertilizer, which increased 5.19 % the 1000-grain weigh of wheat in comparison with control plants (Table 5).

Wheat straw yield was also significantly affected by the experimental treatments (Table 3). The lowest (7.88 t/ha) and the highest (11.14 t/ha) of wheat straw yield was belong to the plants located in 10 and zero percent of farm slope, respectively (Table 4). Increase of farm slope from zero to 10% cause to decrease 29% by weight of straw (Table 4). Results showed that the maximum of wheat straw yield was obtained in wheat plants that treated with integrated fertilizer treatment (Table 5).

The results of the mean comparison showed that the highest biomass of wheat (18.8 t/ha) was belong to the plants at zero slope of the farm and the lowest value (11.5 t/ha) was related to the 10% of farm slope (Table 4). In the fertilizer treatment the highest of wheat biomass was obtained in plants that treated with integrated and chemical fertilizer (Table 5). In fact combined use of bio-fertilizers with manure and chemical fertilizer cause to improve the efficiency of fertilizer by leading to increase of morphological traits and yield components of wheat and thus increase plant biomass (Table 5).

The highest (7.67 t/ha) lowest (3.68 t/ha) of wheat yield were observed in plants at the zero and 10 % of farm slope, respectively (table 4). Therefore, increasing slope from zero to 10% cause to decreasing 52% of the wheat yield (Table 4). The microclimate conditions and physiochemical characteristics of soil in different farm slopes cause increasing wheat yield from zero to 10% of farm slope (Godwin and Miller, 2003).

Wheat plants that treated with integrated fertilizer had the highest seed yield (6.12 t/ ha) and the lowest of wheat yield (5.35 t/ha) obtained from control plants (Table 5). Integrated fertilizer system that includes component of chemical fertilizer, manure and biofertilizer, through positive effects on biochemical reactions, photosynthesis, increasing during the plant growth, shoot dry matter accumulation and yield components cause to increasing the wheat yield (Pilbeam *et al.*, 1997).

Conclusion

The results obtained from this study showed that with increasing in farm slope (from zero to 10%), the wheat yield components such as number of spikelet's, number of grains per spike and 1000-grain weight decreased that leads to a reduction of 52, 38 and 29 percent of grain yield, biomass and straw yield, respectively. Also the highest value of yield and yield components of wheat were obtained in wheat plants that treated with integrated fertilizer system. Thus, the integrated fertilizer treatments with reduced use of chemical fertilizer, recommended to the development of ecological and sustainable agriculture in the wheat fields.

EFFECT OF ACHENES PRE-HYDRATION IN SOLUTION OF SILICA NANOPARTICLES ON EARLY GROWTH PERFORMANCE OF SUNFLOWER (Helianthus annuus L.)

Mohsen JANMOHAMMADI*, Naser SABAGHNIA

Department of Agronomy and Plant Breeding, Agriculture College, University of Maragheh, Iran

Abstract

Seed germination and early seedling growth are the most important stages of plant development. Fast seed germination, stand establishment and uniform field emergence are critical factors to crop production and are essential to achieve optimum performance. Controlled imbibition of seed followed by dehydration could be applied for reducing the time from sowing to seedling establishment and improving germination rate. In present study the effect of pre-germination hydration of sunflower seeds in solutions containing different concentrations of nano-silica (0, 0.2, 0.4, 0.6, 0.8, 1 and 1.2 mM for 8 h) on germination characteristics were investigated. Seed pre- sowing treatment in low concentration of silica nanoparticles (0.2 and 0.4 mM) reduced days to 50% germination and mean germination time and improved germination energy, root length, mean daily germination, germination rate, seedling vigor index, promptness index and final germination percentage. The results of the present experiment agreed with the conclusion that pre-sowing seed treatments with low concentration of nanosilica had favourable effect on sunflower seed germination and seedling early growth. The findings are noteworthy in terms of utilization of suitable concentration nanoparticles as an efficient seed vigour enhancement treatment to improve seedling growth under environmental conditions.

Keywords: *nanosized, silicon oxide, seed priming, germination rate, seedling vigor*

Introduction

Nowadays it has become important to increase crop production to feed the growing world population. To meet this increasing demand, researchers are trying to develop an efficient and ecofriendly production technology based on the innovative techniques to increase seedling vigour and plant establishment through physical seed treatments. Seed germination is an important phenomenon in modern agriculture because it is a thread of life of plants that guarantee its survival.

Poor crop establishment was identified as a major constraint on rainfed crop production (Harris et al., 1999). In this context, it seems that seed priming as one of the seed invigoration strategies would improve seed germination, plant growth, and crop yield. Pre-sowing seed treatments or seed priming performed by various approaches and methods enhances pre- and post-germination activities. Priming is adjusting the hydration level within seeds to permit seedlings to emerge more rapidly and to facilitate the uniform seedling stand (Basra et al., 2006). The main principle of pre-sowing seed treatments is controlled hydration of seed to a point where germination processes are started but not fulfilled. Most priming treatments involve imbibing seed with constrained amounts of water to allow adequate hydration and progress of biochemical processes but hindering the protuberance of the radicle (Ashraf and Foolad, 2005). In respect of the pre-sowing seed treatments effect Wahid et al. (2008) concluded that priming of sunflower achenes with hydrogen peroxide (H_2O_2), salicylic acid (SA), thiourea (TU), gibberellic acid (GA_3) was the best for vigor enhancement compared with other salts and simple hardening.

In semi-arid rainfed areas, particularly in the dominant Mediterranean-type climate, early sowing, rapid seedling establishment and vigorous development could considerably hasten plant growth and may avoid the facing of crucial stages with terminal drought and high temperature stress (Janmohammadi et al., 2013). In recent years, the progress of nanotechnology in combination with biotechnology has appreciably increased the utilization domain of nanomaterials in agriculture fields. Previous studies showed the potential of nanomaterials in improving seed germination and seedling early growth (Zheng et al., 2005; Siddiqui and Al-whaibi, 2014; Sabaghnia and Janmohammadi, 2014). However, the interaction mechanisms at the molecular level between nanoparticles and biological systems are largely unknown. Also, a thorough understanding of the role of nano-sized engineered materials on plant physiology at the molecular level is still lacking. Agricultural utilization of nanoparticles is currently an attractive area of interest. Nanoparticles can easily enter into plant system by overcoming the cell wall barrier in comparison with bulk materials. They have achieved greater consideration because of their highly reactive surface-to-volume ratio property. The recent advances in nanotechnology and its use in the field of agriculture are astonishingly increasing; therefore, it is tempting to understand the role of nanosilicon dioxide ($nSiO_2$) in the germination of seeds.

The purpose of this investigation was to evaluate the effect of seed priming in nanosilica solution on seed germination performance of sunflower to find out the most promising concentration.

Materials and methods

Pre-hydration treatments were including control (non primed seeds) and achenes soaking in solutions containing different concentrations of nano-silica (0.2, 0.4, 0.6, 0.8, 1 and 1.2 mM for 8 h). Achenes of sunflower (*Helianthus annuus* L., cv. Azargol) were used in this experiment. Nanoparticle of silica (SiO_2) was purchased from the Pishgaman Nano, Iran. According to the manufacturer, the particle sizes of SiO_2 ranged from 20 to 30 nm. Specific surface area of nanosized silica was 180-600 m^2 g^{-1} and purity was 99.7%. The result of X-ray analysis of nano silicon dioxide is displayed in figure 1. The high-resolution transmission electron microscopy (HRTEM) image of the nanoparticle sample is shown in figure 2. Mean germination time (MGT) was computed according to Ellis and Roberts (1981) as MGT=Σ*T*i Ni/ΣN*i*, where N*i* is the number of newly germinated seeds at time T*i*. Germination index was calculated as follows: $GI = \Sigma (G_t/T_t)$, where G_t is the number of seeds germinated on day t and T_t is the number of days from beginning of germination test (Hu et al., 2005). The seed lot having greater germination index is considered to be more vigorous.

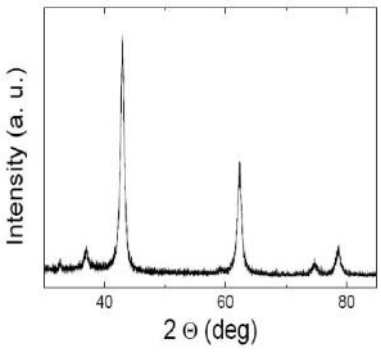

Figure 1. X-Ray diffraction pattern of nano-silicon dioxide particles.

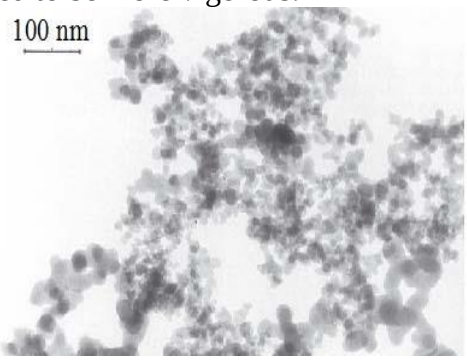

Figure 2. Large area TEM image of silica nanoparticles.

Mean daily germination (MDG), calculated as the cumulative percentage of full seed germination at the end of the test, divided by the number of days from sowing to the end of

the test. The time to 50% germination (T_{50}) was calculated according to the following formula of Farooq et al. (2005). Seedling vigor index based on the length (SVIL) was calculated following modified formula of Ranal and Santana, (2006). Energy of germination (EG) was calculated four day after start of the experiment. It is the percentage of germinating seeds 4 days after planting relative to the total number of seeds tested (Ruan et al., 2002). Promptness index was calculated according to Ashraf et al. (2006). Data were subjected to analysis of variance (ANOVA) procedures (SAS Institute Inc., 1988), and LSD test was applied at 5% probability level to compare the differences among treatment means.

Results and discussions

Germination index (GI) is suitable indicator for comparisons of germination times. Statistical analysis showed that achene pre-hydration in nanosilica solution could considerably affect the GI. The highest value of this trait was recorded in achenes primed with 0.2 Mm nanosilica solution. However priming in higher concentration of nanosilica could not improve this parameter and even achenes primed at 1.0 Mm concentration showed the lowest value of GI (Table 1). Assessment of mean germination time (MGT) revealed that achene priming with 0.2, 0.4 and 0.8 mM nanosilica solutions could appreciably reduce the MGT as compared to intact achenes. However the highest value of MGT was related to priming at 1.0 Mm concentration. This trend also was recognizable by examining the T_{50} and promptness index (PI). Data with respect to the PI clearly show that PI increased by priming in solution with upto 0.6 Mm concentration of nano SiO_2 and decreased significantly in 0.8 Mm concentration of nano SiO_2 as compared to control. A significant ($P<0.01$) effect of achene pre-hydration treatments was seen on the final germination percentage (GP). Mean compression revealed that pre-hydration in solutions containing 0.2, 0.4 and 0.6 Mm nanosilica cause a slight increase in final germinal percentage, while high concentrations of nanosilica noticeably reduced the germination percentage (Table 1).

GP: germination percentage, MDG: mean daily germination, GI: germination index, MGT: mean germination time, T_{50}: days to 50% germination, GR: germination rate, EG: energy of germination, PI: promptness index. In a column figures with same letter (s) or without letter (s) do not differ significantly whereas figures with dissimilar letter are statistically different. * = Significant at 5% level of probability, ** = Significant at 1% level of probability.

Evolution of mean daily germination (MDG) showed that priming treatments have significant effect on this trait. The response of MDG against pre-hydration treatments was relatively similar to GP so and the best performance was recorded for achenes pre-hydrated in solutions with low concentrations of nanosilica. Generally achenes primed in low concentration of nanosilica solution could finish their germination in a closer spread of times. The contrary trend was observed for germination rate (Table 1). Variance analysis showed a significant effect of priming treatments on energy of germination (EG). Mean comparison revealed that

priming of achenes in high concentration of nano SiO_2 reduced the EG compared with control achenes (Table 1).

RL: root length, SL: shoot length, SDW: shoot dry weight (mg), RDW: root dry weight (mg), SVIL: seedling vigor index based on length, SVIW: seedling vigor index based on weight. In a column figures with same letter (s) or without letter (s) do not differ significantly whereas figures with dissimilar letter are statistically different. * = Significant at 5% level of probability, ** = Significant at 1% level of probability.

Results showed that pre-hydration treatment of achenes before germination significantly influenced performance of seedling growth by improving root length, shoot length, shoot dry weight, root dry weight and seedling vigour index (Table 2). Investigation of root length indicated that achene priming in solution with low concentration of nano silica could create the longest roots. However the shortest roots were related to un-primed and primed achenes in solution with high concentration of nano silica (Table 2). Also a significant ($P<0.05$) effect of achene pre-hydration treatments was seen on the shoot length and response trend was similar to status described for root length. Shoot dry weight (SDW) was significantly affected by priming treatments ($P<0.01$). Increasing nano silica concentration resulted in a decrease of SDW (Table 2). However, evaluation of root dry weight (RDW) indicated that significant differences were only recorded for achenes primed in low concentration of nano silica (0.2 and 0.4 mM). Mean comparison of both seedling vigor index suggested that the best performance was related to achenes primed in 0.2 mM solution of nano silica. This status was more evident in SVIL.

Results showed that achenes priming in high concentration of nano silica solution resulted in decreased germination, the present findings seem to be consistent with other research which found that the beneficial influences of the $nSiO_2$ are more pronounced at low concentrations (Sabaghnia and Janmohammadi, 2014; Haghighi et al., 2012). The faster and synchronized germination might be attributed to enhanced metabolic activities in the primed achenes (Wahid et al., 2008). Pre-hydration treatments not only improved the germination rate and time but also enhanced the seedling vigour as indicated by higher values of SVIL, SVIW, root and shoot length and seedling fresh and dry weights.

In semi arid region adverse abiotic stresses, such as high temperatures, soil crusting and shortage of water can reduce the rate or entirely hinder seed germination and seedling emergence in late spring and early summer. In this respect, the application beneficial nano particles for pre-sowing treatments and utilization of seeds with enhanced vigor can be a practicable strategy to obtain healthy seedlings and a better crop stand under unfavorable environmental condition.

Conclusion

Applications of nano-particles can help faster plant germination/production, effective plant protection with reduced environmental impact as opposed to traditional approaches.In conclusion, current results of the reveal that the utilization of nano silicon in germination medium significantly enhanced seed germination potential. However, in order to recognize the possible benefits of applying nano-materials in agriculture, it is important to analyze penetration and transport of nano-particles in the embryo and seedling. Furthermore, the current study invites researchers to evaluate the molecular mechanism involved in invigoration of seed germination after treatments by nano silicon which establishes that nano silicon could be used as a seed coating material or fertilizer for the crop improvement.

Abstract

Crop drought tolerance issue is one of the most challenging objectives of agronomy and plant breeding investigations. Developing an efficient screening technology and identifying the most important traits contributing toward drought tolerance are major steps in this direction. To go in this quest, an experiment was conducted with seven Kabuli chickpea genotypes were grown under three humidity regimes including (i) rain-fed condition, (ii) full irrigation and (iii) rain-fed condition with two supplement irrigations during flowering and grain filling stages. Analysis of variance indicated significant differences among seven chickpea genotypes for the measured traits. Results revealed that plant height, primary and secondary branches, chlorophyll content, day to maturity, grain yield and yield components were significant. However, there was no significant difference for number of pods per plant, number of seeds per pod, 100-grain weight, grain yield per unit area and grain filling rate. Based on the YP drought tolerance index, genotypes FLIP 03-64C and Azad had the highest yield under non-stressed condition, while genotypes FLIP 98-106C and Azad displayed the highest yield under stressed condition. The relationships among drought tolerance indices are graphically displayed in a plot of two first principal components analysis. Genotypes FLIP 98-106C and Azad are good candidates for commercial recommendation to farmers in both rain-fed and irrigated conditions. Principal component analysis indicated that relative water content, photochemical efficiency of photosystem II, and stomatal conductance were the physiological traits with greater contribution toward drought tolerance and should be evaluated ahead of many other traits in making selections for drought-tolerant chickpea genotypes.

Key words: *drought; genotype; grain yield; rain-fed conditions*

Introduction

Chickpea (*Cicer arietinum* L.) is one of the most important cool season pulse crops of dry lands in the world and produced on 700,000 hectares in Iran and ranks fourth in the world after India, Turkey and Pakistan (FAO, 2014). For a wide range of environmental conditions, it is also an alternative pulse crop for increasing the diversification of different cropping systems (Zdemur and Karadavut, 2003). Chickpea yield affected by biotic stresses is quite low, and yield is below its potential. It is traditionally grown as a rain-fed crop on stored soil moisture and this makes terminal drought stress as a primary constraint to productivity. It covers 15% of the cultivated area and contributes to 14% of the world's pulse harvest (FAO, 2014). Besides being an important source of human and animal food, chickpea also plays an important role in the maintenance of soil fertility, particularly in the dry, rain-fed areas.

Irrigated agriculture is the primary user of diverted water globally, reaching a proportion that exceeds highly of the total in the arid and semi-arid areas. The rain-fed agriculture accounts most of the world's farmland and two-thirds of global food production. When water supplies are limited, the farmer's goal should be to maximize net income per unit water used rather than per land unit (Fan et al. 2005). Drought stress is one of the most common adverse environments, which limits crop production in arid and semi-arid areas. It is usually

accompanied by high temperatures, which promote evaportranspiration and hence could accentuate the effects of drought stress (Toker and Cagirgan, 1998). Most crops adapt to drought conditions either through escape, avoidance, or tolerance mechanisms.
Most of chickpea production quantity is done in marginal regions in the spring, and due to lack of rainfall during sensitive periods, terminal drought stress is the major environmental stress for reducing chickpea production in Iran (Sabaghpour et al. 2006). Selection for drought tolerant chickpea genotypes is the most important objective for breeding to drought stress. Breeding for drought tolerance is involved by the lack of fast, screening tools and the inability to create water stress conditions when a large amount of genotypes are to be evaluated. Gain a genetic improvement of seed yield performance under water stressed conditions has been proved to be a difficult task for chickpea breeders while progress in yield performance potential has been much higher in normal condition (Richards et al. 2002).
Stress resistance indices, which provide a measure of drought based on loss of yield under stressed conditions, have been used for screening tolerant genotypes. The genotypes performance under drought stressed and normal conditions seems to be a common starting point in the identification of traits related to drought tolerant and the selection of genotypes for breeding efforts. The stress susceptibility index (SSI; Fischer and Maurer, 1978), the mean productivity (MP; Rosielle and Hamblin, 1981) and tolerance (TOL; Rosielle and Hamblin, 1981), the yield stability index (YSI; Bouslama and Schapaugh, 1984), the superiority index (PI; Lin and Binns 1988), the stress tolerance index (STI; Fernandez, 1992), geometric mean productivity (GMP; Fernandez, 1992), yield index (YI; Gavuzzi et al. 1997), and relative reduction (RR; Sadiki 2006) were proposed to screening drought tolerant genotypes. The objectives of the investigation were to identify drought tolerant genotype(s) of chickpea under rainfed conditions in the semi-arid condition as well as study interrelationships among the resistance indices.

Materials and methods

Seven chickpea genotypes (five newly improved genotypes from International Center for Agricultural Research in the Dry Areas - ICARDA) and two checks cultivars (Arman and Azad from Iran) were used. The experimental fields was ploughed once in early fall and harrowed twice, one week before planting. The experimental design was spilit-plot on the bases of randomized complete block in three replicates. Main plot factor was water regimes (zero irrigation and regular irrigation with irrigation to fill the root zone profile) and sub-plot factor seven chickpea cultivars. Seeds were hand sown on 17 March 2012 in 4 cm depth of soil. In each plot, seeds were sown into 16 rows, at 25-cm row-to-row spacing and 8-cm plant-to-plant spacing. Weeding was done manually. All necessary cultural practices and plant protection measures were followed uniformly for all the plots during the entire period of experimentation. These statistical parameters were calculated:

$$SSI = [1-(Ys/Yp)]/[1-(\bar{Y}s/\bar{Y}p)]$$
$$MP = (Ys+Yp)/2$$
$$TOL = (Yp-Ys)$$
$$YSI = Ys/Yp$$
$$STI = (Yp \times Ys)/Yp^2$$
$$GMP = \sqrt{(Ys+Yp)}$$
$$HM = [2(Yp \times Ys)]/(Yp+Ys)$$
$$YI = Ys/\bar{Y}s$$
$$RR = (Yp-Ys)/Yp$$

where Yp was genotype yield in non-stress conditions; Ys, genotype yield in stress conditions; $\bar{Y}s$, mean yield of all genotypes in stress conditions; $\bar{Y}p$, mean yield of

all genotypes yield in non-stress conditions. The PI (Lin and Binns, 1988) was calculated according to the following formula:

$$Pi = \sum_{j=1}^{n} \frac{(X_{ij} - M_j)^2}{2n}$$

where n is the number of environments, Xij the seed yield of ith genotype in the jth environment and Mj is the yield of the genotype with maximum yield at environment j. Differences were compared by Least Significant Difference Test (LSD) at alpha 0.05. The experimental data were statistically analyzed for variance using the SAS 6.12 (SAS, 1996).

Results and discussion

Based on the SSI, genotypes G2, G3, G5, Arman and Azad were identified as drought tolerance genotypes in stressed condition; while genotypes G1 and G4 displayed the lowest amount of SSI (Table 1). According to MP, genotypes G3 and Azad were found drought tolerance genotypes in stressed condition and genotypes G1, G2, G4 and G5 were identified as drought susceptible ones in stressed condition. Based on the TOL, genotypes G2, G3, G5, Arman and Azad were identified as drought tolerance genotypes in stressed condition; while genotypes G1 and G4 showed the lowest amount of TOL. The genotype G4 was identified as semi-tolerance or semi-sensitive to drought stress conditions (Table 1). According to the stress tolerance index (STI), genotypes G3, Arman and Azad were identified as drought tolerance genotypes; while genotypes G1, G2, G4 and G5 showed the lowest amount of STI (Table 1). Based on the GMP, genotypes G3 and Azad were identified as drought tolerance genotypes in stressed condition while the other remained genotypes displayed the lowest amount of GMP (Table 1). Mevlut and Sait (2011) showed that genotypes with high STI values usually have high difference in yield in two different humidity conditions. They reported relatively similar ranks for the genotypes were observed by GMP and MP parameters as well as STI, which suggests that these three parameters are equal for screening drought tolerant genotypes.

According to the harmonic mean (HM), genotypes G3 and Azad were identified as drought tolerance genotypes while the other remained genotypes showed the lowest amount of GMP (Table 1). The results of both GMP and HM indices were completely similar. It seems that this similarity is due to nature of their calculating formulas and so it is logical to use one of them in the future studies. Based on the YI index, genotypes G3 and Azad were identified as drought susceptible genotypes; while genotypes G2, G4, G5 and Arman showed the lowest amount of YI and were drought tolerance genotypes (Table 1). According to the PI index, genotypes G1, G4 and G5 were identified as drought susceptible genotypes; while genotypes G2, G3 and Arman showed the lowest amount of PI and were drought tolerance genotypes (Table 1). According to the YSI index, genotype G1 was identified as drought tolerance genotypes; while genotypes G2, G5 and Arman showed the lowest amount of YSI as drought tolerance genotypes (Table 1). Based on the RR index, genotypes G2, G5 and Arman were identified as drought tolerance genotypes in stressed condition while the genotype G1 displayed the lowest amount of RR (Table 1). According to the K_1STI index, genotypes G2, G3, Azad and Arman were identified as drought tolerance genotypes in stressed condition while the genotypes G1, G4 and G3 showed the lowest amount of K_1STI (Table 1).

Table 1. Mean yield performances of chickpea genotypes in non-stressed (YP) and stressed (YS) conditions and twelve drought resistance indices.

To better understand the relationships among the Stress tolerance indices, a principal component analysis (PCA) based on the rank correlation matrix was performed. The fitted PCA model indicated that, the first two PCAs explained 95% (59 and 35% for PCA1 and PCA2, respectively) of variation for stress tolerance indices. Considering high magnitude of explanation, the decomposition into PCAs would be useful to understand and explore the relationship among genotypes and indices. The relationships among the different statistics are graphically displayed in a biplot of PCA1 and PCA2 (Fig. 1). In this biplot, the PC1 axis mainly distinguishes the methods of RR and YSI from the other methods (we refer to these as Class 1 (C1) methods) and genotypes G3, G3 and G7 from the other genotypes. The second PCA axis separates YP, K1STI, TOL and SSI (we refer to these as Class 2 (C2) methods) from the PI, STI, MP, GMP, HM, K2STI, YI and YS (we refer to these as Class 3 (C3) methods). Mean yield under normal condition (YP) also groups near Class 2 methods, while mean yield under stressed condition (YS) groups near Class 3 methods. Also, genotypes G2 and G5 group near Class 2 methods and genotypes G1 and G4 group near Class 3 methods.

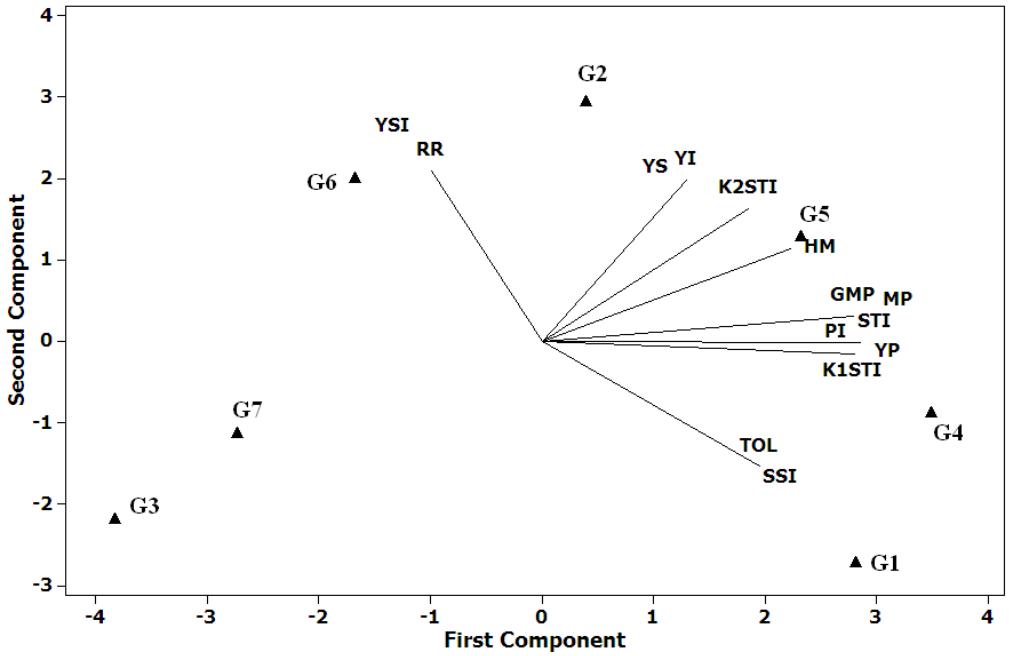

Fig. 1. BIPLOT based on PCA1 and PCA2 scores of drought tolerance indices and genotypes in chickpea.

Ehdaie and Shakiba (1996) found no correlation between stress susceptibility index and yield under optimum condition. The observed relationships in our chickpea genotypes were consistent with those reported by Golabadi et al. (2006) in durum wheat, Khalili et al, (2012) in canola. Several studies indicated that GMP, STI, PI and MP indices are preferred in late drought condition for selecting the most favorable genotypes (Sio-Se Mardeh et al. 2006; Akcura et al. 2011). The HM and K_2STI could be used for screening drought tolerant high yielding genotypes in the both conditions. Such similar conclusion is reported by Mohammadi et al. (2010). The mentioned parameters under level of high to moderate stress were correlated Akcura et al. (2011) with yield under both conditions. Also, they were able to differentiate genotypes belong to genotypes with high yield performance in both conditions, from the others.

Based on biplot of PCA, the indices of STI, K_1STI, MP, GMP, and PI exhibited strong correlation with YP, while YI showed strong correlation with YS, therefore, YS can discriminate drought tolerant genotypes with high grain yield under stress conditions. Also, K_2STI and HM exhibited relatively moderate association with both YP and YS, thus, they can discriminate drought tolerant genotypes with high grain yield at the same manner under stress and non-stress conditions.

Conclusion

Chickpea-sowing strategies vary with environment so as to fit the crop into the farming system and minimize exposure to the prevalent stresses. In semi arid region of Iran with Mediterranean climate Where is characterized by the lowest, most winter- dominant annual rainfall, and the highest summer temperatures management of the irrigation and selection of drought tolerant genotypes is very important. Although in these areas supplemental irrigation can ameliorate drought stress, screening drought tolerant cultivars using ranking method, three dimensional plots should not be ignored. Among different resistance and tolerance indices were evaluated STI, K_1STI, MP, GMP, and PI have high correlation with grain yield under stress and non-stress condition indicating more suitability of these indices for selection of resistant genotype. It is further concluded that genotype G3 and cultivar Azad have uniform superiority under both stress and irrigated conditions. The genotype G3 (1015 kg ha^{-1} at stressed conditions) besides cultivar Azad (940 kg ha^{-1} at stressed conditions) were found to be the most favorable genotypes and are thus recommended for farmers in arid and semi-arid areas of Iran.

PRODUCTION OF FLAVONOIDS IN HAIRY ROOT CULTURES OF TEUCRIUM POLIUM USING FUSARIUM GRAMINEARUM EXTRACT AS ELICITOR

Maryam KHEZRI, Morad JAFARI*, Reza DARVISHZADEH

Department of Plant Breeding and Biotechnology, Faculty of Agriculture, University of Urmia, P. O. Box 165, Urmia, Iran

Abstract

Teucrium polium L. is an important medicinal plant, which has been used for over thousands of years in traditional medicine. It possesses various medicinal properties such as antidiabetic and anticancer effects. The plant is rich in secondary metabolites, such as flavonoids and sesquiterpenes. Flavonoids have a wide distribution in plants and diverse biological activities including antioxidant, antimicrobial, anti-inflammatory effects. Secondary metabolites in plant cells are present in very small quantities. Hairy roots production a valuable system for studying secondary metabolites biosynthesis and production is large-scale drug compounds. Different biotechnological strategies such as elicitation are currently being for increasing metabolites biosynthesis in hairy root cultures. In this research, the effect of various concentrations (0, 0.5, 1, 1.5% v/v) of *Fusarium graminearum* extract (FE) on production flavonoids (FVs) was assayed. The elicitor was added to the hairy root cultures on day 28 and hairy roots were harvested 12 days after an exposure time of 48 h. FE at a concentration of 1% induced the highest increase of FVs (7.41 mg/g DW), which were 12.14-fold, higher than the level in non-elicited control. The enhancing effects of FE on FVs was correlated with increased activity of the enzyme phenylalanine ammonia-lyase (PAL), and the expression of *PAL* gene involved in the biosynthesis of this compounds. These results suggested potential on-demand production of in vitro FVs using elicitation in *T. polium* hairy root cultures.

Keywords: *Teucrium polium, elicitation, Fusarium graminearum, hairy root culture, flavonoid*

Introduction

Human being has used medicinal plants since ages in traditional medicine due to their therapeutic potential and the search on medicinal plants have led the discovery of novel drug candidates used against diverse diseases. *Teucrium polium* L. (known popularly as felty germander), belongs to the Lamiaceae family, is one of the wild-growing flowering herb native to Iran and the Middle East as part of the natural flora (Abdollahi et al., 2003). As a traditional remedy, *T. polium* is used for treatment of convulsion, headache, and digestive diseases in Iran (Baluchnejadmojarad et al., 2005). There are also some reports in the literature for antioxidant effects of crude extract of *T. polium* (Ljubuncic et al., 2006). Its antioxidant activity refers to the presence of flavonoids, iridioids, crisiols, volatile oils (Afifi et al., 2005).

Hairy roots produced by *Agrobacterium rhizogenes* infection are characterized by fast growth, biosynthetic stability, and ability to grow in hormone–free medium, all advantages that make transformed roots efficient sources for secondary metabolite production (Srivastava et al., 2007).

Secondary metabolite biosynthesis in plants depends on environmental stresses; precursors and elicitors can stimulate their accumulation. Elicitors are biological (components of microbial cells and poly- and oligosaccharides), chemical (heavy metals, pesticides, and the signaling compounds in plant defense responses), or physical (cold shock, UV, hyperosmotic stress, ultrasound, and pulsed electric field) factors that induce enzymatic activity against stress (Harsh et al. 2003). Use of fungal elicitors is an important way to enhance secondary

metabolites production in plant tissue cultures. These elicitors were utilized mainly in the form of living or autoclaved mycelia, crude extracts, peptides, proteins, and polysaccharides. Fungal elicitors have successfully stimulated production of many valuable bioactive compounds (Ming et al. 2013).
To the authors' knowledge, there were no previous reports about the effects of fungal elicitors on the growth and flavonoid production in *T. polium* hairy root cultures. Therefore, in this study we investigated the effect *of Fusarium oxyxperium* extract on flavonoid production in hairy root cultures of *T. polium*.

Materials and methods

Hairy root culture

The *T. polium* hairy roots used in this work were derived after infecting the leaf explants with a mikimopine type strain of *Agrobacterium rhizogenes* (A13). Stock cultures of the hairy roots were maintained on solid, hormone-free half-strength B5 medium with 7.5 g/l agar and 20 g/l sucrose, at 25 °C in the dark. All experiments were carried out in shake-flask cultures with 250 ml Erlenmeyer flasks on an orbital shaker set at 25 °C and 180 rpm.

Extract of mycelium preparation and induction

Fusarium graminearum extract (FE) was prepared as described by Esmaeilzadeh et al. (2011). For the elicitation treatment, 28-day-old hairy root cultures of the TP-HR-2 line were inoculated into 100-ml Erlenmeyer flasks containing 25 ml of liquid MS medium supplemented with various concentrations of FE (0, 0.5, 1, 1.5% v/v) at the exposure time of 48 h. The hairy root culture without FE treatment was used as a control. All cultures were incubated on an orbital shaker at 100 rpm in darkness at 25°C. At the end of the exposure time, the root cultures were cultured in a fresh medium and subjected to total flavonoid content analysis after 12 days of elicitation. Growth rate of elicitor-treated hairy root cultures was also determined in term of dry weight (DW, mg/30 ml culture medium). For DW measurement, the samples were lyophilized.

Determination of total flavonoid content

About 100 mg of dry hairy root sample powder was macerated with 2 ml of methanol and kept overnight at room temperature. The extract was collected after filtration using Whatman No.1 filter paper and was dried under reduced pressure at 40 °C using a rotary evaporator. Total flavonoid content was determined using the aluminum chloride colorimetric method (Chang et. al., 2002). Rutin was used for establishing the calibration curve. The total phenolic content was expressed as mg rutin equivalents per 100 g of DW.

Measurement *PAL* gene transcripts and phenylalanine ammonia lyase activity

Total RNA was isolated from the elicited hairy roots using RNeasy plant mini kit (Qiagen, Germany) according to manufacturer's instructions. RT-PCR was conducted using Titan One-Tube RT-PCR Kit (Roche applied science, Germany) according to the manufacturer's instructions. The primer pair used to amplify of the *PAL* gene was: 5′-GACGCTGCTGGGGCCTTCA-3′ (forward) and 5′-GGCGTCAAAAAGCACCATGGAG-3′ (reverse). For a semi-quantitative RT-PCR to quantify the relative transcript levels of target gene, the 18S rRNA transcript was amplified using primer pair 5′-TGTT

GGCCTTCGGGATCGGAGTA-3′ (forward) and 5′-GCTTTCGCAGTTGTTCGTCTTTCA-3′ (reverse). RT-PCR analysis was performed at least three replicates and relative quantification of expression level was calculated as the *PAL*/18S rRNA ratios using with Image J software (NIH).

The phenylalanine ammonia lyase (PAL) was extracted from the fresh hairy root of *F. tataricum* with borate buffer (pH 8.8). The PAL activity was determined based on the conversion of L-phenylalanine to cinnamic acid according to the published method of Wu et al. (2002).

Statistical analysis

All experiments were carried out in triplicate. The data were submitted to analysis of variance (one-way ANOVA) to detect significant differences by the Statistical Analysis System (SAS 9.1) programme package. The means were compared using Duncan's multiple rage test (DMRT) at the 5% probability level.

Results and discussion

Effect of FE on growth and flavonoid production

The time course of FE-treated hairy root growth was evaluated to determine the exact time of elicitor treatment. The kinetics of hairy root growth exhibited a slow growth period in the first week, a rapid, linear growth period between the third-forth weeks, achieving the highest biomass concentration of 1200 mg/ml on 28^{th} days and a stationary phase began after the fourth week with a declining of biomass rate. It has been demonstrated that elicitor treatment at late log phase results in higher biomass yield as well as secondary metabolite production (Chandra and Chandra, 2011). Therefore, we determine the 28^{th} days of growth kinetic as the suitable time of elicitation. All the concentrations of FE were shown to increase the growth of airy roots in a dose-dependent manner. The biomass of *T. polium* hairy roots was intensified compared to non-elicited control (Fig. 1). FE a 1.5% increased the growth of hairy roots by 44%. There are a few reports about the elicitation effect of *F. graminearum* on biomass production and secondary metabolites accumulation in medicinal plants. The enhancement of biomass production *by F. graminearum* was also seen in *Valeriana officinalis* hairy root cultures (Dini Torkamani et al., 2014). In the opinion, the putative mechanism for the plant growth promotion by fungi extracts might be that fungi elicitors induce the local and systemic defence responses of hairy roots (Ming et al., 2013).

The effect of *F. graminearum* extract (0.5–1.5% v/v) on flavonoid production is shown in Fig. 2. FE at concentration of 1% gave a higher content of total isoflavonoid (7.41 mg/g DW) after 12 days of treatment. This level of flavonoid content were 12.14-fold higher than that of non-elicited control (0.61 mg/g DW). Esmaeilzadeh et al. (2011) reported that *F. graminearum* cell extract induced the highest increase of PTOX in *L. album* cell culture in compared with the four other fungal extracts. In another study, the culture filtrate of *F. graminearum* exhibited promoting effects on flavonols and flavonoids content of the *L. album* cell culture (Tahsili et al. 2014).

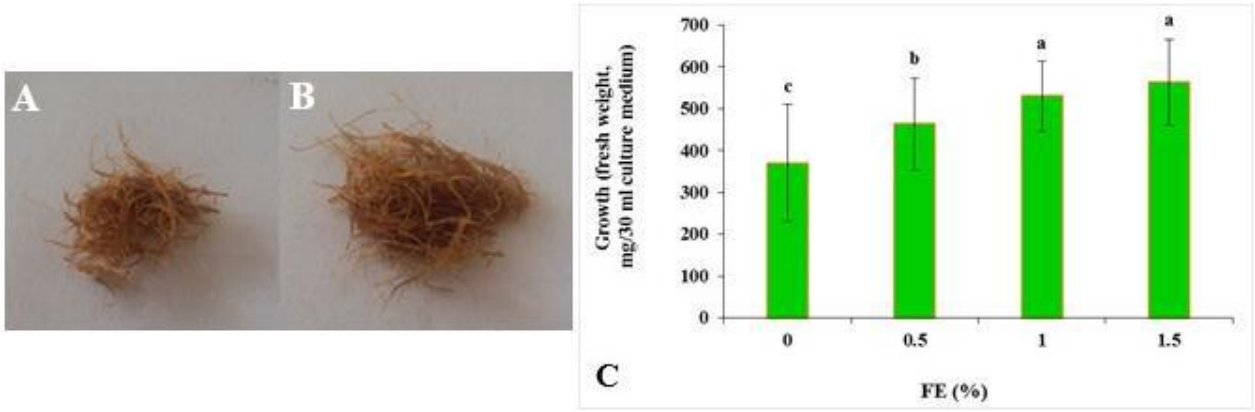

Fig. 1. Effect of *F. garminearum* extract (FE) on biomass production in hairy root cultures of T. *polium*. A: non-elicited root, B: hairy root after treatment with FE (1%), C: growth rate of hairy roots upon treatment with FE.

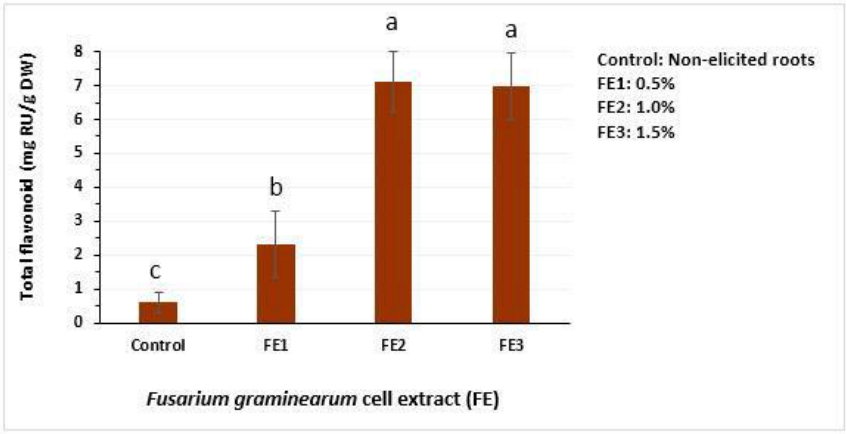

Fig. 2. Effect of *F. graminearum* cell extract on total flavonoid content of hairy roots of *T. polium*. All data are presented as the means ± SD with n = 3. Means with different letters are significantly different (P < 0.05) according to DMRT.

The exposure time of an elicitor is important for effective elicitation of secondary metabolites (Vasconsuelo and Boland (2007). We used a low exposure time (48 h) for elicitation of flavonoids in *T. polium* hairy root culture using *F. graminearum* extract. Similarly, Tahsili et al. (2014) and Kumar et al. (2012) reported an exposure time of 48 h as optimum time of treatment for induction of secondary metabolites production in *L. album* with *F. graminearum* and *P. indica* cell filtrates, respectively. Elicitor concentration and the time of incubation with elicitor as well as the culture conditions and growth stage of the cultured cells are decisive for the elicitation process (Sivanandhan et al. 2013).

Effect of *F. graminearum* cell extract on *PAL* gene expression and enzyme activity We found a high expression of the *PAL* gene in this culture period (Fig. 3). Gene expression in the treated root cultures was increased after the addition of FE, which was 4.26-fold higher than that of the control at 1% of FE (Fig. 3).

PAL, which acts as the bridge between primary metabolism and natural product biosynthesis, catalyzes the first step of phenylpropanoid pathway, i.e. deamination of phenylalanine to cinnamic acid (Kumar et al. 2012). In the present study, total flavonoids were increased in response to the fungi cell extract. With increasing in these compounds, also PAL activity was enhanced after elicitation (Fig. 4). A maximum increase of 3.22-fold in PAL activity (12.26 µM cinnamic acid/mg protein/min) corresponding to 12.14-fold increase in flavonoid content (7.41 mg/g DW) was obtained when FE at a level of 1% was added to hairy root cultures. A correlation between changes in the levels of phenylpropanoid biosynthetic enzymes and product accumulation (Nicholas et al. 1994).

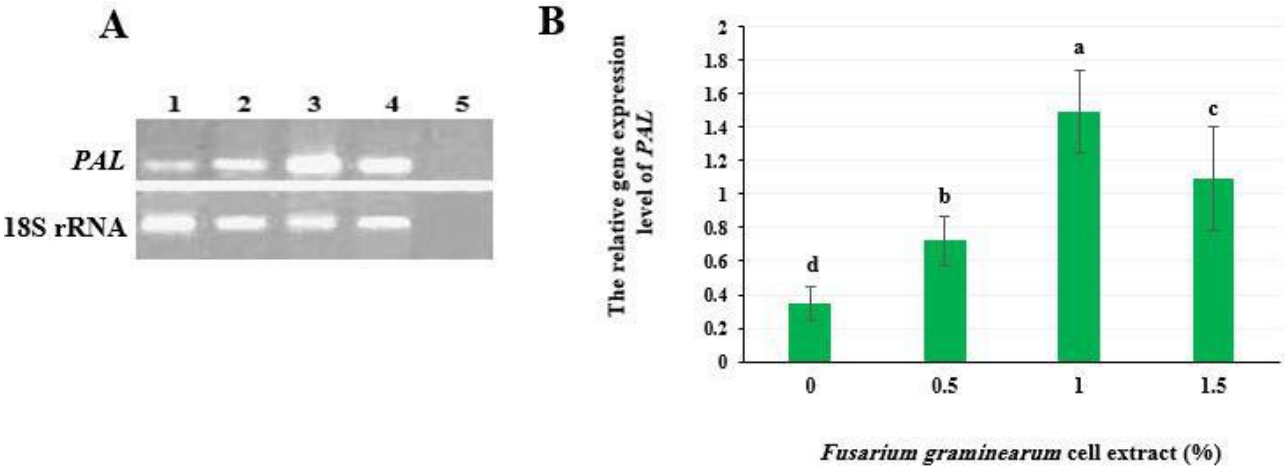

Fig. 3. Dose-dependent transcript level of PAL gene in hairy root cultures of *T. polium* 12 days after treatment with *Fusarium graminearum* cell extract. Relative quantification (B) indicates the *PAL*/T18S rRNA ratio calculated with Image J software (means ±SD, n = 3). 1: non-elicited hairy root, 2-4: hairy roots elicited with 0.5-1.5% of the fungi cell extract, respectively. 5: non-template RT-PCR reaction as negative control

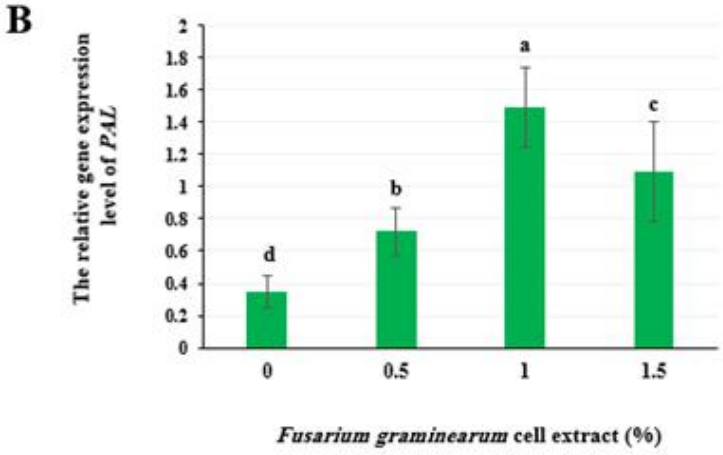

Fig. 4. The phenylalanine ammonia lyase (PAL) activity of *T. polium* hairy root cultures after elicitation treatment with different concentrations of *Fusarium graminearum* cell extract. Fungi cell extract was applied to the hairy root cultures on day 28, and the treatment period was 48 h; Values are presented as means ±SD, *n*=3. Different letters indicate significant differences a t $P < 0.05$ according to the Duncan test.

Conclusion

To the best of our knowledge, there were no previous reports on the use of fungi elicitors for promoting the hairy root growth and flavonoid production of *T. polium*. Without obvious

changes in the appearance of the hairy roots, the exogenous fungal mycelia crude extracts effectively stimulated the flavonoid biosynthesis of *T. polium* hairy root, and the stimulation effect was closely with elicitation concentration. Furthermore, the gene expressing levels were consistent with total flavonoid accumulation levels. These promising results provide a hope for industrial level production of flavonoids or other pharmaceutical compounds from *T. poilum* using elicitation.

Abstract

The effect of foliar fertilization on the chemical content of kernels from *feranjez* almond cultivar in Valandovo region in the period of the year from 2012 to 2013 was determined. The experiment was set in four variants and three repetitions. The variants were: Control (untreated); Ever green co Me (55% organic matter, 2% w/w Mg, 2% w/w Fe, 2% w/w Zn, 2% w/w Mn, 0.5 % w/w Cu, 0.5% w/w B); Biolinfa (34% organic matter 3% N, 5.80% K_2O) and Oligomix (1.20% B, 0.10% Cu, 4% Fe, 1.50% Mn, 0.10% Mo, 2% Zn).
The distance of fruit planting was 4.5 m row by row and 3.5 m in the rows. In each variant and repetition were included 60 plants, and total in all experiment were involved 720. Three foliar treatments were applied with given above fertilizers at a concentration of 0.4%. In the end of the November, soil fertilization with the fertilizer Polyfeed 11-44-11+ME (Fe, B, Zn, Mn, Co, Mo) in quantity amount of 450 kg/ha were done.
Before setting up the experiment, soil agrochemical analyses were made, and was concluded good fertility with nitrogen, medium fertility with phosphorus and potassium. The foliar fertilization has a positive influence on the chemical content of almond kernels. The highest average nitrogen content (3.66%), phosphorus (1.11%), potassium (1.15%) and oils (57.40%) were determined in the kernels from variant Ever green co Me (55% organic matter, 2% w/w Mg, 2% w/w Fe, 2% w/w Zn, 2% w/w Mn, 0.5 % w/w Cu, 0.5% w/w B).
The highest average content of calcium (0.92%) and magnesium (0.39%) were determined in the kernels from variant Oligomix (1.20% B, 0.10% Cu, 4% Fe, 1.50% Mn, 0.10% Mo, 2% Zn).
Key words: *almond kernels, foliar fertilization, oils.*

Introduction

The aim in the modern agriculture is to get higher yield that will characterize with better quality. Plant nutrition is one of the most important agrotechnical measures, that together with the others have to allow uninterruptible, high and economically production (Datnoff et al., 2007). The right plant nutrition regime is necessary for normal growth, yield and getting quality product (Domagalski et al., 2008). It means available of all macro and micro biogenic elements in appropriate phenophase of plant growth. Each biogenic element has its specific influence on different parts of the plants. Plant nutrition has an influence on numerous physiological – biochemical processes, that affecting growth, development and yield (Dzamič and Stevanović, 2000; Glintic and Krstic, 1990). Plants that have timely and right nutrition are getting fruits with characteristic shape, color, size and with typical organoleptic properties. Limited of the nutritious elements is happened because of the different reasons. Intensive agriculture and use of high productivity cultivars led to a continuous decrease in soil micronutrient content (Jekić snd Brković, 1986; Sarić et al., 1989).
Using of foliar fertilizers the fruit cultures nutrition, has a big importance in getting higher yields as well as products with better quality. Foliar fertilizers allow direct supplying of leafs,

flowers and fruits with nutritious elements in a period when they are necessary. Foliar spray with fertilizers is necessary to further activity in the whole system of optimal mineral nutrition of plants (Kostadinov and Kostadinova, 2014). It provides more economical water regime of plants and allows overcoming the physiological disturbances caused by adverse soil conditions that hamper mobility and nutrients absorption.

In unregularly soil conditions, unregularly pH value, low or high soil temperature, fixation in different nutrients, the root cannot adopt the nutrients at all (Sarić et al., 1986; Šaćiragić and Jekić, 1988). In such cases, the foliar nutrition has an important influence. It is an additional nutrition and measure that allow rapid and efficiency effect of correction of the plant nutrition (Velićković, 2002).

The almond, *Amygdalus communis*, is kernel fruit that bellows at the family of *Rosaceae*, and under family *Prunoidae*. It is old fruit culture that is counts in economically importance kernel fruit and has numerous positively characteristic, too.

The importance of almond is because of the kernel, which is very reach in fats, proteins, mineral matters, sugars, cellulose, vitamins and amino acids (Bulatović, 1985). On the other hand, the almond has a big value for human nutrition, pharmaceutics, cosmetic industry and so.

The aim of our explorations was to obtain the influence of soil and foliar fertilization on the chemical content of kernels by almond cultivar *feranjez*, grown in Valandovo region.

Materials and methods

The field experiment with almonds was set in Valandovo region (Republic of Macedonia), during the years of 2011 and 2012. During the field experiment setting, the fruits were 7 years old. The material of work was almond cultivar *feranjez*.

The planting distance was 4.5 m row by row and 3.5 m in the rows. The nutritional area were 15.75 m^2, i.e. 635 fruits/ha.

In the exploration were included 4 variants in 3 repetitions. In each variant and repetition were included 60 plants, or total in whole experiment the number of plants was 720.

The field experiment was set in terms of watering in system drip. During the almond vegetation period were applied all basic agricultural measures.

Variants in experiment were:

Control (untreated);

Ever green with Me (55% organic matter, 2%w/w Mg, 2%w/w Fe, 2%w/w Zn, 2% w/w Mn, 0.5 %w/w Cu, 0.5 %w/w B);

Biolinfa (34% organic matter, 3 %N, 5.80 % K_2O);

Oligomix (1.20 % B, 0.10 %Cu, 4 % Fe, 1.50 % Mn, 0.10 % Mo, 2 % Zn).

The soil fertilizing was applied in the end of November and the fertilizer Polyfeed 11-44-11+ME (Fe, B, Zn, Mn, Co, Mo) was used in the quantity amount of 450 kg/ha.

Each variant and repetition were treated foliar with 0.4% solution of the tasted fertilizers. The application of fertilizers was done with manually spraying the played leaves. The treatments were made in the evening hours. During the vegetation period were conducted 4 foliar treatments. The first treatment was made 10-15 days before flowering, and the other treatments was made after flowering at a distance of 15-20 days.

The harvesting was carried out separately by variants and repetitions.

Before setting up the experiment soil samples were taken for agrochemical analyses and were performed on the following parameters:

pH value - determined potentiometric with pH meter (Bogdanović et al., 1966);

Content of easy available nitrogen – determined by method of Tjurin and Kononova;

Content of easy available phosphorus – determined by AL method and reading of spectrophotometer (Bogdanović et al., 1966);

Content of easy available potassium – determined by AL method and reading of spectrophotometer (Bogdanović et al., 1966);
Content of humus – determined by permanganese method of Kotzman (Bogdanović et al., 1996)
Content of carbonates–determined with Schaiblerov Calcimeter (Bogdanović et al., 1966).
In the kernels were determined the following parameters:
The content of nitrogen (N) - determined using Kjeldal method (Sarić et al., 1989);
The content of phosphorus (P_2O_5) - determined using atomic emission spectrometry with inductively coupled plasma (ICP - AEC) (Sarić et al., 1989);
The content of potassium (K_2O) - determined by incineration of the material with concentrated H_2SO_4 and phlamenphotometar (Sarić et al., 1989);
The content of calcium (SAT) - determined using atomic emission spectrometry with inductively coupled plasma (ICP - AEC) (Sarić et al., 1989);
The content of magnesium (Mg) - determined by applying atomic emission spectrometry with inductively coupled plasma (ICP - AEC) (Sarić et al., 1989);
The content of oil was determined with Sokslet method (Sarić et al., 1989);

Results and discussion

Climate is one of the most important environmental factors from which successful raising depends of all fruit kinds with no exception of almonds (Šoškić, 1996).
The influence of climate elements manifest as time of vegetation of fruit as well as in the phase of resting.Almonds best gain a head in regions with short winter without big temperature variants with absents of frost in annual amount of average temperature over 3000^{o}C (Bulatović, 1989). Valandovo region is known as region with lots of shiny days. Temperature requirements of almond for growth and development in the period of standby are large. It is enough in sequel of 100 hours, the temperature to move from 0 to 6^{o}C for almond awakening. Average year temperature of the air in the Valandovo region is 15^{o}C. Sensibility of low temperatures is brand characteristic. Almond varieties that blossom early are more sensitive than other. Unopened blossoms can be damaged on -3^{o}C to -4^{o}C, and open on -1.5 to - 2.8^{o}C, and just planted fruit on - 1 to -1.5^{o}C (Bulatović, 1985). Almonds are sensitive on very high atmospheric humidity and suffer from diseases and don’t give good yields. Average year relative humidity in Valandovo region is 71 % with maximum of 80 % in November, December and January. Soil conditions have an especially importance on growing, developing and fruits quality. The almond has the best growth and yield in deep, alluvial - diluvial, loamy - sandy, humus carbonate soils with significant content of lime (Ubavić et al., 2001). Particularly suitable are soils with neutral reaction and good penetration of water and air. Salty and acidic soils, too wet and clay are unsuitable for growing almonds.

Table 1. Agrochemical analyses of soil

Lab. No.	Depth cm	pH		Available mg/100g soil			Humus %	$CaCO_3$ %
		KCl	H_2O	N	P_2O_5	K_2O		
1	0-20	7.14	7.62	14.70	6.60	20.00	1.86	/
2	20-40	7.19	7.98	15.26	6.20	17.00	1.90	/
3	40-60	7.05	7.86	11.48	5.00	17.00	1.80	2.50
	Average 0-60	**7.13**	**7.83**	**16.20**	**5.93**	**18.00**	**1.85**	**0.83**

Table 2. Chemical content of kernels in % of dry matter (average 2011/2012)

Variant	N	P_2O_5	K_2O	CaO	MgO	Oils
1	3.25	0.99	0.99	0.84	0.34	55.15
2	3.66	1.11	1.15	0.88	0.37	57.40
3	3.53	1.04	1.08	0.89	0.37	55.50
4	3.39	1.02	1.06	0.92	0.39	53.70

LSD (0.05) = 0.13 LSD (0.05) = 0.04 LSD (0.05) = 0.06 LSD (0.05) = 0.03 LSD (0.05) = 0.02
LSD (0.01) = 0.10 LSD (0.01) = 0.06 LSD (0.01) = 0.08 LSD (0.01) = 0.04 LSD (0.01) = 0.03

From data shown in Table 1, can be concluded that soil in which the field experiment was set, has neutral pH value, good fertility with available nitrogen, but a medium fertility with available phosphorus and potassium. It has medium fertility with humus, too. There is low presence of carbonates.

From data shown in Table 2, can be concluded that soil and foliar fertilization have positive influence on the chemical content of kernels. In all of the variants treated with different kinds of fertilizers, analyzed parameters have higher value compared with the control, untreated variant.

The highest average nitrogen content (3.66%), phosphorus (1.11%), potassium (1.15%) and oils (57.40%) is determined in kernels in variant 2.

For the nitrogen content, statistically significance differences are determined in all of the variants at both levels. For the phosphorus content statistically significance differences at LSD 0.05 level is determined in variants 2 and 3, and at LSD 0.01 level in the variant 2. For the potassium content statistically significance differences at LSD 0.05 level is determined at all variants, and at LSD 0.01 level in the variant2 and 3.

The highest average content of calcium (0.92%) and content of magnesium (0.39%) is determined in the kernels from variant 4. For calcium and magnesium content are obtained statistically significance differences at LSD 0.05 level in variants 2, 3 and 4. At LSD 0.01 level for the content of calcium are obtained significance differences in variants 3 and 4, and for the magnesium content in the variant 4.

Higher content of tested elements in all of the variants, compared with the control variants is a result of the chemical content of used foliar fertilizers as well as their absorption in the plant organs, i.e. kernels.

Macro and micro biogenic elements in the content of used fertilizers have an influence on numerous physiological – biochemical processes that are of vital importance in plant vegetation cycles.

Conclusion

Based on the obtained results for the influence of foliar fertilization on the chemical content of almond kernels from *feranjez* cultivar grown in Valandovo region, the following conclusion can be made:

The soil where the field experiment were carried out, was characterized with neutral pH value, good fertility with available nitrogen and medium fertility with available phosphorus and potassium;

In all of the variants treated with foliar fertilizers, in kernels were obtained higher content of all tested elements compared with the control variant;

The highest average content of nitrogen (3.66%), phosphorus (1.11%), potassium (1.15%) and oils (57.40%) were determined in kernels from the variant 2 (Ever green with Me (55% organic matter, 2%w/w Mg, 2%w/w Fe, 2%w/w Zn, 2% w/w Mn, 0.5 %w/w Cu, 0.5 %w/w B));

The highest average content of calcium (0.92%) and magnesium (0.39%) was determined in kernels from variant 4 (Oligomix (1.20 % B, 0.10 %Cu, 4 % Fe, 1.50 % Mn, 0.10 % Mo, 2 % Zn);
For the nitrogen content, statistically significance differences are determined in all of the variants at both levels. For the phosphorus content statistically significance differences at LSD 0.05 level is determined in variants 2 and 3, and at LSD 0.01 level in the variant 2;
For calcium and magnesium content are obtained statistically significance differences at LSD 0.05 level in variants 2, 3 and 4.

Abstract

The vegetative propagation of the plants in *in vitro* conditions enables to abbreviate the process of selection, enhance the genetic stability of plants and improve the production of healthy plants free of viruses.

In this paper the results of our experimental work for determination of the potential of *in vitro* morphogenesis and micropropagation of some agricultural species are presented (*Apium graviolens* L., *Daucus carota* subsp. *sativus* L., *Cucumis sativus* L., *Cucurbita pepo* var. *cylindrica, Raphanus sativus* var. *radicola,* and important agricultural species from *Apiaceae, Brassicaceae, Cucurbitaceae* and *Solanaceae* family). Different initial explants were cultivated *in vitro* on various media supplied by different combinations and concentration of plant growth regulators. The main objective of this research was to set up meristem tissue culture and non-meristem explants, to explore the properties of the tissues *in vitro*, and to observe their possibilities for morphogenesis and micropropagation.

Keywords: *in vitro, vegetative propagation, phytohormones, regeneration, micropropagation.*

Introduction

Biotechnological approaches like micropropagation, somaclonal variation, *in vitro* conservation, protoplast fusion, and development of novel transgenic plants have great potential in conservation, utilization and increasing the production of spices. Efficient micropropagation systems are available for many spices which are being used for propagation, conservation, safe movement and exchange of germplasm, crop improvement through somaclonal variation and transgenic pathways (Babu et al., 2015).

At the peak of the plant tissue culture era in the 1980s, in a relatively short time, many commercial laboratories were established around the world to capitalize on the potential of micropropagation for mass production of clonal plants for the horticulture industry. Today plant tissue culture applications encompass much more than clonal propagation (Akin-Idowu et al., 2009).

Micropropagation has been employed a large scale production of decease free planting material and germplasm conversation. High rate of multiplication coupled with the additional advantage of obtaining diseases free planting material makes micropropagation a viable alternative to a conventional propagation.

Morphogenesis in plants is a complex phenomenon and is being regulated by numerous factors and in-between relationships of plant organs, tissues and cells also. The correlation between cells tissues and organs of a plant plays important role in the growth and development in *in vivo* and in *in vitro* conditions. The study of such complex system can be simplified with cell, tissue or organ isolation and their cultivation *in vitro*. In such conditions, the influence of certain factors on the organogenesis and differentiation of the plant tissue can be traced (Koleva Gudeva and Trajkova, 2012). Even today much more is not fully understood about micropropagation, and morphogenesis in tissue culture, and although general guidelines for micropropagation have been established, each plant species is unique.

Despite this problems, there are e large number of species being micropropagated on a commercial scale throw the world (Kitto, 1997).
This paper surveys the effect of plant growth regulators as an important role in the plant morphogenesis of some important agricultural species form *Apiaceae, Brassicaceae, Cucurbitaceae* and *Solanaceae,* as a main factor for successful commercial micropropagation.

Material and methods

This study was conducted in the Laboratory for Plant Biotechnology at Faculty of Agriculture, Goce Delcev University-Stip, Republic of Macedonia during the period 2010-2015. The plant material used for isolation of the initial explants, was sterilized in the following manner: rinsing with tap water, than with distilled water, followed by 15-20 seconds in 70% C_2H_5OH, Tween 20 enriched, 10-15 minutes in 5% $Ca(ClO)_2$ enriched with Tween 80, and on the end the explants were rinsed few times with sterile water. Sterilized initial explants were cultivated on MS medium in which various concentrations and combinations of plant hormones were added.

Plant growth medium ingredients

In the following tables is shown that all plant explants except pepper anthers were cultivated on either on MS (Murashige and Skoog, 1962) or LS (Linsmaer and Skoog, 1965) media containing 3% sucrose, 0,7% agar, 100 $mg \cdot l^{-1}$ inositol, 200 $mg \cdot l^{-1}$ casein hydrolysate, 0,1 $mg \cdot l^{-1}$ B1, 1,0 $mg \cdot l^{-1}$ B6 and 0,5 $mg \cdot l^{-1}$ nicotinic acid. Different phytohormones were used in a medium such as: IAA (indole-3-acetic acid), IBA (indole-3-butyric acid), NAA (α-naphtaleneacetic acid), BAP (6-benzylaminopurine), BA (N6-benzyladenine), KIN kinetin (6-furfuryl aminopurine), ZEA zeatin (N^6-4 hydroxyl-3-methyl-trans-2butenyl anunopurine), 2iP (N^6-2-isopentyl adenine) and 2,4 D (2,4-dichlorophenoxy acetic acid).
In order to favorite the microtuberisation of potatoes the medium for cultivation the nodal explant form *Solanum tuberosum* L. was supplemented also with different concentrations of sucrose (30, 60 and 90g/l) (Anoop et al., 2009; Dieme et al., 2013)
The androgenetic potential of the pepper was examined on medium developed by Dumas de Valux et al. (1981) method for pepper anther culture.

Growth conditions

Apical buds, cotyledons and hypocotyls from the species under research originated from plant seeds germinated on basal media. All the explants and their subculture to an new medium supplemented by same or different plant hormone were cultivated in climate chamber with controlled conditions and temperature of 25±2ºC, photoperiodic of 16/8 light/dark, 50% relative humidity, and 50 $\mu mol \cdot m^{-2} \cdot s^{-1}$ light intensity. The growth conditions for examination of morphogenetic potential in pepper anther culture and the ability for androgenesis and/or somatic embryogenesis was set up according the method of Dumas de Valux et al. (1981).

Results and discussion

Micropropagation of some species form *Apiaceae* family

The species from family *Apiaceae* are a well-known source of many important herbal products. A number of research studies focus on the biosynthesis of secondary metabolites in *in vitro* plant cultures. There are also numerous reports concerning the methods of plant micropropagation, especially using somatic embryogenesis (Ekiert, 2000). The results from experiment shown in Table 1, confirmed that these species have an excellent potential for micropropagatein. Two types of initial explants, apical buds and shoots, were used to set up a tissue culture from celery, carrot and parsley on six different growth mediums. The best potential for morphogenesis of all mediums have the cultures from *Apium graviolens* L.

Micropropagation of some species form *Brassicaceae* family

This family includes many economically important edible and industrial oilseed, vegetable, condiment, and fodder crop. It also includes the molecular plant model, such as *Arabidopsis thaliana* and a rich source of agronomic and economic traits in its highly diverse wild germplasm (Warwick, 2011). Therefore the knowledge about the ability of micropropagation of these economically important species is of great importance for plant biotechnology. In Table 2 are presented the results of morphogenetic potential research of *in vitro* culture of broccoli, cabbage and radish. The best potential for morphogenesis of all examined mediums have the cultures from *Brassica oleracea* var. *italica.*

The family *Cucurbitacea* along with the other two *Brassicaceae* and *Asteraceae* can be consider as a family of extraordinary importance to humans, as they follow cereals and legumes in their economic significance to human kind (Lebeda et. al., 2006). A good micropropagation protocol could reduce the cost of hybrid seed production, which can account for 30% of the total seedling cost. The commercial application of *in vitro* techniques in *Cucurbitaceous* taxa has been well demonstrated and the regeneration of plants has been reported from different types of tissue cultures (Ahmad and Anis, 2005). Our experimental work involved meristem and non-meristem tissues cultivated on MS and LS media. The results show that *Cucumis sativus* L. possess bigger potential for morphogenesis as compared to *Cucurbita pepo* var. *cylindrical* (Table 3).

Micropropagation of some species form family *Solanaceae* family

The *Solanaceae* family provides some of the world's most popular vegetables. The family ranges from annual and perennial herbs to vines, lianas, epiphytes, shrubs, and trees, and includes a number of important agricultural crops, medicinal plants, spices, weeds, and ornamentals. Many members of the family contain potent alkaloids, and some are highly toxic.

In the current research the meristematic apical buds and non-meristematic cotyledonary and hypocotyledonary segments were used as initial explants for research of regenerative potential and further morphogenesis of pepper in *in vitro* culture (Table 4). The androgenetic potential of the pepper and the ability for embryos induction in pepper anther culture were tested as well (Table 4). From all tested media and treatments, haploid embryo production was accomplished only by the method of Dumas de Valux et al. (1981).

As experimental material for tomato micropropagation, apical buds, cotyledons and hypocotyls were used (Table 4). Tomato possesses excellent potential for *in vitro* morphogenesis which was proven by our and in many other experiments (Bhatia et al., 2004; Chandra, 2013; Koleva Gudeva et al., 2006)

The results from micropropagation of *Solanum tuberosum* L. presented in the Table 4 are in line with results of Dieme et al. (2013) who found that media enriched with BAP, KIN and sucrose give better microtuber formation. Different researchers agreed that higher percent of sucrose in the medium has positive results on microtuberisation process and increases the number and quality of microtubers (Farran and Mingo-Castel, 2006; Motallebi-Azar and Kazemiani, 2012; Ahmed et al., 2013; Iqbal et al., 2014; Koleva Gudeva et al., 2014) which confirm our findings during this research.

Conclusion

Today, without the use of *in vitro* plant methodology, many sophisticated and complex processes at the molecular level cannot be imagined and implemented, which is one of the most important challenges of the XXI century. The mass production of many species is based on the use of tissue culture and micropropagation. Furthermore, the ability to produce disease free plant material transformed plant propagation to an emerging industry for commercial micropropagation. This industry will continue to expand, but expansion will not be completed without introduction of new improved protocols for successful morphogenesis in plant tissue culture for economically important species, as they were presented in these paper.

Abstract

In this research were included seven clones of the variety Merlot (R-12, R-18, R-3, 181, 184, 348, 346). Fertility of each clone is determined by elements: fertility shoots per vine (%),absolute coefficient (number of clusters per fertile shoot), mass of bunch, and the yield expressed of unit area or kg/m^2.The obtained results from this work were statistically processed using the SPSS statistical software package 19, from where it can be measure the frequency, the percentage share of data, measures of central tendency (median, standard deviation, dispersion, arithmetic mean), such as graphic representation of data (a histogram).The analysis showed than all clones had larger correlation coefficient or there exists a greater dependence between the mass of the cluster and yields. From all clones, only two of them (R18, 346) proved more than greater dependence or greater correlation coefficient between absolute coefficientand the percentage of fertility shoot. The Merlot clone 348 proved the highest correlation between the mass of the cluster and yields where correlation coefficient is 0.983 which is approximately the value of 1, which indicates a very high connectivity.

Key words:*clones, merlot, fertility,correlation coefficient*

Introduction

Successful viticulture is based on quality vine varieties that are well adapted to external conditions and contributing to the high economic efficiency. In viticulture there are numerous clones of the grape vines, produced by clone selection. Clone selection is long procedure consists from finding, tagging and detailed describing of the variety on which is registered positive characteristic of a significant property. Clones of some varieties are actually descendants received from the vine variety, in that there are certain positive characteristics, permanent and stable in the next descendants that will grow from year to year. (Chien L. Mark,2008). After numerous testing and research on the resulting clone, he still carries the name of the variety where it belongs, and despite the name has a certain code or additional name, which would differ from the rest. Basic goals of the modern clone selection is separating a new clones which have to be virus free, to own resistance to the burners, ashtrays, and of course grapes hold better technological properties in relation to the native variet. (M. J. Benz et al.,2006).

Merlot vine variety is very important for the Republic of Macedonia, suggested to produce premium red wines. Merlot population contains many variations, features and clones.(V.Dimovska et. al., 2011).

The clone selection of Merlot is the most represented in France, Italy, Spain. As regards of technological features, selected Merlot clones which have larger yield, clusters with bigger weight give lower quality of the wine in accordance to less productive Merlot clones.(T.Slavtcheva, P.Pourtchev, 2007).

In order of population, clones from one selection differentiate with better characteristics of the grape and the quality of produced wines. (Larry J. Bettiga, 2003). The clones also differentiate between themselves in certain characteristics (yield, weight of the cluster, sugar

content, total acids and anthocyanin), which is a result of the assortment specification and less on the impact of cultivation conditions. (Matthew W.F. et.al., 2007).
In this study are included seven clones of Merlot (R-12, R-18, R-3, 181, 184, 348, 346). The clones were planted in the period 2009/2011 at the Agricultural Institute in Skopje, introduced from France. The main goal of this work is to compare the relationship or correlation between the mass and yields to individual clones and the correlation between the absolute correlation coefficient and the percentage of fertile shoots per vine.

Material and method

As a material for testing were used seven clones from Merlot: R-12, R-18, R-3, 181, 184, 348, 346 separately have grown in vineyards in the period 2009/2011, by applying appropriate agro-technical and ampelo-technical measures. Clones are introduced as certificated virus free planting material in 2000 from France. The test was performed at the Agricultural Institute in Skopje. The process of cultivation was a fruit-wall with two legged Gio's way of pruning, distance of planting of 2.5m between the lines and 1.3m between the grapevines in line.The clones were cultivated in same agro-ecological conditions with application of regular agro-technical and ampelo-technical measures.The most important parameters analyzed in this research were agrobiological properties, including fertility of shoots, expressed in % of developed and % of fertility shoots and yield of clones expressed inkg/m^2.After appearance of the shoots and the appearance of the earliest blossoms is determined number of fertility tendrils. These indicators allow the determination of the coefficient of fertility. During the harvesting was determined the number of bunches per vine, i.e yield of grapes expressed in kg/m^2. The obtained results from this work are statistically processed using the statistical software package SPSS 19, where we have measure for the frequency, the percentage share of data, measures for central tendency (mode, median, standard deviation, dispersion, arithmetic mean) and graphic display of the data (histogram). For the analyzed properties is calculated the correlation coefficient. Dependent variables critical in our work are the yields, a mass, the absolute coefficient of fertility and the percentage of fertility shoots at seven clones of Merlot over a period between 2009 and 2011. Using the software package SPPS 19 is made table display of correlation between mass and yields at individual clones and the correlation between absolute coefficient of fertility and the percentage of fertily shoots at the clones of Merlot. Comparing by the Pearson's coefficient of correlation we can see which parameters have a higher connectivity at the relevant clone. If $\rho = 1$, it means that there is a perfect linear dependence and the growth of the one variable well the other variable is growing. Correlation coefficient ranging between 0.9 and 1 means a very high connectivity. If $\rho = -1$ means that there is a perfect linear dependence, but with a growing the one variable declines other variable.

Results and discussion

In Table 1. is detailed overview of the main elements of fertility of these seven clones of Merlot, for the period 2008-2010. For all elements is calculated the average value for these three years.Having into account this average value, we can note that in view of fertility shoots maximum value is occurs for the clone R-18,while a minimum value for the clone R-3. It is calculated the average value of the absolute coefficient, which shows again that the clone R-18 has the highest value, while the clone 346 minimum. According to Table 1.the average value for the mass of bunch shows the maximum value for the clone 184, while the minimum valuefor the clone 346. As an important element in the correlation yield expressed in kg / m^2 is included. The maximum value of the yield, refers to the clone R-18 and R-3, while a minimum value for the clone 181.

Table 1. Elements of fertility

Clone	Year	Fertile shoots per vine (%)	Number of bunches per fertile shoot (absolute coefficient)	Mass of cluster (g)	Yield (kg/m^2)
181	2008	69.47	1.69	124	2.728

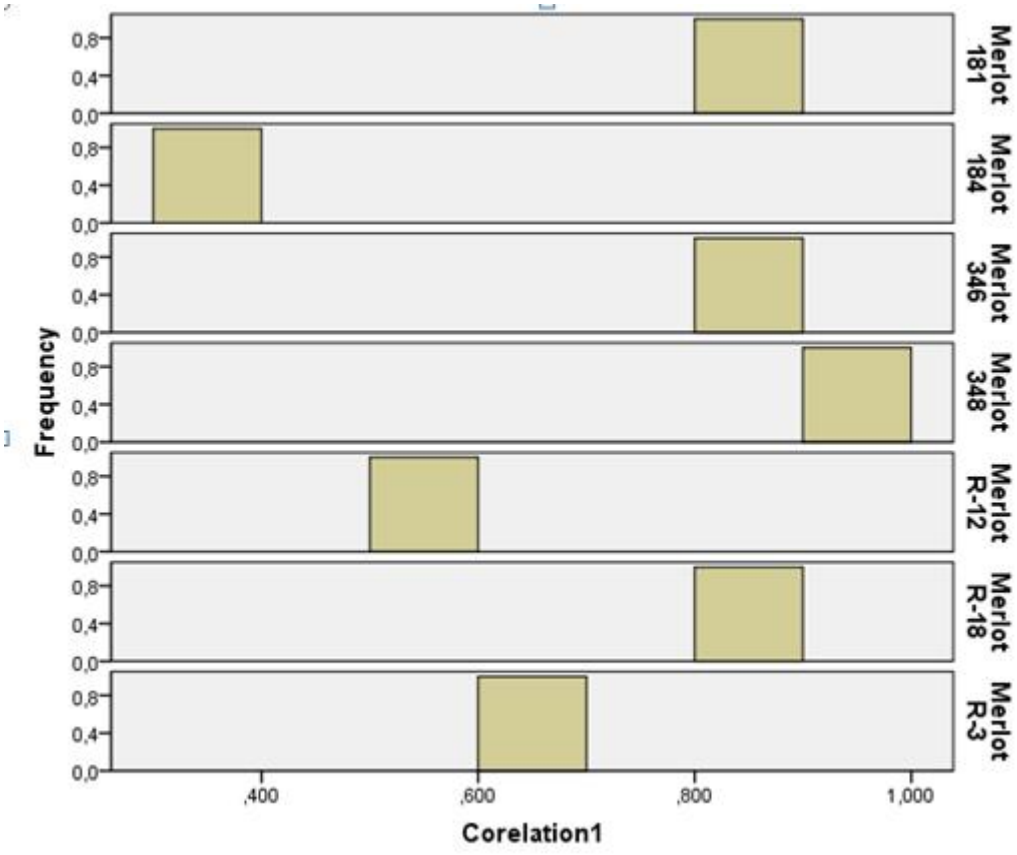
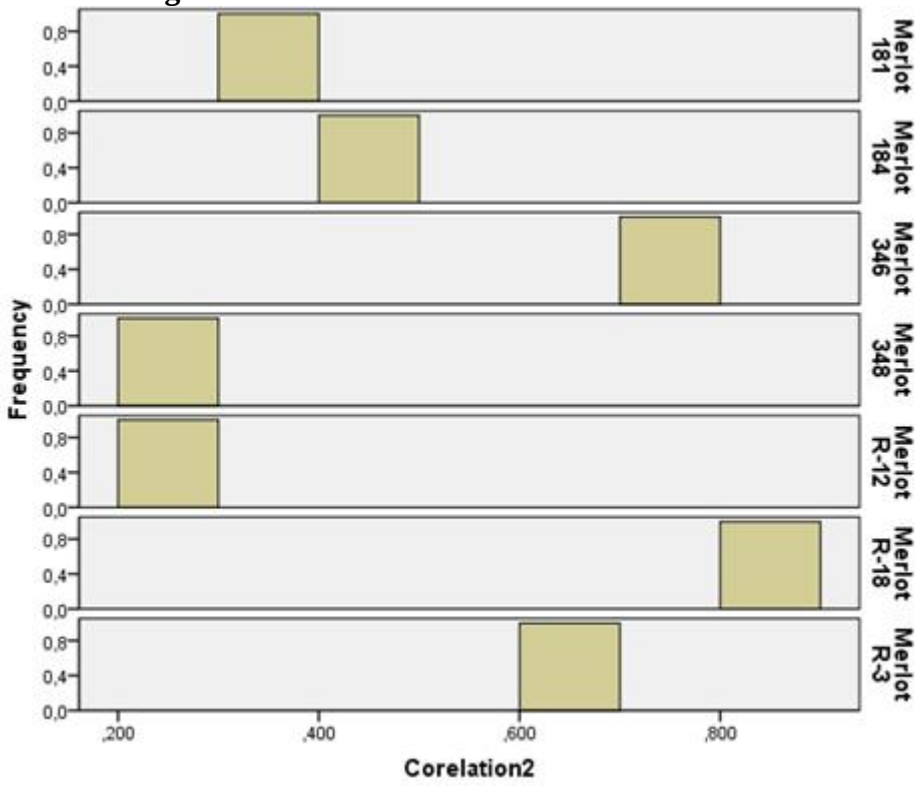
	2009	56.67	1.63	95	1.615
	2010	66.28	1.60	122	2.565
	08/10	**65.69**	**1.53**	**105**	**2.15**
348	2008	82.94	1.67	158	3.296
	2009	65.58	1.58	113	2.147
	2010	69.30	1.76	175	4.200
	08/10	**72.61**	**1.67**	**148.6**	**3.21**
R-12	2008	76.92	1.82	118	3.200
	2009	72.25	1.62	133	3.465
	2010	61.18	1.69	144	2.767
	08/10	**70.12**	**1.71**	**131.6**	**3.14**
R-18	2008	84.61	2.19	123	3.688
	2009	70.00	1.60	138	3.045
	2010	65.29	1.79	120	3.438
	08/10	**73.30**	**1.86**	**127**	**3.39**
R-3	2008	73.23	1.98	131	3.407
	2009	57.00	1.45	140	2.752
	2010	58.29	1.88	155	4.025
	08/10	**62.84**	**1.77**	**142**	**3.39**

Table 2. Display of Pearson's coefficient of correlation received from corelation 1 (mass *(g)*and yield*(kg/m^2)*) and correlation 2 (fertile shoots per vine *(%)* and absolute coefficient)

Clones	Corelation 1	Corelation 2
181	,868	,321
184	,332	,441
346	,804	,773
348	,983	,203
R-12	,542	,287
R-18	,851	,849
R-3	,605	,699



Graph. 1. The histogram shows correlation coefficient between the mass and yields



Graph. 2. The histogram shows correlation coefficient between the absolute coefficient and fertile shoots per vine

The first histogram shows that the Merlot 348 have the highest value of the correlation coefficient between the mass and yields while Merlo 184 lowest value. At the next histogram

indicates the correlation coefficient between the absolute coefficient and the percentage of fertility shoots to individual clones. The Merlot R-18 has the highest value of the correlation coefficient and Merlot and 348 and R-12 lowest value.

Conclusion

Under this research can be observed that for all seven shoots of Merlot higher correlation coefficient or greater dependence exists between the mass of the bunch and yields, unlike the percentage of fertily shoots and absolute coefficient of fertility.

From a total of seven shoots of Merlot, only two of them showed greater dependence, or greater correlation coefficient have absolute coefficient of fertility with the percentage of fertility shoots, and the values are close to the correlation coefficient of the mass and yields. In most of the cases it was proven that the correlation between the mass of bunch and the yield is higher, i.e. approximately equal for most clones of Merlot.

For the Merlot clone 348 has proved the highest correlation between the mass of bunch and the yield relative to other clones, where the Pearson's correlation coefficient is 0.983 which is approximately the value 1, indicating a very high connectivity.

Abstract

Consumption of minerals is very important in human nutrition. Some play essential role in cell functions, while some are important in body maintenance and enzyme reactions. Healthy diet means getting enough of the essential mineral ingredients the body needs during the day. Minerals are inorganic substances and are found in the soil or in the water which is absorbed by plants. Montenegro as a Mediterranean country recommends in nutrition habits consumption of different kind of green vegetables. The aim of this paper was to determine the mineral content of some leafy vegetables such as spinach (*Spinacia oleracea)*, swiss chard (*Beta vulgaris)*, collard greens (*Crambe maritima*) and parsley (*Petroselinum crispum*) as a spice. Vegetable samples were collected from the private property "Green Home Jovović" during May 2015. 1g of washed, grounded and air dried sample was acid digested. Content of calcium, magnesium, potassium, copper, zinc and phosphorus was determined by ICP-OES. Based on the obtained data it can be concluded that Ca, Mg, K, Zn and P concentrations are the highest in spinach, 13.23 g/kg, 11.7 g/kg, 33.3 g/kg, 123.2 mg/kg and 5.4 g/kg, respectively, and spinach is a great source of Ca, Mg, K, Zn and P in daily diet. The lowest concentration of minerals is observed in parsley. As a good source of copper can be used collard greens, because it contains 93.0 mgCu/kg. The results showed that these values may be useful for the evaluation of dietary information.

Key words: *minerals, vegetables, human nutrition, diet*

Introduction

Agriculture, besides enhancing food production, is aimed to provide almost all the essential minerals and organic nutrients to maintenance a human health. Green vegetables, especially the ones that have been considered as functional foods, constitute the main source of minerals in the human diet (Acho et al., 2014; Martınez-Ballesta et al., 2010; Hanif et al., 2006). In Montenegro, production of vegetables increases because of better technical equipment and an improved technological level of production and use of high yield species and hybrids. The soil and climatic conditions of Montenegro are congenial for the production of vegetables such as swiss chard, spinach, collard greens and parsley as a spice (Borah et al., 2009; http://ec.europa.eu/agriculture/analysis/external/applicant/montenegro_en.pdf Accessed on 05/06/2015). These green leafy vegetables are inexpensive, are easily and quickly cooked, and constitute the main source of minerals in the human diet (Amaghol et al., 2012; Hanif et al., 2006; Rahmatollah et al., 2010).

Humans need inorganic nutrients, some of them are required in large amounts such as N, P, Ca, Mg, K, but others, are required in trace amounts (Fe, Zn, Cu, I ,Se) because higher concentrations can be harmful. Epidemiologically studies showed that optimal intake of elements, such as sodium, potassium, magnesium, calcium, manganese, copper, zinc, and iodine, could prevent disease such as cardiovascular disorders. There is a growing interest in the dietary minerals even though they comprise only 4–6 % of the human body. The major

minerals serve as structural components of tissues and function in cellular and basal metabolism and water and acid–base balance. The aim of this paper was to determine the mineral content of some leafy vegetables such as spinach (*Spinacia oleracea)*, swiss chard (*Beta vulgaris)*, collard greens (*Crambe maritima*) and parsley (*Petroselinum crispum*) cultivated in Montenegro. (Acho et al., 2014; Martınez-Ballesta et al., 2010; Rahmatollah et al., 2010).

Material and methods

For the purposes of this study content of minerals and nutrients have been analyzed in green vegetables that are the most consumed in Montenegro, as follows: Swiss chard, Spinach, Collard greens and parsley, as a spice. Vegetable were collected from private greenhouse Jovovic, near Podgorica, Montenegro. Sampling was carried on May 2015. It was analysed only the green part of the plant. All the products were washed with de-ionized water to remove the dust and soil particles and the fertilizers and spray residues and dried at room temperature. The samples were homogenisied until the powder is gained. Contamination during this step is avoided by using stainles steel equipmnt. Dried samples (0.5 g) were prepared by microwave digestion (ETHOS1), using HNO_3 and H_2O_2, in accordance with the recommendations of the manufacturer (7ml of HNO3 65% and 1ml of H_2O_2). Total concentrations of Ca, K, Mg, N, P, Cu and Zn were determninated using ICP-OES (Spectro Arcos) instrument For preparation of all reagents and calibration standards were used chemicals high purity and ultra pure de-ionized water (TKAMilli Q-Ultra Pure Water System, Germany). The standards for the calibration curve were prepared by several dilutions of certified solution concentration of 1000 mg / l from producers (JTBaker). All the experiments were carried out in triplicate (Borah et al., 2009).

Results and Discussion

The minerals and nutrient concentrations for each vegetables are shown in Figure 1-4. The results of the analyses were established to give nutrient/minerals values per 1000 grams of used portion of dried weight. Recommended daily intake minerals for healthy adult are showed in Table 1(http://www.healthbosnia.com/ishrana/klinicka/rdd.htm Accessed on 05/06/2015; http://www.lenntech.com/recommended-daily-intake.htm Accessed on 05/06/2015).

Calcium content ranged from 1.34 g / kg to 13.23 g / kg, potassium 20.80g / kg to 33.30g / kg, 3.23g of magnesium / kg to 11.70g / kg, of nitrogen 42.90g / kg to 61.90g / kg of phosphorus from 3.02g / kg to 5.40g / kg, copper from 0.016mg / kg to 0.039mg / kg, zinc from 0.028mg / kg to 0.123mg / kg. The highest mineral content is visible in the spinach, and the lowest in collard greens. The Spanach is also located the largest amounts of zinc, while the lowest content of copper and zinc has been observed in the parsley.

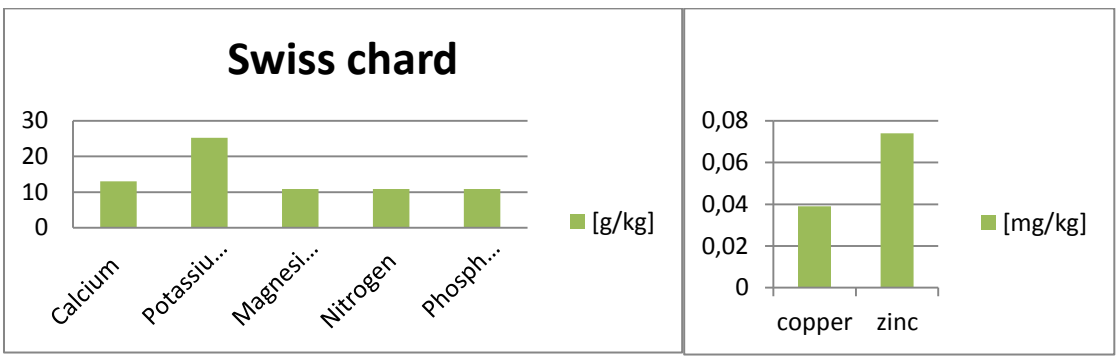

Figure 1. Minerals and nutrient concentrations in swiss chard

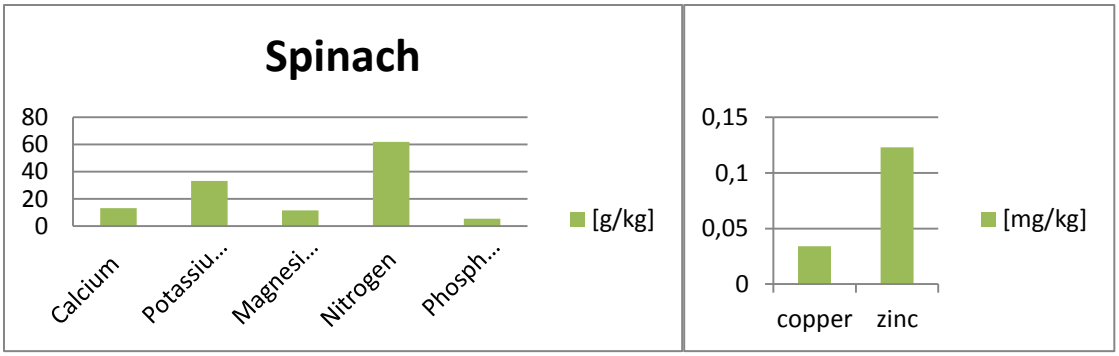

Figure 2. Minerals and nutrient concentrations in spinach

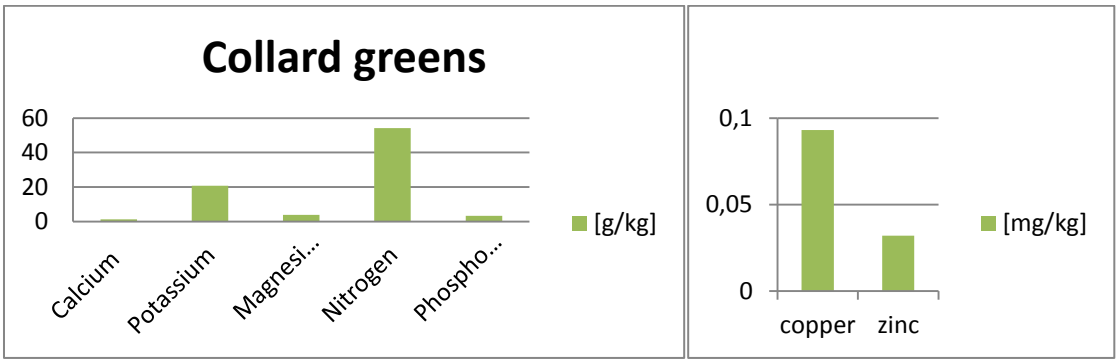

Figure 3. Minerals and nutrient concentrations in collard greens

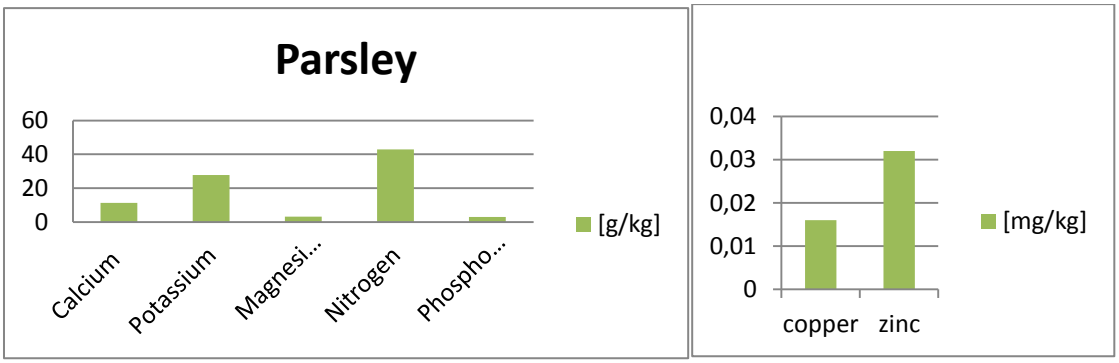

Figure 4. Minerals and nutrient concentrations in parsley

Table1: Recommended daily intake minerals for healthy adult)

Minerals	quantity (g)/ day	Over dosage
Ca	0,9	Doses larger than 1500 mg may cause stomach problems for sensitive individuals
K	2.0	Large doses may cause stomach upsets, intestinal problems or heart rhythm disorder
Mg	0.35	Doses larger than 400 mg may cause stomach problems and diarrhea

P	9.00	Larger doses may cause stomach problems for sensitive individuals
Cu	0.0009	As little as 10 mg of copper can have a toxic effect
Zn	0.013	Doses larger than 25 mg may cause anemia and copper deficiency

Conclusions

The results confirmed the well-known fact that green vegetables have an important role in the diet as a source of important nutrients and minerals. It was found that nutrients and minerals composition in all the selected vegetables was different. Some vegetables were rich in Mg and Ca such as s. chard and spinach but their concentration in other vegetables were poor especially parsley and collard greens. The results showed that these values may be useful for the evaluation of dietary information. The intake of these vegetables could be expected to contribute a large proportion of the mineral requirement in the body. It is recommended to use green vegetables in diets considering the facts that it is poor sources of fat that make them good food for obese people.

Abstract

The interest in chemicals that act as antioxidants has increased during the last two decades because they are important in prevention of diseases which are a consequence of oxidative stress.

Antioxidants are chemically diverse group that prevent or slow the oxidation of other molecules by numerous mechanisms. They are very important in living world because they fight against free radicals. Based on a fact that food and health will always be getting priority for mankind, plant biotechnology techniques are employed for nutrition improvement of plants crops and production of antioxidants chemicals in vitro, for prevention of diseases. The main approaches of plant biotechnology for antioxidants production are plant genetic/metabolic engineering and plant tissue culture. The aim of this paper is to introduce some of the most potent exogenous antioxidants molecules for human health and how plant biotechnology can improve their content in commonly used crops. Also, this paper presents plant cell cultures technology as a factory for antioxidant production. Since the nutrition and health promotion are always been a priority of human kind improvement of food quality, its enrichment with components that act on prevention of chronic diseases, could be achieved through genetic engineering and breeding transgenic plants. The development of modern plant biotechnology is directed to overcoming obstacles in the form of bioavailability of plant products which have antioxidant properties and other useful features through concept of functional foods and nutraceuticals.

Key words: *antioxidants, plant biotechnology, genetic engineering, plant tissue culture*

Introduction

The interest in chemicals that act as antioxidants has increased during the last two decades because they are important in prevention of diseases which are a consequence of oxidative stress (Uttara et al., 2009). The state referred as oxidative stress is consequence of reactive species that are known as free radicals and can lead to numerous chronic diseases such as cardiovascular, inflammatory disease, cancer, aging and neuro-degenerative disorders (Alzheimer's and Parkinson's disease) (Djordjevic et al., 2008; Droge, 2002; Kunwar et al., 2011; Lobo et al., 2010). The most important free radicals molecules are reactive oxygen species (ROS) and reactive nitrogen species (RNS). ROS and RNS are formed in cell during normal cell activities and in pathological states (Djordjevic et al., 2008; Valko et al., 2007. Antioxidants are chemically diverse group that prevent or slow the oxidation of other molecules by numerous mechanisms. They fight against free radicals and prevent the harmful effect on macromolecules (proteins, lipids and DNA). The harmful effects of ROS/RNS are balanced by the antioxidant action of non-enzymatic antioxidants in addition to antioxidant enzymes (Fang et al., 2002; Lobo et al., 2010; Valko et al., 2007). Plant biotechnology techniques are employed for nutrition improvement of plants crops and production of antioxidants chemicals *in vitro*, for prevention of diseases. The main approaches of plant

biotechnology for antioxidants production are plant genetic/metabolic engineering and plant tissue culture (Kirakosyan et al., 2009).
The aim of this paper is to introduce some of the most potent exogenous antioxidants molecules for human health and how plant biotechnology can improve their content in commonly used crops. Also, this paper presents plant cell cultures technology as a plant factory for antioxidant production.

Plant genetic/metabolic engineering

In order to improve plant corps or introduce of novel products, in plants have been incorporated foreign gene so the transgenic plant is generated. Plants transformations is process in which genes are incorporated in organism's genome for amelioration of some plants traits. Figure 1 represents the most common used strategy in the formation of transgenic plants which is *Agrobacterium tumefaciens*-mediated transfer bipolar vectors into plant cells (Kirakosyan et al., 2009; Madigan et al., 2006).

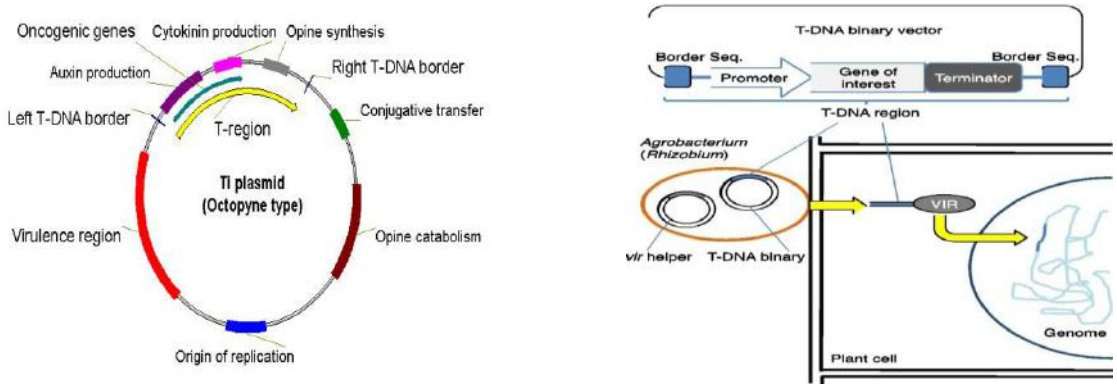

Figure1: Detailed view of Ti plasmid components; Incorporation of binary vector into plant cell for *A. tumefaciens*-mediated transfer

Genetic/metabolic engineering of flavonoid and carotenoids compounds

Flavonoids are class of phenolic compounds which perform a wide range of functions, such as antioxidant activity, UV-light protection and defense against phytopathogens (e.g. soflavonoids), legume nodulation, male fertility, visual signals and control of auxin transport (Balasundram et al., 2006; Ververidis et al., 2007).
Carotenoids are the pigments that give fruits and vegetables such as carrots, cantaloupe, sweet potato, and kale their vibrant orange, yellow, and green colors. There are over 600 known carotenoids; they are split into two classes, xanthophylls (which contain oxygen) and carotenes (which are purely hydrocarbons, and contain no oxygen) (Rao et al., 2007; Schoefs, 2002).
The strategies of genetic engineering can be described with three approaches: 1) increment endogenous synthesis flavonoids using structural and regulatory genes; 2) blocking flavonoid pathway by RNA interference technique; 3) production of novel flavonoids inserting new branches in pathway (Bovy et al., 2007).

Strategy of regulatory genes engineering

Regulatory gene AtMYB12, originally transcriptional activator in *Arabidopsis thaliana*, when it is engineered in tomato fruit, activates biosynthetic pathway of polyphenols, chlorogenic acid and flavonol. In transgenic tomato fruit, engineering of this regulatory gene directs tissue specific expression (in tomato fruit), in plants parts that normally doesn't produce any flavonoids (ectopic expression) (Luo et al., 2008; Sanghera et al., 2013; Bovy et al., 2007).

Engineering of carotenoids content is not well developed (and use of regulatory genes), as in the case of flavonoids, because transcription factors that are control the synthesis of isoprenoids are not known. What has been done in this field is the observation that the Or gene (regulatory gene), isolated from the cauliflower and incorporated into potatoes leads to 6 times higher content of carotenoids in transgenic potatoes (Lopez et al., 2008; Sanghera et al., 2013; Lu et al., 2006).

Engineering of structural genes

In tomato fruit peel it is possible to detect some flavonoids while in the flesh all flavonoid genes show very low expression levels. In order to increase flavonoid level in tomato flesh, the four flavonoid biosynthetic genes from *Petunia* (*chs*, *chi*, *f3h* and *fls*) assembled in tomato and result was increased levels of flavonols in both peel (primarily quercetin glycosides) and flesh (primarily kaempferol glycosides) (Muir et al., 2001; Bovy et al, 2007; Verhoeyen et al., 2002).

To increase carotenoid content in plant crops, structural genes are mainly used, such as a crt B gene (originally from the bacterium *Erwinia uredovora*), whose product is phytoene synthase. When crt B gene is over-expressed in the transgenic tomato, result are increased total carotenoid content of 2.4 times compared to the control (Fraser et al., 2002; Sanghera et al., 2013).

Blocking specific steps in biosynthesis using RNA interference technique

RNA which is complementary with RNA transcript of some gene, is called RNA interference (RNAi). As example of this strategy is tomato *chs*1 gene (encode for the first enzyme in flavonoid synthesis) inhibition and result was decreased activity of chalcone synthase, which finally resulted in 99% reduction of the total flavonoid levels relative to wild type (Schijlen et al., 2007; Bovy et al, 2007).

Potato contains low levels of carotenoids, mainly lutein and violaxanthin which do not have the activity of vitamin. It was managed to increase the level of β-carotene 38 times, and 4.5 times of total carotenoids by blocking *chy1* and *chy*2 genes. Those genes coding for the enzyme β-carotene hydroxylase which is along with ε cyclization of lycopene is a key regulatory step in carotenogenesis of potatoes. Silencing of β-carotene hydroxylase directs metabolic flux towards the formation of β-carotene and lead to dramatic increase in a compound that is a precursor of vitamin A (Diretto et al., 2007; Sanghera et al., 2013; Bovy et al, 2007).

Introducing a novel branches in flavonoid biosynthetic pathway

Stilbens are the most important novel compound that had been introduced in transgenic vegetable. Stilbens are phenolic compound with antioxidant properties, and trans reverstatol is a major compounds. Reverstatol synthesis is controlled by the key enzyme stilben synthase (StSy) that majority of plant doesn't naturally produce. The production of revarstatol should be possible if StSy gen is provided. Revarstatol synthesis in tomato could be achieved by engineering of StSy gen from grape. This enrichment in nutrient content and antioxidant improvement of transgene tomato fruits doesn't affect the content of other phenolic compounds that are normally present in tomato (Giovinazzo et al., 2005; Bovy et al, 2007).

Plant Tissue Culture

The culture of plant cells, tissues or organs can be used, among other, also as a factory for production of antioxidant compounds in specifically formulated nutrient enriched media. A variety of different types of plant tissue cultures can be generated for antioxidant production and the most common used are callus culture, cell suspension culture, and plant organ culture.

In most *in vitro* culture system, the accumulation of biomass and production of the desired products (secondary metabolites) requires various medium conditions. The media composition has to be optimized so it would allow transit from cell growth to a state of production of metabolites (Kirakosyan et al., 2009; Matkowski, 2008).

Production of flavonoid by plant tissue culture

The most important group of flavonoids is flavone C-glycosides, because they are rare in plants and very important therapeutic molecules for disorders related with oxidative stress. It was shown that callus culture of *Passiflora quadrangularis* increase production of flavones when is treated with UV-B irradiation. Antioxidant activities compare to untreated calluses is higher with an increase ranging from 28% to 76% (Antognoni et al., 2007; Matkowski, 2008). Production of anthocyanins was obtained from selected callus cultures of *Ajuga reptans* in darkness and under a light-dark cycle and from cell suspensions culture which could only be established in a light-dark cycle. Anthocyanins which were detected was tentatively identified as a glucosylated cyaniding but the cell suspensions culture was not stable and end up either in low production line or in a complete colorless line (Callebaut et al., 1990; Matkowski, 2008).

Carotenoid production by plant tissue culture

Carotenoid production was achieved by suspension cell culture of *Artemisia annua*. It was found that suspension cell culture of produce carotenoids (lutein) and quinones (Q9 and Q 10) when suspension is treated with 2,6-dimethyl-B-cyclodextrins (DIMEB). Compare to untreated samples of cell suspension, application of elicitors, enhance production up to 2,5-fold of carotenoids and quinones (Rizzello et al., 2014; Matkowski, 2008).

Conclusion

Nutrition and health promotion are always been a priority of humankind. Improving the quality of food, its enrichment with components that act on prevention of chronic diseases is achieved through genetic engineering and breeding transgenic plants. Techniques of plant tissue cultures were investigated through potentials of antioxidants compound to be use in medical purposes, i.e. therapeutic application. The development of modern plant biotechnology is directed to overcoming obstacles in the form of bioavailability of plant products which have antioxidant properties and other useful features through concept of functional foods and nutraceuticals.

Abstract

The aim of this study was to determine the effects of three different commercial yeasts, two different lactic acid bacteria (LAB) as well as addition of oak chips and blocks on quality parameters of Vranac, Kratošija and Cabernet Sauvignon young wines produced in vintages 2012 and 2013. The basic quality parameters of grape must were determined, and a total of 84 wine samples were analysed on quality parameters (alcohol content, total dry extract, pH value, total polyphenols and total anthocyanins).

Addition of different commercial LAB did not significantly influenced wine quality parameters, while oak addition influenced sensory properties of all examined wines. Regarding to Vranac wine, the highest content of polyphenols and anthocyanins was achieved when alcoholic fermentation was inoculated with commercial yeast BM 4x4, while alcohol content and total extract didn’t vary among experimental wines. In Kratošija wines combination of BM 4x4 and ICV D21 with oak blocks showed good results. In Cabernet Sauvignon wines addition of oak chips combination showed good results in all wines, while control wine had significantly lower marks. Results obtained in this study indicate the important role of variety, climate and winemaking techniques in the accumulation of these compounds in wine.

Keywords: *wine, yeast, lactic acid bacteria, oak, polyphenols, anthocyanins, wine quality*

Introduction

Montenegro is country with favourable conditions for viticulture and winemaking, what is confirmed by long tradition of grapevine breeding, where autochthonous varieties (‘Vranac’, ‘Kratošija’, ‘Krstač’ and ‘Žižak’) prevail. Among them, Vranac variety represents about 70% and it is used for production of premium red wines. Vranac has dark red ruby colour, full body, fruity taste and pleasant astringency, potential for aging and maturating in oak. According to Maraš et al. (2000), Ulićević et al. (1966) and Pejović et al. (1988), 'Kratošija' is Montenegrin autochthonous grapevine variety, grown in Montenegro for centuries. Kratošija wine is characterized by an intense ruby-red color and aroma of red berry fruits and an extremely pleasant taste; beside autochthonous, big attention is given to international introduced grapevine varieties, at first place to Cabernet Sauvignon and to its agrobiological, technological and economic characteristics in agro-ecological conditions of sub-region Podgorica.

Diversity of wine quality is quite unique among the products and determined mainly by interaction between grapes, yeast and technology. There are hundreds of different commercially available wine yeast strains that potentially provide a means by which winemakers can tailor their wines for different consumer market segments. For red wine, where non-volatile components that influence colour and mouth feel are critical determinants of style (Mercurio et al., 2010), the role of yeasts in modulation of phenolics may be of equal importance. Wine phenolics are extracted from grape skins and seeds during fermentation, interact with insoluble cell wall material from the grapes (Bindon et al., 2010b), and undergo

a range of chemical transformations during maturation (McRae et al., 2012). Selection of yeast strain has been shown to impact on the concentration of anthocyanins (Monagas et al., 2007; Morata et al., 2006) and other phenolics (Barcenilla et al., 1989; Monagas et al., 2007; Sidari et al., 2001; Torrens et al., 2008) in finished wine.

The role of lactic acid bacteria in winemaking is ambivalent. After alcoholic fermentation, LAB converts L-malate into L-lactate by decarboxylation. The so called malolactic fermentation leads primarily to a biological deacidification, but also to flavour modifications and microbial stabilisation. It has therefore a positive effect on wine quality (Liu, 2002). Even though, malolactic fermentation can occur spontaneously, *Oenococcus oeni* is often used as bacterial starter culture because of its high tolerance against ethanol and acidity.

Wine ageing is a well-known winemaking practice for improving wine quality and organoleptic characteristics. This practice modifies wine composition due to the compounds extracted from the wood and to chemical reactions that take place when oxygen passes through the wood pores or staves. Ageing wines in wood is expensive and barrels take up a lot of space in the winery and their lifetime is not too long. For this reason new inexpensive techniques have been developed to simplify the ageing process, while ensuring that the wood-related volatiles are released into the wine and with sensory properties similar to wines aged in barrels. These alternatives include oak chips, shavings and larger pieces of oak (Hooper and Marks, 1992). These alternatives to oak ageing have been an extended practice in the USA, Australia and other countries, such as Chile, for several years, but it was not a legal practice in EU countries until October 2006 when the EU approved the use of wood chips in winemaking and the designation and presentation of wine so treated (Commission Regulation (EC), 2006). The regulation states that “the pieces of oak wood” must come exclusively from the *Quercus* genus.

The aim of this study was to determine the effects of three different commercial yeasts, two different lactic acid bacteria (LAB) as well as addition of oak chips and blocks on quality parameters of Vranac, Kratošija and Cabernet Sauvignon young wines produced in vintages 2012 and 2013.

Material and methods

The trial was carried out during the 2012 and 2013 growing seasons. Autochthonous grapevine varieties Vranac and Kratošija, as well as, introduced one Cabernet Sauvignon were planted in the commercial vineyard of the company “13. Jul Plantaže” in the Cemovsko field in sub-region Podgorica (Montenegro).

Grapes of varieties Vranac nad Kratošija were planted in2003, grafted onto Paulsen 1103 rootstock, trained to a modified single Guyot training system, rows spaced 2.6 m apart and with 0.7 m between plants in the row. The grapevines of Cabernet Sauvignon were planted in 2006 (clone VCR 8), grafted onto Paulsen 1103/107 rootstock and trained to a single Guyot training system. The vine had a between-row and within-row spacing of 2.60 m x 0.70 m. All standard agro-technical operations were applied and vineyards were in good and healthy condition.

Wines were produced on a microvinification scale in the experimental cellar at the company “13. Jul Plantaže”. At harvest, grapes from all examined varieties were harvested manually and transported to the experimental cellar. Alcoholic fermentation of all trial was performed in PVC barrels using traditional method. For the vinification of control wines, an average grape sample of both varieties was 100kg of grapes. For trials with yeast addition we used an average grape sample of both varieties as follows: 400 kg of Vranac nad Kratošija varieties and 320 kg of Cabernet sauvignon variety. Potassium metabisulfite, purchased from Agroterm KFT, Hungary was added; 8 g 100 kg^{-1} of grapes from both varieties. All enzyme, wine yeasts, lactic acid bacteria and yeast nutrients were obtained from Lallemand, Australia. Three commercial yeasts, dominantly used for production of red wines, were chosen to induce

alcoholic fermentation. Within both varieties commercial yeasts that were used are: Enoferm BDX, Lalvin BM4x4 and Lalvin ICV D21 (30 g hL^{-1}). Enzyme Lalvin EX-V for maceration (2 g 100 kg^{-1}) and yeast nutrient Go-ferm protect (30 g hL^{-1}) were added during vinification, while yeast nutrient Fermaid E (25 g hL-1) was added during fermentation of both varieties. After alcoholic fermentation; wines were racked and separated in three same quantities for malolactic fermentation (two with different commercial LAB and one without addition of LAB). Commercial lactic acid bacteria that were used are: Enoferm ALPHA and Lalvin VP41. After completion of malolactic fermentation wines were racked, again separated in three same quantities for three months aging with oak alternatives, medium toasted (chips, blocks and control) produced by Toneleria Nacional. Also potassium metabisulfite was added in amount depending of free SO_2 in analyzed wine samples.
For determination of basic wine chemical parameters: alcohol, total acidity, tartaric acid, pH value, total dry extract, total and free SO2 the reference methods of European Union (Commission regulation (EEC) No. 2676/90 determining, 1990) were used. Total polyphenols and anthocyanins content were determined by spectrophotometer. Total polyphenols were quantified by Folin-Ciocalteu index method (Compendium of international methods of wine and must analysis-OIV, 2014). The total anthocyanins were determined using the pH differential method Giusti and Wrolstad (2001).

Results and discusion

Grape quality

Quality parameters of examined grape varieties are shown in Table 1. Vranac variety is known as variety with high total anthocyanin content, what is confirmed in this research. In average, Kratošija accumulates high content of sugar; low anthocyanins content and high total acidity is its varietal characteristics. Cabernet Sauvignon variety confirmed its high polyphenolic potential; however the larger berry size of Vranac and Kratošija in comparison to Cabernet Sauvignon dilutes the content of polyphenols in grapes (Pajović et al., 2014). Based on achieved results it can be concluded that Cabernet Sauvignon variety achieve good results in agro-ecological conditions of sub-region Podgorica.

Meteorological data

In vintage 2013 the average air temperature in June was 23.3 °C, while in July and August was 27.2 °C and 26.9 °C, respectively (*Boreas*, agrometeorological station). Comparing average air temperatures during grape ripening (June, July and August), in 2012 the temperature was lower for 2.08, 1.45 and 0.20, respectively. In this period the total amount of rainfalls in 2013 were 153 L/m² and didn't distinguish so much from the climate normal, but it was much higher comparing to 2012, when during the same time the amount of rainfalls was 46.5 L/m². Unfavourable period was in the third decade of August when during the four

rainy days fell 84 L/m² of rain, and it could affect the quality of the yield, in contrast to August 2012, when the extreme temperatures in the same month (0.5 mm of rainfall) caused dehydration and premature harvesting berries.

Table 2. Average monthly air temperature (°C) in 2012 and 2013

	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
2012	4.9	3.0	13.3	14.5	19.9	27.3	30.4	29.7	23.9	18.2	13.3	5.6

Wine quality

Quality parameters of examined wines are shown in Tables 4-6. Vranac achieved higher content of alcohol, total extract, total polyphenols and anthocyanins in 2013. The highest content of polyphenols and anthocyanins is achieved when alcoholic fermentation was inoculated with commercial yeast BM 4x4, while alcohol content and total extract didn't vary among experimental wines. Addition of different commercial LAB did not significantly influenced wine quality parameters among all examined wines. Oak addition influenced sensory properties of all examined wines (Graphs 1-3). Vranac wines showed potential for aging with oak chips and blocks, especially when alcoholic fermentation was inoculated with BM 4x4 and ICV D21.

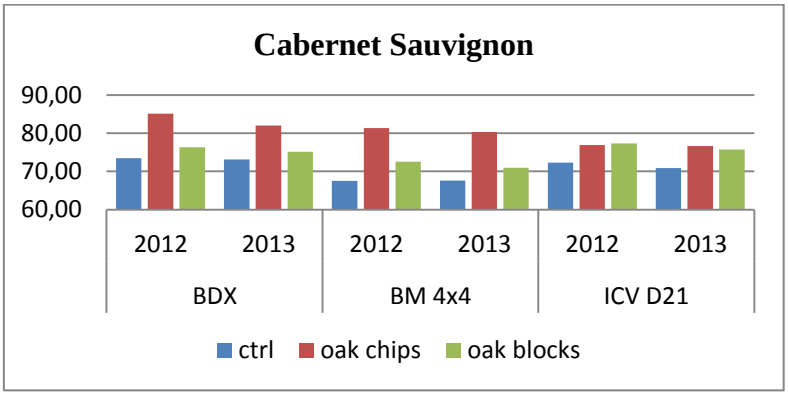

Graph 3. Sensory evaluation of Cabernet Sauvignon wines

Conclusion

This kind of research can be very useful to winegrowers and winemakers, in order to provide proper procedure for wine quality improvement. Regarding to Vranac wine, the highest content of polyphenols and anthocyanins was achieved when alcoholic fermentation was inoculated with commercial yeast BM 4x4, while alcohol content and total extract didn't vary among experimental wines. Addition of different commercial LAB did not significantly influenced wine quality parameters, while oak addition influenced sensory properties of all examined wines. Within Kratošija wines quality parameters it is noticed that there is no significant differences among used yeast and LAB, while they influenced sensory properties of its wine. In Kratošija wines combination of BM 4x4 and ICV D21 with oak blocks showed good results, while when BDX was used control wines had better sensory evaluation. Cabernet Sauvignon wines quality parameters also did not show significant differences among used yeast and LAB, while they influenced sensory properties of its wine. In Cabernet Sauvignon wines addition of oak chips combination showed good results in all wines, while control wine had significantly lower marks. Results obtained in this study indicate the important role of variety, climate and winemaking techniques in the accumulation of these compounds in wine.

COEFFICIENT SURFACE SPRAYED PLANTS: POTENTIAL TOOL OF EFFICIENCY PLANT SPRAYING

Katarzyna DEREŃ*, Antoni SZEWCZYK, Beata CIENIAWSKA, Tomasz KLIMZA

Wroclaw University of Environmental and Life Sciences, Institute of Agricultural Engineering, Poland
*Corresponding author: katarzynaderen@gmail.com

Abstract

The objective of the paper was to evaluate the average coverage of sprayed plants depending on coefficient surface sprayed plants (W_{po}). Research was conducted in the laboratory at the Institute of Agricultural Engineering at the University of Life Sciences in Wroclaw (Poland) in 2015 years. The experiment was performed in three stages. In the first stage was defined the horizontal and vertical surface of the plants in order to determine the characteristics of the spray plant. To this was used specially constructed research position to which allowed taking pictures of the plants from all sides. The size of the surface projections is obtained by developing images in a graphics program AutoCad. The collected results allowed determining the coefficient of surface spray (W_{po}) adopted by the authors as a criterion that determines the number of spray characteristics of plants.

Then determined the degree of coverage of horizontal and vertical surfaces of plants. In research used four types sprayers: two standard and two ejector. Objects which were sprayed with artificial plants on which was mounted water sensitive papers. In order to determine the degree of covering, the papers were subjected to computer image analysis. Plants were sprayed at a constant operating speed (8 $km \cdot h^{-1}$) and the two pressures of 0,2 and 0,4 MPa. In the third stage of the research designated the average degree of coverage plants in the aspect of designated for him spraying the surface coefficient (W_{po}).

Analysis of the results led to the conclusion that the coefficient surface sprayed plants (characterized by the sprayed plant and its stage of development), may be helpful in selecting the right kind of sprayer to perform the surgery spraying plants.

Keywords: *average degree of coverage, sprayer type, spraying plants, the quality of the spray treatment*

Introduction

The quality of a spraying depends primarily on the degree of coverage of the liquid spray application as well as the uniformity of covering and the application of the liquid sprayed plants. The quality of a spraying depends primarily on the degree of coverage of the liquid spray application as well as the uniformity of covering and the application of the liquid sprayed plants. One of the deciding factors for obtaining the best quality, and thus the effectiveness of the treatments spraying is to choose the right type of surgery performed sprayer (Hołownicki et al., 2002; Lipiński et al., 2007; Godyń et al., 2008; Szewczyk et al., 2012). The indicators cannot fully assess the quality of surgery performed spraying, however allow compare used for surgery equipment and its accessories (types and kinds of nozzles).

Till now research showed that there is a correlation between the degree of coverage and the effectiveness of the biological treatment plant protection products. According to some scientists to provide plant protection against pests, degree of coverage of the plants through sprayer liquid should be at least 30% (Hołownicki et al., 2002). The research is not clear about what cover parts of plants going on and whether the value refers to the average degree of coverage calculated with reference to all components of the sprayed plants. In studies degree of coverage as samplers are most frequently used papers water sensitive. These samplers can be used for research in the field (Lipiński et al., 2007) and laboratory (Foque et

al., 2012). They are mounted directly to a lamina of the test plants. In the laboratory water sensitive papers are also trailed on artificial plants (Szewczyk et al., 2012). The advantage of artificial plants is always constant, the predetermined position of samplers in the space, that the results for research like this in authors opinion, are reproducible and comparable (Szewczyk, 2010).

Additional information in the assessment of a spraying plant may provide the user with spraying parameters such as - the average coverage of sprayed objects, and the spray characteristics of the plant, which defines the surface projections at different stages of development of the plant (Łuczycka et al., 2014).

Therefore, at the Institute of Agricultural Engineering at the University of Life Sciences in Wroclaw (Poland) we carried out the study whose aim was to determine the effect of the sprayed plants surface coefficient (W_{po}), on average cover plants taking into account the nature and type of sprayer used to spray treatment.

Materials and methods

Research was conducted in the laboratory at the Institute of Agricultural Engineering at the University of Life Sciences in Wroclaw (Poland) in 2015 years. The research was conducted in three stages. In the first step determined horizontal and vertical projected surface of plants, and then set the coefficient surface sprayed plants (W_{po}). The coefficient determined for the following crops: white beet in development 8 leaves and the initial phase of covering the spacing, rape in the phase formation of rosettes and shoot elongation phase, corn on the stages of development of the fifth leaf and the fifth node and potato in the early phase leaf growth and the creation of side branches.

Overall view and a schematic position of the spray characteristics of the test plants are shown in figure 1.

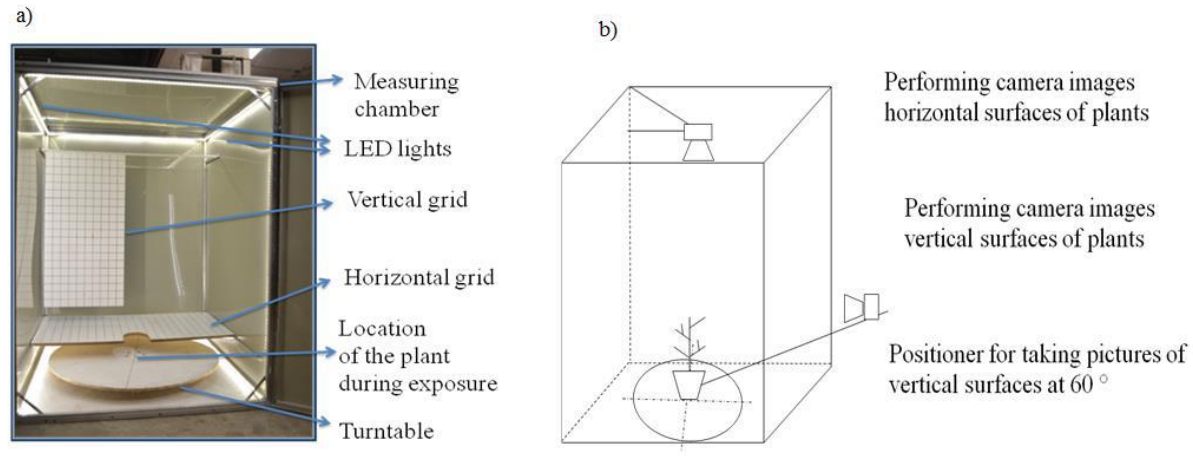

Fig.1 Position to study the characteristics of a plant spray a) general view, b) scheme (Source: own study)

Examined plants were placed into the measuring chamber on a turntable and rotating disc, every 60 degree were made pictures of the surface of vertical projections. In the horizontal surfaces camera placed over the center of the chamber and moved in a position up - down and front - back, depending on the size of the examined plants. The surface ratio of the examined plants was analyzed, so the distance between the camera and the plant did not make difference. The background of the surface plants was grid, where one side of the square had a dimension of 5 cm. As a result, with further analysis of photographs in a graphics program AutoCad read precisely the size of the surface projections of the test plants.

After reading the surface projections of plants, according to the formula 1 -calculated W_{po} for the various phases of development of plants. Surface values of vertical and horizontal projections of plants and W_{po} for the various phases of development are shown in table1.
The second stage of the research was to determine the degree of coverage of horizontal and vertical samplers. Samplers were water sensitive papers that were placed on artificial plants respectively on surfaces: horizontal (upper and lower) and vertical (inrun, departure, left and right).

$$W_{po} = \frac{projection\ vertical\ surface}{projection\ horizontal\ surface}\ [-]\ (1)$$

For testing selected four nozzles: standard (one-stream sprayers XR 11002 and two-stream sprayers DF 11002) and air induction sprayer (one-stream sprayers CVI 11002 and two-stream sprayers CVI TWIN 11002), and adopted the following operating parameters: a constant operating speed of the sprayer V =8 km·h^{-1}; various pressure: 0,2 and 0,4 MPa for which capability nozzles amounted to 0,65 l · min^{-1}and 0,91 l · min^{-1}; the height of the nozzles 0,5 m from sprayed objects. The scheme of test stand the degree of coverage shown in fig.2.

Table1. Characteristics of the spray plants

Cultivated plants	Development phase	Characteristics of the spray plants		
		Projection vertical surface [cm²]	Projection horizontal surface [cm²]	W_{po} [-]
White beet	8leaves	415,99	174,64	2,38
	beginning covering spacing	1470,34	612,90	2,40
Rape	forming rosette	190,80	89,40	2,13
	elongation shoot	1734,43	981,90	1,77
Corn	the fifth leaf development	354,47	116,70	3,04
	development of the first node	470,92	163,20	2,89
Potato	beginning leaf growth	68,70	55,30	1,24
	creation of side branches	2100,86	1078,90	1,95

Sprayers during the study time on the strictly designated track driving, which consisted of three parts (figure 2): a - run line, b - a measurement line, c - ending line. On the measuring placed three artificial plants. Degree of coverage was determined using a computerized image analysis method (in Adobe Photoshop). On the water sensitive papers three random selected parts on an area of 1 cm² was marked, which was read value of the surface covered with liquid during spraying. Then the formula 2 calculated the degree of coverage.

$$P_{sp} = \frac{W_k \times 100}{W_p}\ [\%]\ (2)$$

where:
P_{sp} – the degree of coverage of tested objects [%],

W_k – surface covered with liquid [piksele],
W_p – surface samples from 1cm² [piksele].

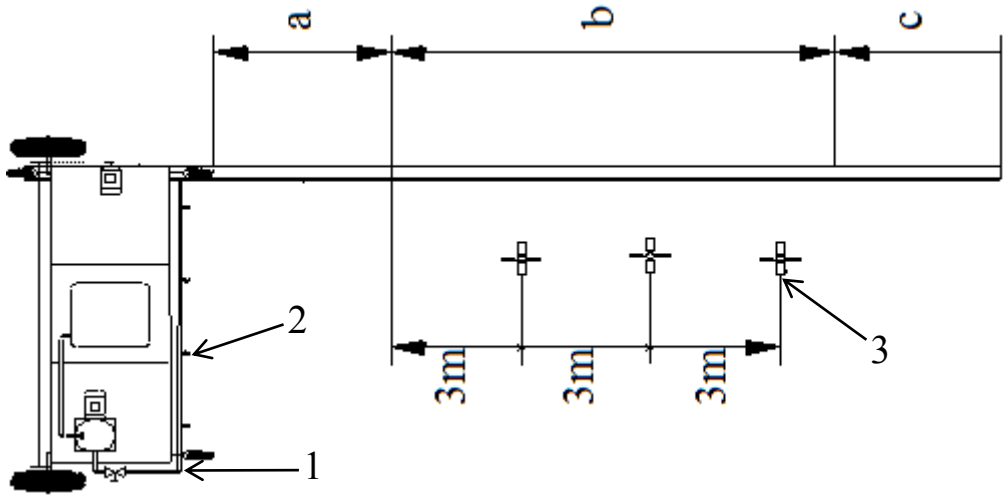

Fig.2. Schematic representation of the measurement stand: a – run line, b – a measurement line, c – ending line, 1 – sprayers carrier, 2 – nozzles, 3 – an artificial plant (Source: own study)

In the third stage of the research on the basis of the formula 3 determined the average coverage of sprayed objects.

$$P_{śr} = \frac{P_c}{\sum \text{projections vertical and horizontal surfaces}} \times 100\ [\%] \quad (3)$$

where:
$P_{śr}$ – the average coverage of sprayed objects [%], P_c – cover complete [cm²].
Complete cover (P_c) is the sum of those parts of the vertical and horizontal surfaces plants which have been covered with liquid during a spraying.

Results and discussion

The results of the average coverage for the test phase of development of individual plants and specific surface coefficient spray nozzles for pressure of 0,2 MPa is shown in figure 3, while the pressure of 0,4 MPa in figure 4.

The highest values of the average coverage at a pressure of 0,2 MPa was recorded for standard sprayer XR, the smallest whereas for sprayer air induction (two-stream) CVI TWIN. When the best average coverage for higher pressure (0,4 MPa) obtained for a standard (two-stream) DF, the weakest for CVI TWIN sprayer. After increasing the pressure to 0,4 MPa has also been observed general increase in the average coverage. eg. for potato in the beginning stage of development leaves (W_{po}= 1,2), the average coverage increased by approx. 6%.

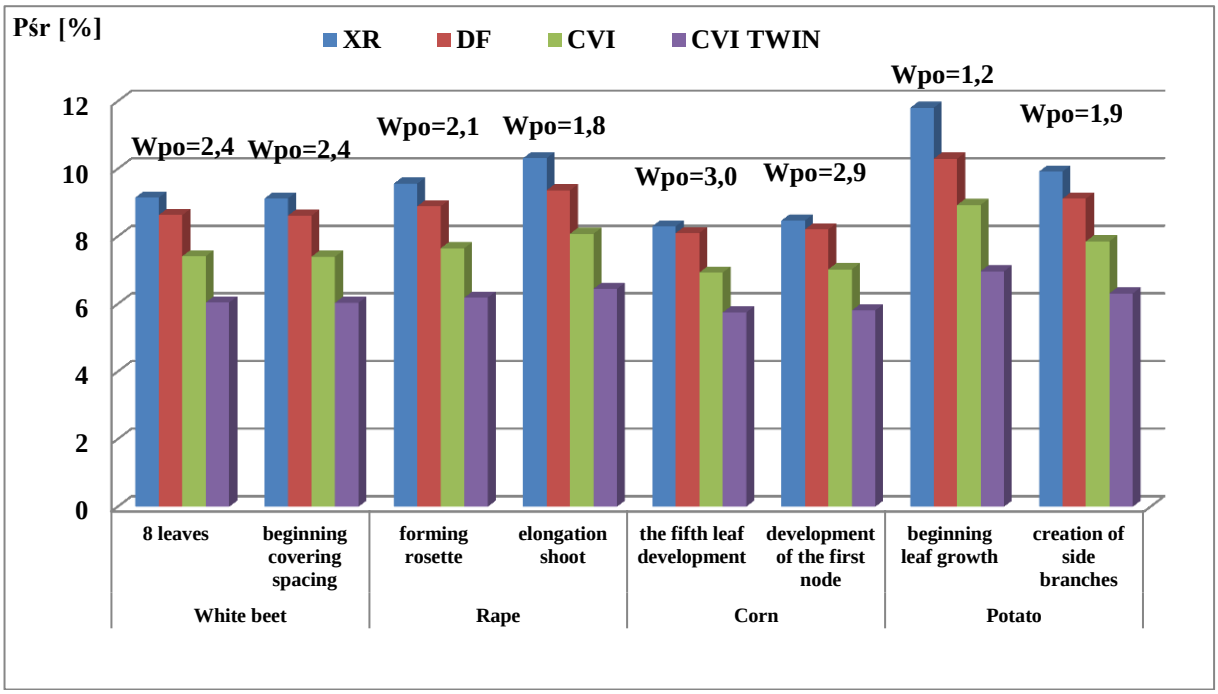

Fig. 3. Average coverage for selected phases of plant development and specific (W_{po}) tested spray nozzles at a pressure of 0,2 MPa (Source: own study)

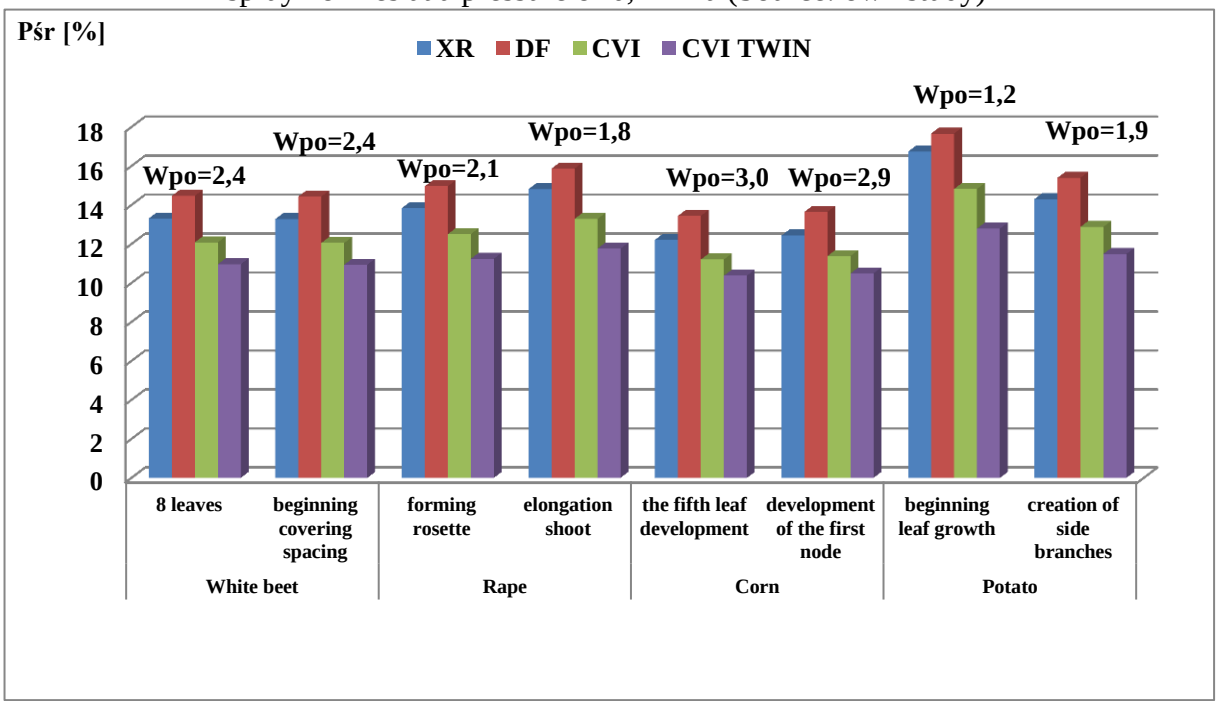

Fig. 4. Average coverage for selected phases of plant development and specific (W_{po}) tested spray nozzles at a pressure of 0,4 MPa (Source: own study)

The analysis graphs also show that the higher the value of the spray surface, (ie. the plant has more vertical surface), the lower the note value of average coverage. When the plant is characterized by a higher proportion of horizontal surfaces (lower values W_{po}), the higher the recorded value of average coverage of sprayed plants.

Conclusion

Based on the results obtained from the research and analysis the following conclusions: Adopted spray surface coefficient (W_{po}), characterized by the plant and its stage

of development have a decisive effect on the average coverage sprayed object.When the (W_{po}) obtained lower values (ie. the larger the surface area of the horizontal projection) is preferable to use spray nozzles standard, and when a definite advantage to vertical surfaces may be considered the use of standard dual stream nozzles, and in worse weather conditions ejector nozzles.

Abstract

Triticale is a man-made crop obtained by crossing the wheat with rye. Among the characteristics that make this species of interest are the high yields of grains and biomass in a great diversity of climatic conditions and crop technologies with low inputs. The aim of the paper is to present the dry biomass yield and biomass moisture content at different varieties of triticale studied under different soil tillage conditions, different preceding crops, and different nitrogen application variants. In this respect, there were studied two varieties of triticale (Gorun 1 and Tulus) under the following technological conditions: two soil tillage, respectively ploughing and harrowing; two preceding crop, respectively sunflower and maize; six nitrogen application variants, respectively 0+0+0 kg.ha^{-1}, 40+40+40 kg.ha^{-1}, 40+80+0 kg.ha^{-1}, 0+40+80 kg.ha^{-1}, 0+80+40 kg.ha^{-1}, and 0+120+0 kg.ha^{-1}. Researches were performed in the agricultural year 2013-2014, in field experiments located in South Romania, respectively at Moara Domneasca Experimental Farm (44^{o}29’44’’ North latitude and 26^{o}15’28.5’’ East longitude) belonging to the University of Agronomic Sciences and Veterinary Medicine of Bucharest, on a reddish preluvosoil. The biomass determinations were performed at early dough growing stage. In the case of sunflower as preceding crop, the highest dry biomass yields were obtained for the nitrogen fertilization of type 40+40+40. For the soil tillage harrowing, when sunflower is the preceding crop for triticale, it was remarked also the nitrogen fertilization variant of type 40+80+0. In the case of maize as preceding crop and the soil tillage harrowing, the highest dry biomass yields were obtained for the nitrogen fertilization of type 0+120+0.

Key words: *triticale, dry biomass, soil tillage, preceding crop, nitrogen.*

Introduction

Triticale (*Triticosecale* Wittmack) is a man-made crop obtained by crossing the wheat with rye. It was designed in order to obtain a cereal which combines the good quality and high yielding capacity which is specific for the wheat with the tolerance to abiotic and biotic stress factors which is specific for the rye. Among the characteristics that make this species of interest are the high yields of grains and biomass in a great diversity of climatic conditions and crop technologies with low inputs. Triticale is able to resist some unfavourable biotic and abiotic environmental factors and thus produce good yield in marginal regions (Martinek et al., 2008; Lalević et al., 2012). Drought and frost tolerance are the primary advantages that triticale has over the other cereal crops and thus it reduces weather risk (Loha at al., 2007). In the specific growing conditions from South Romania this species is used for grain yields but also for producing biomass. The area from South Romania provides favourable growing conditions for triticale (Dumbrava et al., 2014). Triticale biomass was firstly of interest as fodder, but it has become also of interest as raw material for producing biogas (Ion et al., 2014). For biogas production, triticale should be harvested in the vegetation stage “grain in the milk stage” to “grain in the dough stage” (Amon et al., 2007). Understanding the

fertilization effect has been a continuous endeavour toward improving fertilization technology and strategy to reduce the negative impacts to increase the crop yield (Janušauskaitė, 2013). Nitrogen fertiliser application at different plant stages has an essential effect on the height of stems and grain yield quality (Alaru, 2004), and it is supposed to have an essential effect on the dry biomass yield. Also an essential effect on the dry biomass yield it is supposed to have the soil tillage and preceding crop.

The aim of the paper is to present the dry biomass yield and biomass moisture content at different varieties of triticale studied under different soil tillage conditions, different preceding crops, and different nitrogen application variants.

Materials and methods

Researches were performed in the agricultural year 2013/2014 in field experiments located in South Romania, these being implemented in the specific conditions from Moara Domneasca Experimental Farm (44°29'44'' North latitude and 26°15'28.5'' East longitude) belonging to the University of Agronomic Sciences and Veterinary Medicine of Bucharest. In the studied area, the specific soil is reddish preluvosoil. In this area, during the nine months of interest for triticale, respectively from September 2013 to June 2014, the average temperature was 9.5°C, while the multiannual average temperature is 8.5°C. The sum of rainfall was 572 mm, while the multiannual average rainfall is 408.9 mm. There were studied two varieties of triticale (Tulus and Gorun 1) under the following conditions: two soil tillage, respectively ploughing and harrowing; two preceding crops, respectively sunflower and maize; six nitrogen application variants, respectively 0+0+0 kg.ha^{-1}, 40+40+40 kg.ha^{-1}, 40+80+0 kg.ha^{-1}, 0+40+80 kg.ha^{-1}, 0+80+40 kg.ha^{-1}, and 0+120+0 kg.ha^{-1}. For the experimental variants having maize as preceding crop, we were not able to take valid samples of plants from the variants with soil tillage ploughing because of the high plant heterogeneity due to the poor and staggered plant emergence. For the variants with ploughing as soil tillage, one harrowing work was performed on 26th of September 2013, and the ploughing was performed at a depth of 18 cm two days later, on 28th of September 2013. For the variants with harrowing as soil tillage, two harrowing works were performed on 26th of September 2013, at a depth of 12 cm. Soil bed preparation was performed on 29th of October 2013, with a seed bed cultivator with two passages for the variants with ploughing and with one passage for the variants with harrowing. The sowing was performed in the same day as seed bed preparation, at 12.5 cm row spacing and at a density of 600 germinal seeds per square meter. Nitrogen applications were the following: first application in the autumn, before seed bed preparation (on 29th of October, 2013); second application in the spring, in the tillering growing stage (on 14th of March, 2014); third application in the spring, in the two nodes growing stage (on 26th of April, 2014). In the spring, the weed control was realised by applying the herbicide Dicopur Top 464 SL (344 g/l acid 2.4 D from SDMA + 120 g/l dicamba) at a rate of 1 l.ha^{-1}, the treatment being performed on 2nd of April 2014. The biomass determinations were performed at early dough growing stage. In this respect, the plants from 0.5 square meters, respectively four rows of plants on 1 m length were cut at soil level and were weighed immediately in the field. This procedure was performed in four replications for each experimental variant. For each experimental variant, ten average plants were taken and weighed immediately in the field and then dried in the laboratory into the oven at 80°C for 24 hours for determining the dry biomass and moisture content. The obtained data were statistically processed by analyses of variance. The yield of dry matter was calculated in tons.ha^{-1} and represents actually the yield of above-ground biomass.

Results and discussion

The highest dry biomass yield (expressed as above-ground biomass) was registered for Tulus variety (17.97 t.ha^{-1}) when the preceding crop was sunflower, the soil tillage was ploughing,

and the nitrogen fertilization was 0+40+80 (0 kg of N.ha^{-1} in autumn, 40 kg of N.ha^{-1} in the tillering growing stage, and 80 kg of N.ha^{-1} in the two nodes growing stage). But, for the Gorun 1 variety, the highest dry biomass yield (19.16 t.ha^{-1}) was registered when the preceding crop was maize, the soil tillage was harrowing, and the nitrogen fertilization was 0+120+0 (Figure 1). These data put into evidence the different reaction of the triticale variety to the technological measures. This idea is sustained also by the average values of the dry biomass yield at different nitrogen application variants. Thus, when the preceding crop was sunflower, the average dry biomass registered at different nitrogen application variants at Tulus was higher when the soil tillage was ploughing (15.45 t.ha^{-1}) compared to harrowing (13.32 t.ha^{-1}), while at Gorun 1 on the contrary the average dry biomass was higher when the soil tillage was harrowing (13.92 t.ha^{-1}) compared to ploughing (12.97 t.ha^{-1}).

In the variants with sunflower as preceding crop and when the soil tillage was ploughing, the highest dry biomass yields for Tulus variety was registered at nitrogen fertilization of 0+40+80 (17.97 t.ha^{-1}) and of 40+40+40 (17.60 t.ha^{-1}), in both cases with differences very significant compared to control represented by unfertilised variant (0+0+0). For Gorun 1 variety, the highest dry biomass yield was registered at nitrogen fertilization of 40+40+40 (16.04 t.ha^{-1}), with a difference significant compared to unfertilised variant (0+0+0). The high dry biomass yields registered at an application of nitrogen of 40+40+40 (autumn+early spring + later spring) put into evidence the importance of a well balanced nitrogen fertilization for triticale when the sunflower is the preceding crop and when the soil tillage is ploughing.

In the variants with sunflower as preceding crop and when the soil tillage was harrowing, the highest dry biomass yields for both triticale varieties (Tulus and Gorun 1) were registered at nitrogen fertilization of 40+80+0 (14.74 t.ha^{-1} for Tulus and 18.05 t.ha^{-1} for Gorun 1) and of 40+40+40 (14.56 t.ha^{-1} for Tulus and 16.83 t.ha^{-1} for Gorun 1). For both varieties and nitrogen fertilization variants the differences compared to unfertilised variant (0+0+0) were very significant. Compared to Gorun 1, at Tulus the difference very significant compared to unfertilised variant was registered also at nitrogen fertilization of 0+80+40 (15.64 t.ha^{-1}).

In the variants with maize as preceding crop and when the soil tillage was harrowing, the highest dry biomass yields for both triticale varieties were registered at nitrogen fertilization of 0+120+0 (14.54 t.ha^{-1} for Tulus and 19.16 t.ha^{-1} for Gorun 1), with differences very significant compared to unfertilised variant (0+0+0). This means that after maize as preceding crop, the highest dry biomass yields were registered when the nitrogen was applied in one application of 120 kg.ha^{-1}, early in spring (in the tillering growing stage), without nitrogen application in autumn or later in spring (in the two nodes growing stage).

The nitrogen fertilization variant of 0+40+80 determined the smallest dry biomass yields when the soil tillage was harrowing at both triticale varieties for sunflower as preceding crop (11.15 t.ha^{-1} for Tulus and 9.98 t.ha^{-1} for Gorun 1), and at Gorun 1 also for maize as preceding crop (13.76 t.ha^{-1}). These small dry biomass yields are determined by the lack of nitrogen in the autumn, less nitrogen applied early in spring (in the tillering growing stage) and the less efficient use of the high nitrogen rate applied later in spring (in the two nodes growing stage).

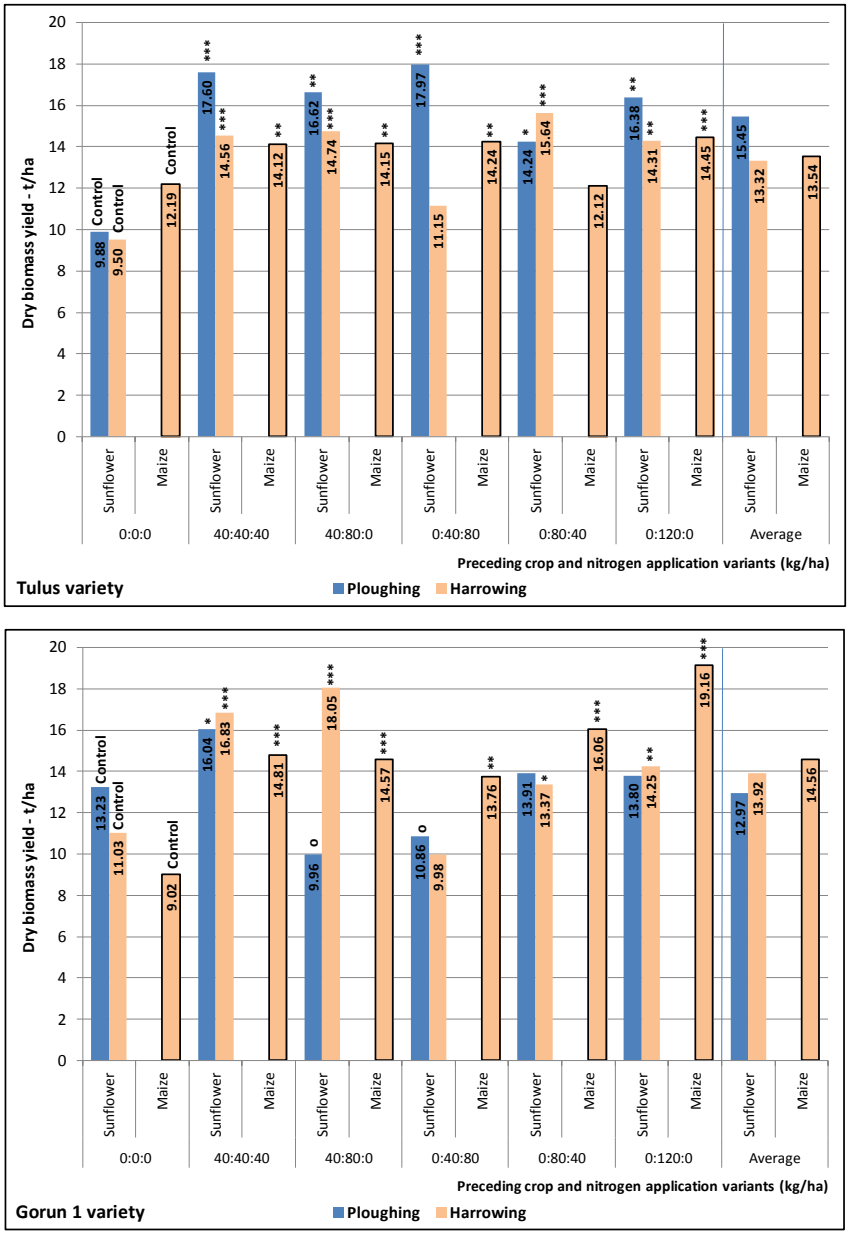

Figure 1. Dry biomass yield at Tulus and Gorun 1 triticale varieties under different soil tillage, preceding crops and nitrogen application variants

Nitrogen application of 0+40+80 with soil tillage harrowing and sunflower as preceding crop determined the highest values of the biomass moisture content for both studied varieties (Tulus and Gorun 1), respectively 49.42% for Tulus and 47.86% for Gorun 1. Also a high value of the biomass moisture content was registered under the same experimental conditions for maize as preceding crop, respectively 41.16% for Tulus and 40.85% for Gorun 1 (Figure 2). This is explained by the fact that the high nitrogen rate applied late in spring (in the two nodes growing stage) keeps the plants green, respectively the vegetative plant components.

The smallest values of the biomass moisture content (respectively the driest plants) were registered for both triticale varieties when the preceding crop was sunflower and when the soil tillage was ploughing, but at nitrogen application of 0+80+40 for Tulus variety (22.59%) and at nitrogen application of 40+40+40 for Gorun 1 variety (19.26%). It has to be emphasised that also for Gorun 1 variety the nitrogen application of 0+80+40 with soil tillage ploughing determined a small value of the biomass moisture content, respectively 22.74% (Figure 2).

When the preceding crop was sunflower, for both triticale varieties the average biomass moisture content was smaller when the soil tillage was ploughing than when the soil tillage was harrowing. When the soil tillage was harrowing, for both triticale varieties the average biomass moisture content was smaller when the preceding crop was maize than when the preceding crop was sunflower.

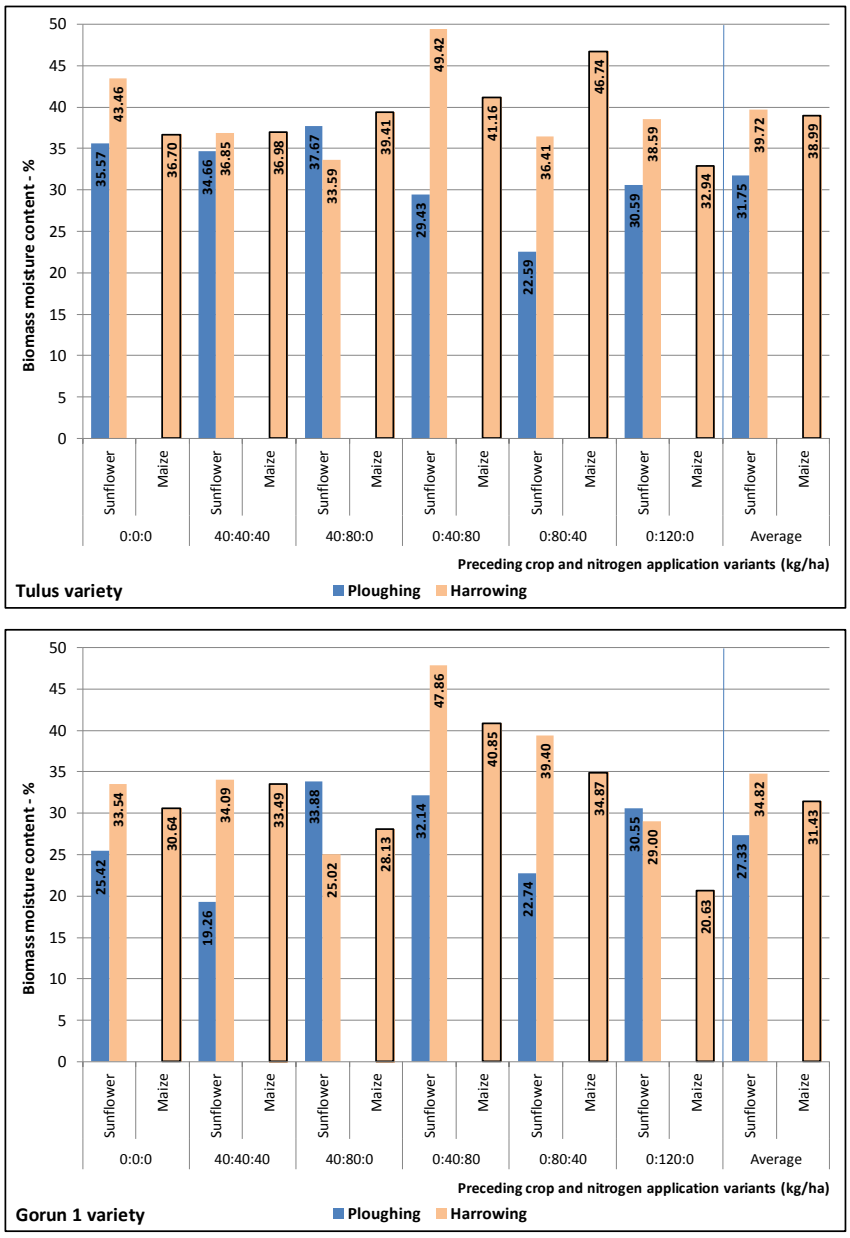

Figure 2. Biomass moisture content at Tulus and Gorun 1 triticale varieties under different soil tillage, preceding crops and nitrogen application variants

Conclusion

Taking into account the data we have obtained one can conclude that triticale varieties react different to the technological measures.

In the case of sunflower as preceding crop for triticale, the highest dry biomass yields were obtained for the nitrogen fertilization of type 40+40+40 (autumn + early spring + later spring) both for soil tillage ploughing and harrowing. For the soil tillage harrowing, when sunflower is the preceding crop for triticale, it was remarked also the nitrogen fertilization variant of type 40+80+0.

In the case of maize as preceding crop for triticale and the soil tillage harrowing, the highest dry biomass yields were obtained for the nitrogen fertilization of type 0+120+0.
In the case of soil tillage harrowing, the nitrogen fertilization variant of 0+40+80 determined the smallest dry biomass yields, this being a consequence of the lack of nitrogen in the autumn, less nitrogen applied early in spring (in the tillering growing stage), and less efficient use of the high nitrogen rate applied later in spring (in the two nodes growing stage).
Nitrogen fertilization variant of 0+40+80, with high nitrogen rate applied later in spring (in the two nodes growing stage), kept the plants green, which determined the highest values of the biomass moisture.
Nitrogen fertilization variant of 0+80+40, in the case of soil tillage ploughing and with sunflower as preceding crop determined the smallest values of the biomass moisture (respectively the driest plants).
In the case of sunflower as preceding crop, the average biomass moisture content was smaller when the soil tillage was ploughing than when the soil tillage was harrowing.
In the case of soil tillage harrowing, the average biomass moisture content was smaller when the preceding crop was maize than when the preceding crop was sunflower.

MORPHOLOGICAL PLANT PROPERTIES OF SWEET CORN CULTIVATED WITH DIFFERENT TECHNOLOGIES

Ferenc OROSZ

Sapientia University, Department of Horticulture, 540485 Targu Mureș, Șoseaua Sighișoarei 1C, Romania
*Corresponding author: oroszferenc67@gmail.com

Abstract

Aim of experiment set up in 2013, to study evoluation of sweet corn growing period with application of some technological elements: propagation time, propagation method, floating row cover. The choosen variety was a conventional sweet corn hybrid, very early ripening 'Spirit'. The following growing technologies were compared: 1. direct sowing of plants with floating row cover, early period 2. direct sowing of plants without row cover, early period 3. plants transplantation with floating row cover, normal period and 4. direct sowing of plants without row cover, normal period (regarded as control).

It was studied the influence of above mentioned technological elements on some important morphological properties of sweet corn plant: evolution of phenological phases, plant highness, tassels length, ear weight, highness of ear insertion.

Key words: *earliness, sweet corn, transplantation, fleece covering*.

Introduction

Based on its present growing area, the sweet corn is the vegetable which is grown on the greatest area in Hungary. After dates of Hungarian Fruit & Vegetable Interprofessional Organization in 2003 the growing area was about 38,000 hectares. After 2003 followed a suddenly and sharp decline. After diminishing, the plant returned in rise, in 2006 against over 30,000 hectares. The recession mentioned above affected not only Hungary but also the holdings of the USA and Western Europe. In the case of the former, however, the increase in fresh consumption partly counterbalanced the rate of decrease. Near 50% of world sweet corn production came from US (Slezák *et al.*, 2012). In 2013 the growing area was 34, 000 hectares, less with 1000 ha, compared to 2012 (Avar, 2013).

In order to promote fresh consumption, as well as to maintain and increase the sweet corn exports, it is necessary to promote investigations so as to be able to ensure a further increase in the growing area and yields of sweet corn with the help of the experiences. The literature mainly is concerned with maize growing technology, but a lot of dates could be used by sweet corn. Of the production technology elements, a number of researchers studied or are currently studying the sowing time of sweet corn.

As early as at the ending of 19^{th}- and the beginning of the 20^{th} century some researchers (Cserháti, 1901) highlighted the importance of the sowing date. Ripening can occur earlier when sowing earlier and using high quality seeds as compared to normal or late sowing. I'só (1969) and Pásztor (1966), after their multi-year sowing date trial, concluded the following: in the case of an earlier sowing seed germination will be more protracted, but silking and harvesting occur sooner than by lately sowing time. After multi-year trial Berzsenyi et al (1998) have studied the effect of different sowing times on maize development.

Several techniques are known in the art for the purpose of early fresh market shipments: seedling growing or direct seeding with temporary plant cover (Hodossi, 2004).

About the covered early sowing as a technological variation Aylswirth (1986) mentioned, that from an early sowed crop, made in first week of April, arranged in twin rows (42 cm) and covered by plastic, we could harvested marketable cobs by the fourth of July. In case of direct

sowing, as propagation method, another earliness increasing solution is the temporary covering with plastic or vlies, used in different combinations (Hodossi and Kovács, 1996).
The most widespread method of seedling production is the use of soil blocks (Pereczes, 1999) which can also significantly increase earliness. The combined application of seedling growing and floating row cover can advance harvest by three weeks as compared to the traditional technology and can give farmers a three to four times greater income (Kurucz, 1998). Rattin et al., (2006) compared direct sowed and transplanted sweet corn varieties, without covering and concluded no difference, in ear weight and ear length, between transplanted treatments plant's, in comparison to direct sowing treatments plant's.

Materials and methods

The experiment were set up in 2013 on an area equipped for irrigation at Carei, Satu Mare County, situated in NW part of Romania. Conventional, reliable and sufficiently known among growers sweet corn variety, Spirit, was used as a reference variety in the variety comparison trials of the Central Agricultural Office. Hybrid has short growing period of 85 days and yellow kernels. Average height of plants is 159 cm, average ear height is 37 cm, ear length 19.6 cm and average ear weight is 245 g. The variety was granted official recognitions in 1988 and has been the dominant variety of the early ripening category till now. In the year prior to the experiment the area was under wheat.
The following treatments, each with four replications, were applied during the experiment:
P1 = direct sowing of plants with floating row cover, early period (11^{th} April)
P2 = direct sowing of plants without row cover, early period (11^{th} April)
P3 = plants transplantation with floating row cover, normal period (21^{th} April)
P4 = direct sowing of plants without row cover, normal period, regarded as control (21^{th} April)
For the frame structure of the treatments with cover we used ø 4.2 mm zinc coated wire coils. The fleece, 60 cm in width, was stretched over a small tunnel of 40 cm in height and then its edges (25-25 cm, respectively) were covered with soil using a hoe and the its ends were tied to the stakes hammered down. The construction of the frame structure and the setting out of the fleece cover were carried out at the same day as direct seeding and out planting. For the purpose of seedling growing, the seeds were sown on 5^{th} April 2013, in trays with rigid walls having 3,7x4x5,4 cm size. For growing the seedlings, commercial mix made of white peat 10-20 mm, PG Mix 1 kg/m^3 + micro nutrients, bentonite 40 kg/m_3, pH 5,5-6,5 was used. The seedlings were planted out at the 3 to 4 leaf phenological stage. At the two propagation times the treatments P1 and P3 were covered with Novagryl floating row cover, having a weight of 19 g/m^2, (using the small tunnel technique) in order to enhance earliness. The stand was created to contain 60,607 plants per hectare, according to the recommendations of the owner of the variety, at a spacing of 110+40x22 cm in twin rows. Each plot had an area of 6x3,5m (8 parallel rows and 16 seeds sown in each row). Sowing depth was 3 cm. The edge was the respective outer rows of the 4 twin rows of the plot. In October 2012, 35 t/ha of farmyard manure was worked into the soil with ploughing on area. Nitrogen fertilizer (120 kg/ha) was applied at the 6-7 leaf stage, the form of top dressing. The fertilizer application was worked into the soil with a rotary hoe.
During the experiment, we studied plant growth rates and recorded the time of the occurrence of the major phenological stages. For this purpose, we carried out regular observations (every 3 to 5 days) according to the following:
beginning of seed emergence (appearance of first germs),
appearance of tassels (by 50% of the plants),
beginning of tasseling (pollen shed has begun on the axes of tassels),
50% silking (silks have reached a length of 2 cm on half of the ears) "milky stage" (harvest).

During the experiment, we studied some plant morphological properties according to the following:
highness of plants (cm),
length of tassels (cm),
highness of ear insertion (cm).
Ears, together with the husks, were collected from the four central (two twin) rows and 20 ears of average appearance were selected from each row for following measurement:
unhusked and husked ear weight (gram).
The statistical analysis of the results was carried out by using the programme *RopStat 1.1.* When the standard deviations were identical the mean values were compared by pairs using the *Tukey-Kramer* test, while in the case of the non identical standard deviations the means were compared using the *Games-Howell* test (Vargha, 2007).

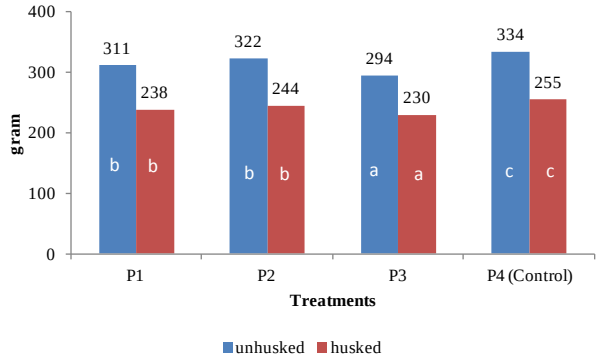
Results and discussion

Table 1. illustrates the times of sowing, emergence as well as the number of days elapsed from the date of direct seeding or transplanting to the different phenological stages.

Treatments (sowing day)	Date of emergence (days)	Tassels appearance by 50% (days)	Stigma appearance by 50% (days)	Starting harvest (days)
P1 (IV. 11)	17 days (IV. 28)	58 days (VI. 8)	63 days (VI. 13)	79 days (VII. 1)
P2 (IV. 11)	17 days (IV. 28)	62 days (VI. 12)	67 days (VI. 17)	82 days (VII. 3)
P3 (IV. 21)		34 days (V. 31)	40 days (VI. 6)	60 days (VI. 26)
P4 (control)	8 days (IV. 28)	57 days (VI. 17)	62 days (VI. 22)	81 days (VII. 9)

Table 1: Rhythm of emergence and generative phenophases

It can be observed that time of germination in the treatment sown at the first sowing date and having no cover had no delay as compared to the germination time of the covered treatment and only 2 days earliness in beginning of harvesting time in 2013. Covering helped in earlier appearance of generative phenophases (tassels and stigma) by 4 days respectively, in case of harvesting by 3 days earliness. In the case of the plants sown at the second sowing date the emergence could be considered practically normal as common. According to our results of experiment, the male flowers (tassels) appeared in the shortest time in the transplanted treatments. The transplant growing, at this stage of development, resulted in 5 to 7 days earliness as considers the treatment P3, compared to the treatments P1 and P2 which had been direct seeded at a similar time. Compared to the control (P4), the P3 treatment transplanted at the same date, could be harvested 13 days earlier.
Results of the one of the major characteristics in connection with yield rating, unhusked and husked ear weight, are summarised in Figure 1.

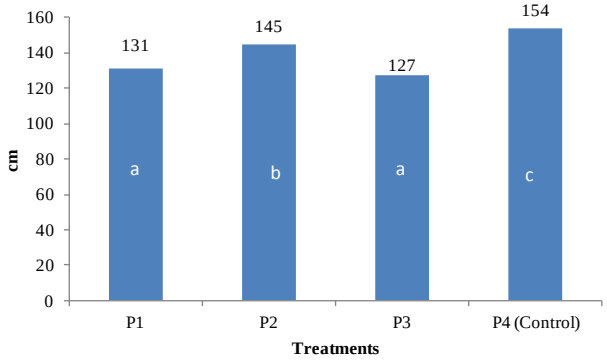


F(3;316)=25,143; F(3;316)=11,836;Sd=99%

Fig. 1. Unhusked and husked ear weight (g).

Analysing the data measured for unhusked ear yield, it is noticeable that the average weight of the ears of the transplanted, covered treatment P3 was significantly (at *p<0.01* level) lower as compared to the sowed, covered and uncovered treatments P1, P2 and P4 (control). Though there was some difference between the plants of the treatments P1 and uncovered, sowed, treatment P2 in unhusked ear weight, statistically this was not significant. Significantly highest value, supported statistically (at *p<0.01* level), of unhusked ear weight was produced by ears of control treatment (P4). In case of husked ear weight the same tendencies were observed as in case of unhusked ear weight.

The highness of plants indicator of general condition is represented by Figure 2.

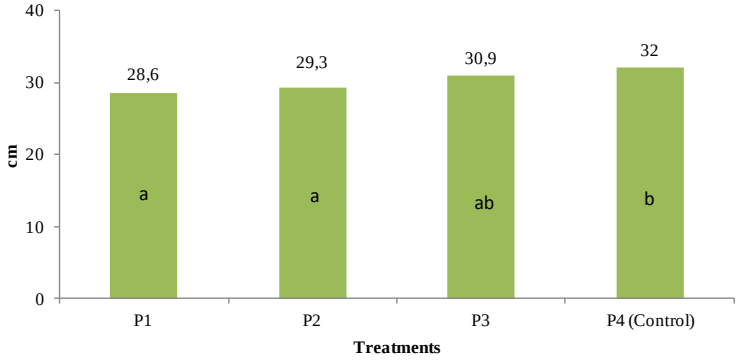


F(3;316)=61,240; Sd=99%

Fig. 2. Highness of plants (cm).

The highest value of plant highness was registered by plants of (P4 control) treatment, difference was significantly (at p<0.01 level), compared to earlier sowed (P1) covered and P2 earlier sowed (uncovered) treatments. Covering (P1) had not favourable on plant highness compared to uncovered (P2) treatment by earlier sowing time. Among covered (P1, P3) treatments plant highness no significantly difference.

Evolution of tassels length, supposed to carry more male flowers and implicitly better pollination, is summarised on Figure 3.

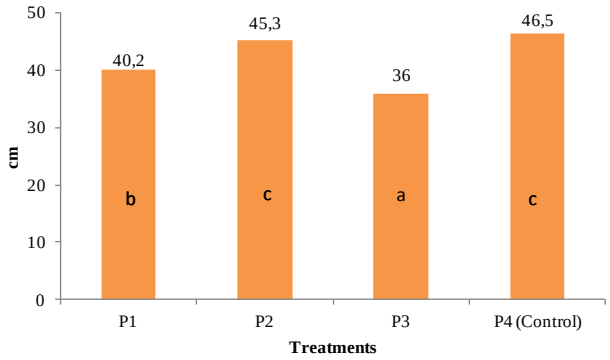


F(3;316)=16,702; Sd=99%

Fig. 3. Tassels length (cm).

In case of tassels length the time of later sowing has higher influence. Plants from later sowed uncovered, control (P4) treatments had significantly (at p<0.01 level) longer tassels compared to earlier sowed covered (P1) and uncovered (P2) treatments and longer, but not significantly, compared to transplanted covered (P3) treatment.

Highness of ear insertion is a very important morphological plant property in case of mechanical harvesting, because adapters of usual harvesting machines can cut only de sweet corn ears inserted higher than 40 cm, is illustrated on Figure 4.



F(3;316)=5,499; Sd=99%

Fig. 3. Highness of ear insertion (cm).

Obtained data confirmed significantly (at $p<0.01$ level) higher insertion of ears in case of earlier and later sowed, uncovered (P2 and P4) treatments compared to transplanted P3 treatment. Covering on earlier sowed (P1) treatment produced favourable effect on highness of ear insertion. This positive effect seems to offer possibility apply mechanical harvesting on earlier sowed sweet corn crops in open field production. Mechanical harvesting by P3 transplanted treatment can not be used.

Conclusions

Based on the results of the 2013 year experiment, the following conclusions can be made:
In case to compare the earlier sowed P1 and P2 treatments, covering resulted no effect on date of emergence, but shortened with 4 days, appaerance of generative organs (tassels and stigmina) and shortened harvesting time at least with 2 days.
The growing period was significantly shortened with transplantation of sweet corn plants compared to direct seeded. Harvest time occurred 15 days earlier in the case of transplantation and floating row cover (P3) application compared to direct sowed, uncovered, control (P4) treatment, and 8 days earlier compared to direct sowed, covered P1 treatment. At the same time the floating row cover produced 6 days shortening in the growing season between P1 (direct sowing of plants with floating row cover) and P4 (direct sowing of plants with no row cover) control treatments.
In case of direct sowed treatment (P2) the effect of covering had positive effect on unhusked, husked ear weight and highess of ear insertion.
Insertion point of ear, higher than 40 cm, offer possibility, in case of row covering in open field earlier sowing time of sweet corn crop, to use mechanical harvesting.
Covering resulted no significantly positive effect on plant highness and tassels length.

Abstract

Maize is known as being one of the most important and most used energy crops for obtaining biomass as substrate for producing biogas. In this respect, the maize crop is important for biogas production taking into account the methane produced by one unit of dry matter, but also taking into account the high biomass yields provided by the crop. However, the high yields are possible to be obtained using the appropriate cultivation techniques according to the growing conditions. The aim of this paper is to present the biomass yield obtained at different maize hybrids under different sowing conditions (different row spacing and plant densities) and under different growing conditions (different soil and climatic conditions) from South Romania. Also, it is intended to identify the average repartition of the biomass on maize plant components under different sowing and growing conditions. Researches were performed in field experiments under rainfed conditions in the years 2013 and 2014, and in two places in South Romania. In both experimental locations and both experimental years, a number of four maize hybrids were studied under three row spacing (75 cm, 50 cm, and twin-rows of 75/45 cm) and under three plant densities (60,000, 70,000, and 80,000 plants ha^{-1}). The determinations of fresh and dry biomass were realized in the early dough - dough plant growth stage. In the specific growing conditions from South Romania, as average values for 2013 and 2014, the highest biomass yields were registered at narrow rows, especially at twin-rows of 75/45 cm, and at plant density of 80,000 plants ha^{-1}.

Key words: *maize, biomass yield, row spacing, plant density, growing conditions.*

Introduction

Maize (*Zea mays* L.) is considered as one of the most suitable crops for biomass production which can be used as substrate for producing biogas (Balodis et al., 2011; Basa et al., 2013). Most efficient utilization of maize is supply of green maize biomass directly to biogas plants for heat and power energy production (Dubrovskis et al., 2010). The maize crop is important for biogas production taking into account the methane produced by one unit of dry matter, but also the high biomass yields provided by the crop. The biomass of maize plant is depending on a sum of growth factors among which the cultivated hybrid, plant population, row spacing and soil conditions have a significant influence on the accumulation of the above-ground biomass and its repartition between plant components (Ion et al., 2014).

Selection of hybrids and FAO maturity group is of great importance in order to obtain satisfactory yield of biomass in the optimal stage of maturity even in a shorter growing season (Dubljević et al., 2013).

Row spacing and plant density are among cultivation techniques that could contribute to the production of biomass in an efficient way. Through these cultivation techniques, it is intended to reduce the intraspecific and even interspecific plant competition for acquiring the growing factors in view to be maximized the biomass production.

Maize produced in narrow rows can increase yields and result in a quicker canopy closure (Satterwhite et al., 2006). Twin-row planting systems in maize have been proposed as an

alternative spatial arrangement that should theoretically decrease plant-to-plant competition, alleviate crop crowding stress and improve yields (Robles et al., 2012).
Yields of dry biomass increase with increases in planting density (Averbeke and Marais, 1992; Yilmaz et al., 2007; Nik et al., 2011). However, this is expected to happen up to a level which could be defined as optimum plant density beyond which the dry biomass yield will start to decrease.
The aim of this paper is to present the biomass yield obtained at different maize hybrids under different sowing conditions (different row spacing and plant densities) and under different growing conditions (different soil and climatic conditions) from South Romania. Also, it is intended to identify the average repartition of the biomass on maize plant components under different sowing and growing conditions.

Materials and methods

Researches were performed in field experiments located in two places in South Romania, respectively at Fundulea (44°28’ N latitude and 26°27’ E longitude) and Moara Domneasca (44°29’ N latitude and 26°15’ E longitude). The field experiments were performed under rainfed conditions in the years 2013 and 2014.
The soil from Fundulea area is chernozem, with humus content of 2.8-3.2%, loam to clay loam texture, and pH of 6.4-6.8, while the soil from Moara Domneasca area is reddish preluvosoil, with humus content of 2.2-2.8%, clay loam texture, and pH of 6.2-6.6.
For the period April-August and at Fundulea area, the average temperature was 20.1°C in 2013 and 18.9°C in 2014, while the multiannual average temperature for this period is 18.6°C. For the same period (April-August), the sum of rainfall was 381.1 mm in 2013 and 399.0 mm in 2014, while the multiannual average rainfall is 327.9 mm.
For the period April-August and at Moara Domneasca area, the average temperature was 20.5°C in 2013 and 18.8°C in 2014, while the multiannual average temperature for this period is 18.5°C. For the same period (April-August), the sum of rainfall was 115.0 mm in 2013 and 408.0 mm in 2014, while the multiannual average rainfall is 313.2 mm.
In both experimental locations (Fundulea and Moara Domneasca) and in both experimental years (2013 and 2014), four maize hybrids were studied, respectively: Cera 450 (FAO precocity group 450), Flanker (FAO precocity group 450), PR35T36 (FAO precocity group 500), and ES Feria (FAO precocity group 550). Every hybrid in each location and in each experimental year was studied under three row spacing (75 cm, 50 cm, and twin-rows of 75/45 cm) and at three plant densities (60,000, 70,000, and 80,000 plants ha^{-1}). Each variant consisted in four lines with a length of 10 m.
In 2013, the sowing was performed on 17th of April at Fundulea location (chernozem soil) and on 26th of April at Moara Domneasca location (reddish preluvosoil). In 2014, the sowing was performed on 8th of May at Fundulea location and on 25th of April at Moara Domneasca location.
The preceding crop was sunflower in both locations and experimental years. The fertilization was performed with 106 $kg.ha^{-1}$ of nitrogen and 40 $kg.ha^{-1}$ of phosphorus. The weed control was performed by the help of herbicides, which were completed by one manual hoeing.
In each location, in each experimental year, and from each variant the maize plants from one square meter were cut at soil level and were weighed immediately in view to be determined the fresh biomass yield, respectively the yield of above-ground biomass. One average maize plant for each variant was taken into the laboratory and dried in the oven at 80°C for 24 hours in view to be determined the dry biomass yield.
Determinations were performed in the early dough - dough plant growth stage, respectively in the growth stage when the maize biomass is of importance to be used as substrate for

producing biogas. The data are presented and analyzed as average values for the four studied maize hybrids.

Results and discussion

Biomass yield at maize under different row spacing conditions. On chernozem soil, the highest biomass yields were registered at narrow rows. Thus, in average for 2013 and 2014 it was obtained 72.82 tons.ha^{-1} of fresh biomass at 50 cm between rows (Figure 1.a) and 20.71 tons.ha^{-1} of dry biomass at twin-rows of 75/45 cm (Figure 1.b). The same tendencies were registered also on reddish preluvosoil, where the highest yields were 55.59 tons.ha^{-1} of fresh biomass at 50 cm between rows (Figure 1.a) and 20.15 tons.ha^{-1} of dry biomass at twin-rows of 75/45 cm (Figure 1.b).

The biomass yields were higher on chernozem soil conditions respectively at Fundulea location, which was characterised by more rainfalls and smaller values of temperatures compared to the conditions registered on reddish preluvosoil at Moara Domneasca location. In average for 2013 and 2014 and in average for the three variants of row spacing, the fresh biomass yield was of 69.84 tons.ha^{-1} on chernozem soil and of 53.36 tons.ha^{-1} on reddish preluvosoil, while the dry biomass yield was of 19.89 tons.ha^{-1} on chernozem soil and of 19.28 tons.ha^{-1} on reddish preluvosoil (Figure 1). The smallest variations between the two experimental years regarding the yield of dry biomass at different row spacing were registered on reddish preluvosoil.

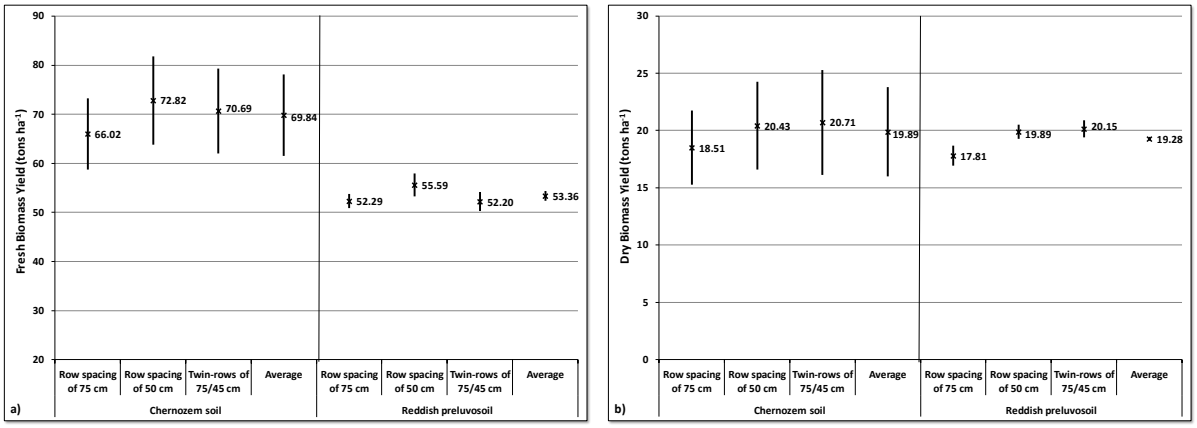

Figure 1. Fresh (a) and dry (b) biomass yield at maize under different row spacing conditions, on different types of soils from South Romania, as average values and limits of variations in 2013 and 2014 climatic conditions

Biomass yield at maize under different plant density conditions. Increasing of plant density from 60,000 to 70,000 and further to 80,000 plants ha^{-1} determined the increasing of fresh and dry biomass yield (Figure 2). In average for 2013 and 2014, the highest yields of dry biomass were registered at plant density of 80,000 plants ha^{-1} both on chernozem soil (20.32 tons.ha^{-1}) and reddish preluvosoil (20.18 tons.ha^{-1}), while the highest yield of fresh biomass was registered at 80,000 plants ha^{-1} on chernozem soil (70.35 tons.ha^{-1}) and at 70,000 plants ha^{-1} on reddish preluvosoil (55.53 tons.ha^{-1}).

In average for the two experimental years (2013 and 2014) and for the three variants of plant density (60,000, 70,000 and 80,000 plants ha^{-1}), the fresh and dry biomass yields were higher on chernozem soil then on reddish preluvosoil. As in the case of fresh and dry biomass yields registered at different row spacing, the smallest variations between the two experimental years were registered on reddish preluvosoil (Figure 2).

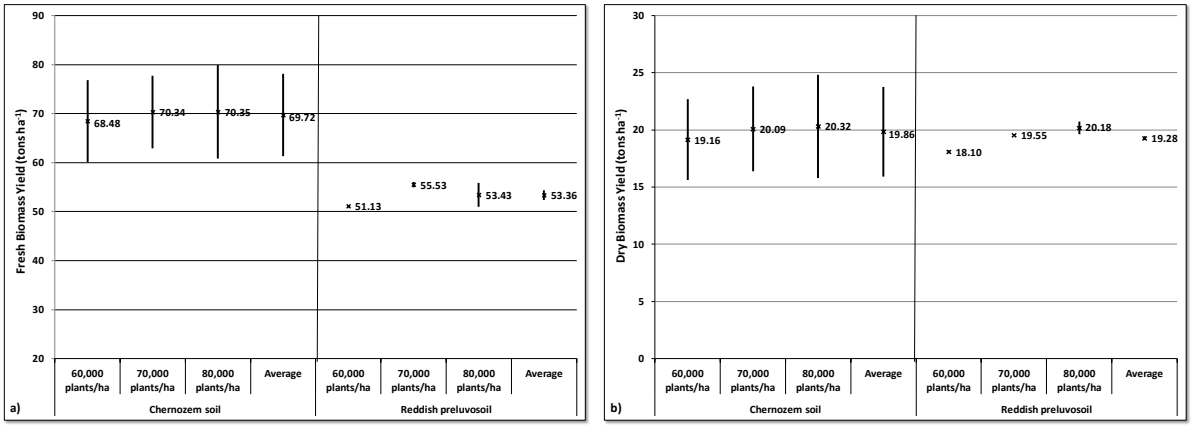

Figure 2. Fresh (a) and dry (b) biomass yield at maize under different plant density conditions, on different types of soils from South Romania, as average values and limits of variations in 2013 and 2014 climatic conditions

Share of dry biomass on plants components at different row spacing. Regarding the share of dry biomass on stalks (including leaf sheaths and tassels), leaves (leaf blades), ears and husks in the early dough - dough plant growth stage, the highest ration were registered by the ears both on chernozem soil and reddish preluvosoil and both at different row spacing and plant densities (Figures 3 and 4).

On chernozem soil, the narrow rows increased the share of dry biomass on ears and leaves and decreased the share of dry biomass on stalks and husks (Figure 3.a). On reddish preluvosoil, compared to the shares registered at 75 cm between rows, the row spacing of 50 cm increased the share of dry biomass on stalks, leaves and husks, while the twin-rows of 75/45 cm increased the share of dry biomass on ears and husks (Figure 3.b).

In average for the two experimental years (2013 and 2014) and for the three variants of row spacing (75 cm, 50 cm and twin-rows of 75/45 cm), on chernozem soil the shares of dry biomass on plant components were the following: 44.8% for ears, 32.7% for the stalks, 15.0% for the leaves, and 7.6% for the husks (Figure 3.a). On reddish preluvosoil, the average shares of dry biomass on plant components were the following: 48.7% for ears, 29.5% for the stalks, 14.8% for the leaves, and 7.0% for the husks (Figure 3.b). So, on reddish preluvosoil in average it increased the share of dry biomass on ears and decreased the share of dry biomass on all other plant components compared to the values registered on chernozem soil.

Share of dry biomass on plants components at different plant densities. On chernozem soil, the increasing of plant density from 60,000 to 70,000 and further to 80,000 plants ha^{-1} increased the share of dry biomass on stalks and leaves and decreased the share of dry biomass of ears and husks (Figure 4.a).

On reddish preluvosoil, the increasing of plant density increased the share of dry biomass on ears and leaves and decreased the share of dry biomass of stalks and husks (Figure 4.b).

In average for the two experimental years (2013 and 2014) and for the three variants of plants densities (60,000, 70,000, and 80,000 plants ha^{-1}), on chernozem soil the shares of dry biomass on plant components were the following: 44.9% for ears, 32.6% for the stalks, 15.0% for the leaves, and 7.5% for the husks (Figure 3.a). On reddish preluvosoil, the average shares of dry biomass on plant components were the following: 48.8% for ears, 29.5% for the stalks, 14.8% for the leaves, and 7.0% for the husks (Figure 3.b).

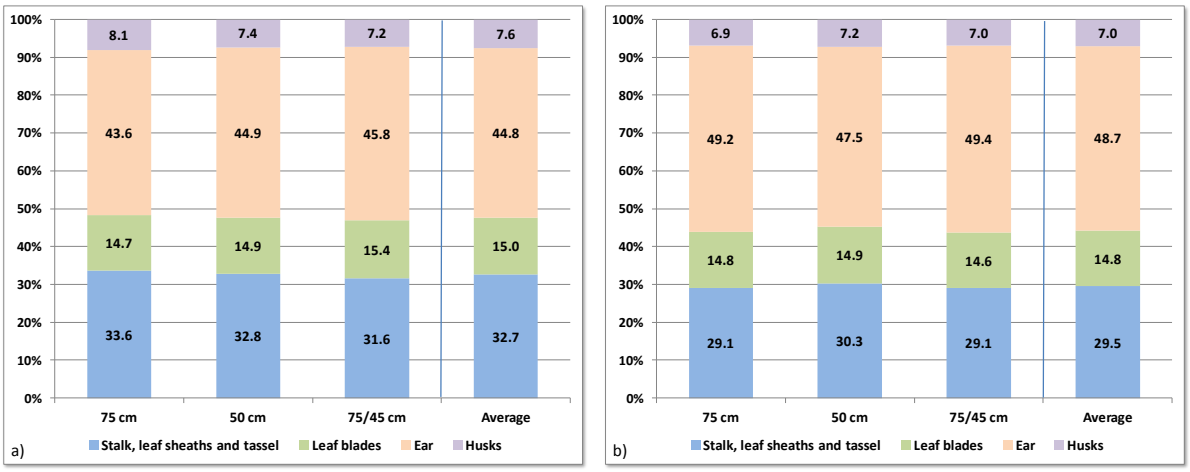

Figure 3. Percentage of dry biomass on maize plant components under different row spacing, on different types of soils (a- chernozem soil; b- reddish preluvosoil) from South Romania, as average values in 2013 and 2014 climatic conditions

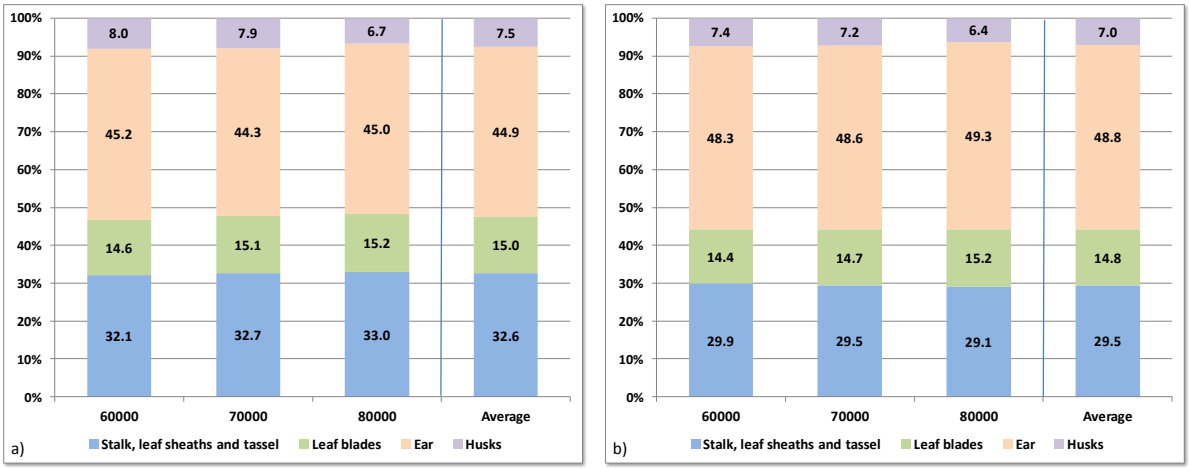

Figure 4. Percentage of dry biomass on maize plant components under different plant densities, on different types of soils (a- chernozem soil; b- reddish preluvosoil) from South Romania, as average values in 2013 and 2014 climatic conditions

Conclusion

In the specific growing conditions from South Romania, as average values for 2013 and 2014, the highest biomass yields were registered at narrow rows, especially at twin-rows of 75/45 cm, and at plant density of 80,000 plants ha^{-1}.

The biomass yields were higher on chernozem soil conditions, which were associated with more rainfalls and smaller values of temperatures compared to the conditions registered on reddish preluvosoil.

Among the plant components, the highest ration of dry biomass were registered by the ears both on chernozem soil and reddish preluvosoil conditions, as well as under different row spacing and plant densities.

On chernozem soil, the narrow rows increased the share of dry biomass on ears and leaves, while on reddish preluvosoil the row spacing of 50 cm increased the share of dry biomass on stalks, leaves and husks, and the twin-rows of 75/45 cm increased the share of dry biomass on ears and husks.

On chernozem soil, the increasing of plant density increased the share of dry biomass on stalks and leaves. On reddish preluvosoil, the increasing of plant density increased the share of dry biomass on ears and leaves.
Compared to the average values registered on chernozem soil, on reddish preluvosoil the share of dry biomass on ears increased while the share of dry biomass on all other plant components decreased.

Abstract

The total grain production of maize reaching 11.34 million tons in 2013 placed Romania on the second position in the EU. In this context, selecting of the proper hybrid for each agricultural region is an essential condition for farmer to achieve their production goals.
The purpose of the paper was to present the results regarding the yield components at different maize hybrids under the specific conditions from the South Romanian Plain. In this respect, there have been studied an assortment of eleven maize hybrids under the conditions of the cambic chernozem from Baneasa area (44o03’ N latitude and 26o05’ E longitude), Giurgiu County, under the favourable climatic conditions of 2014. The hybrids tested in the comparative crop were the following: PR37Y12, Rapsodia, Olt, PR35F38, P0216, P0412, Generos, Fundulea 376, Florencia, P0105, Kitty. At full maturity stage, it was determined the total biomass, the yield components, the grain yield, and the harvest index. The maize hybrids react considerably function of their precocity, plant density, fertilization strategy, weed control and rainfall distribution during vegetation phases.
Key words: *maize hybrids, growing conditions, yield, yield components.*

Introduction

Assortment of maize hybrids have a high yield potential, but the crop technology and the climatic conditions have a considerable influence on the yield components and the average yield of hybrids. The maize hybrids have a different behaviour according to cultivation area, soil and climatic conditions, rainfall distribution during phases of vegetation, used fertilization dosage, weed control and the plant density according to the field conditions (Dumbravă, 2004). The yield components are influenced by the hybrids selected for cultivation in an area and the fertilizer doses used (Adeyemi, 2011). The effect on sowing on plant density expressed that delay in sowing reduces the number of kernels in cob and performance components of maize (Cantanero et al., 2000). Early and intermediate sowing tends to best utilize solar radiation for grain production (Koca and Canavar, 2014). This could be due to a better growing and development of the crop which is a consequence of a good photosynthesis products accumulation in leaves and their transfer to economic components of the of plants like cobs and grains (Otegui et al., 1995). The plant density correctly established function of hybrid precocity, fertilization doses, weed control and water reserve in soil has a considerable influence on the competition among the plant populations which use the natural resources and determines the yield components for each hybrid (Sharifi et al., 2009).
The aim of this paper was to present the results related to the yield components, total biomass and grain productions for maize hybrids under the conditions of performance crop technology and under pedoclimatic conditions from Romanian plain.

Materials and methods

The comparative hybrid crop was located in an experimental field on cambic chernozem in Baneasa Giurgiu County under the specific climatic condition of 2014. The annual amount of rainfall was 450 mm in the period April-September, with a good distribution to second decade of July, and the average annual temperature was 11.8 C.

Studied maize hybrids were the following: PR37Y12 (FAO 380), Rapsodia (FAO 400), Olt (FAO 400), PR35F38 (FAO 450), P0216 (FAO 450), P0412 (FAO 480), Generos (FAO 500), Fundulea 376 (FAO 500), Florencia (FAO 490), P0105 (FAO 400), Kitty (FAO 490).

Each hybrid had 4 rows with a length of 10 m, 4 replications. Seeding data was 7 April, and plant density was of 55,000 harvestable plants for hectare. The crop technology was the following: the preceding crop was wheat, the fertilization was performed with 100 kg/ha of complex 20:20:0 and 150 kg/ha of ammonium nitrate at the 7 leaf stage; the weed control was performed postemergent with the following herbicides: Dicopur Top 464 SL (344 g/l acid 2.4 D from SDMA + 120 g/l dicamba) at a rate of 1 l/ha, and Novapower 40 SC (nicosulfuron 40 g/l) at a rate of 1.5 l/ha, which were applied at 5 leaves stage of maize plants.

At harvesting determination and analysis were performed regarding: total biomass maize production, weight of grains per ha, grain ratio on cob, number of grains per ear, grain yield, grain humidity, the hectoliter mass, mass of 1000 grains and standard yield at 15% humidity.

Experimental data were processed using the analyses of variance.

Results and discussion

Above-ground biomass. The plants were cut at soil surface at harvesting and the above-ground biomass was calculated after weighing.

The highest total biomass yield was recorded for the hybrids P0216 (24.8 t/ha), F376 (22.2 t/ha) and Florencia (21.3 t/ha). The lowest biomass was recorded for hybrids Rapsodia (16.1 t/ha) and PR37Y12 (16.4 t/ha). In the comparative crop, 6 hybrids achieved total biomass yield higher than the average for the experiment (Figure 1).

The total biomass yield was boosted by the favorable pedoclimatic and technologic conditions but the high temperature and rainfall shortage in July and August had influences on the yield potential for the tested hybrids.

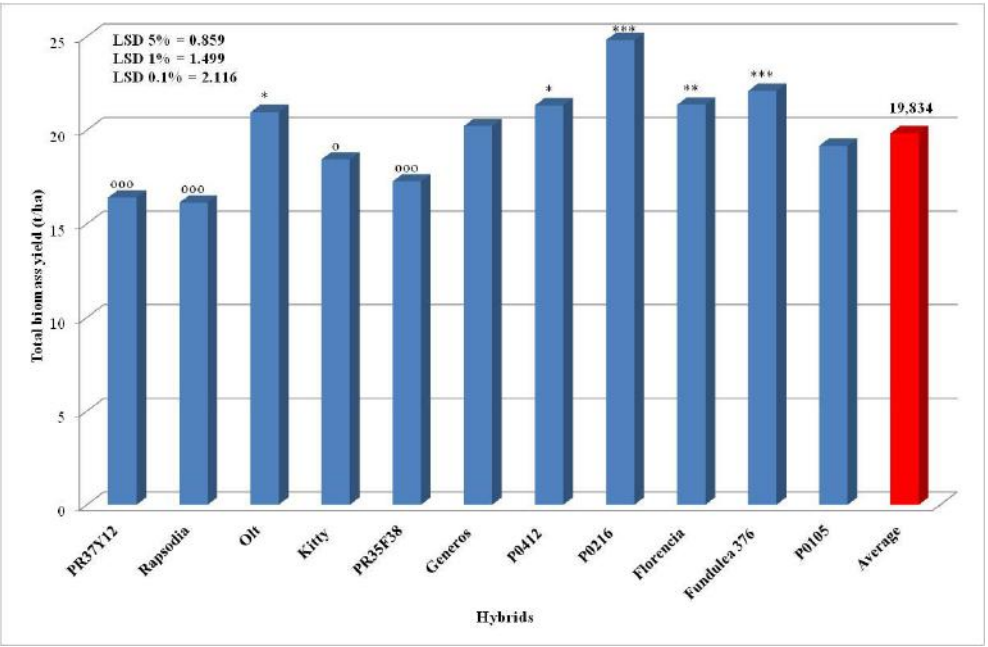

Figure 1. Total biomass yield

The maize ear yield. The average ear yield was 10.4 t/ha with significant variations among hybrids. The highest ear yield was registered at hybrids P0216 (13.8 t/ha), Florencia (13.7 t/ha) and F376 (13.6 t/ha), with grain humidity between 17.7% and 18.5%.
Lower ear yield were recorded for the hybrids PR37Y12 (9.4 t/ha), Rapsodia (9.5 t/ha) and PR35F38 (10.7 t/ha) (Figure 2).

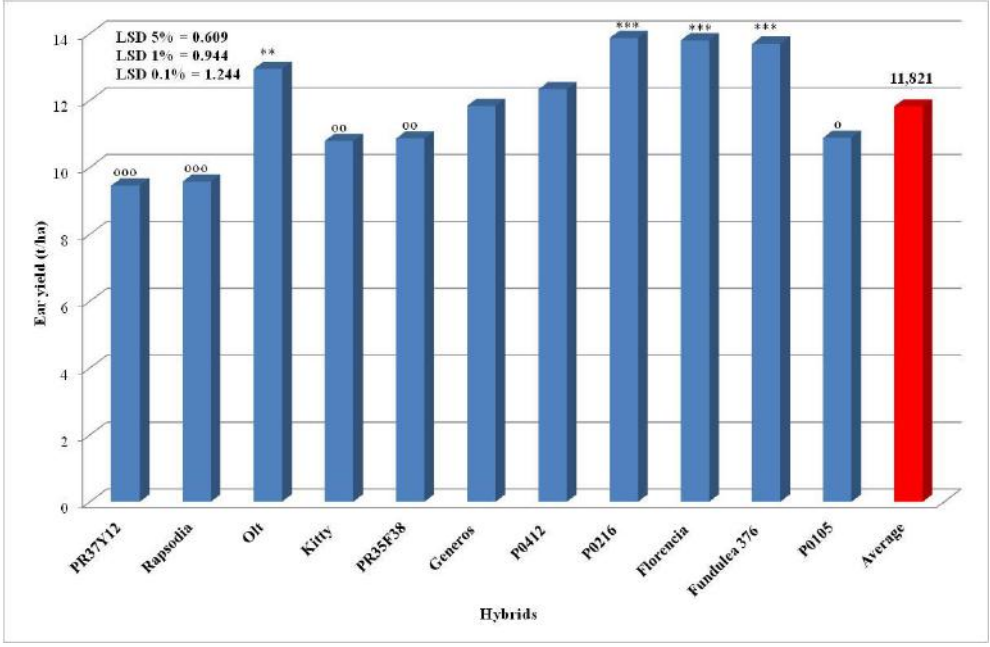

Figure 2. The maize ear yield

The average weight of maize ear. The average weight of maize ear is correlated with number of grains per ear, grain mass per ear, grain humidity, grain yield, and grain ratio on ear.
For the eleven studied hybrids the average weight of ear was 209.33g. There were remarkable the hybrids P0216 with 254.11 g and a grain ratio on ear of 83.5%, Florencia with 247.11 g and grain ratio on ear of 80.2%, and P0412 whit 225.5g and grain ratio on ear of 82.3%. Lower value of the weight of maize ear was 170.80g for PR37Y12 with a grain ratio on ear 81.3% and 171.24g for Rapsodia and grain ratio on ear 80.5% (Figure 3).

Number of grains per ear. Number of grains per ear is correlated with mass ear, grain ratio on ear, grain humidity and mass of 1000 grains. For the eleven studied hybrids the average number of grains on ear was 562.45 grains.
The number of grain per ear was influenced by hybrid. We noticed a variation from 592 grains per ear for Rapsodia hybrid to 630 grains per ear for PR35F38 and significantly value exceed the average the hybrids PR35F38, Kitty, and F378.

Grain weight per ear. The grain mass per maize ear was influenced by the ear mass, grain size on ear, grain ratio on ear and grain humidity.
We noticed a variation of the grain mass per ear from 137.89 g at Rapsodia hybrid to 212.37 g at PO216 hybrid. The big significantly value exceed the hybrids PO216 with 212.37 g, Florencia with 198.3 g and PO412 with 185.86 g. Lower values of the grain mass per ear were recorded for the hybrids Rapsodia, PR35F38, and PR37Y12. The harvest plant density influenced directly the grain yield per ear.

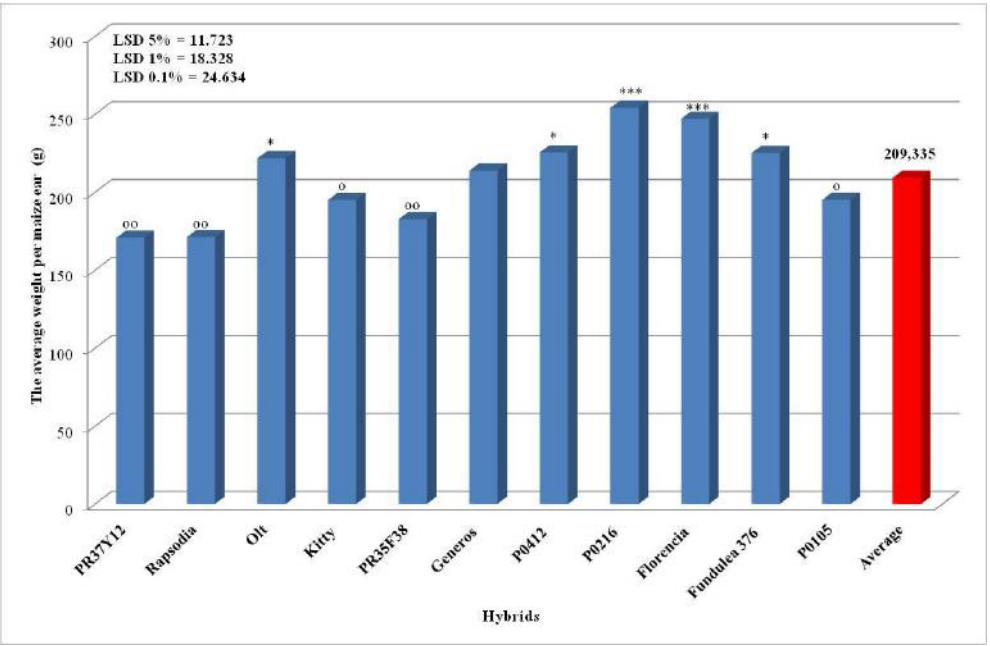

Figure 3. The average weight of maize ear

Grain ratio on ear. The grain ratio on ear is influenced by the grains mass per ear, grains humidity and maize ear mass. The grain ratio on ear is not significantly different for the eleven tested hybrids in experimental field. Based on this indicator, we point out the hybrids P0216 with grain ratio on ear 83.5%, P0412 (82.3%), and P0105 (81.9%). For the Romanian hybrids, the grain ratio on ear had low values, respectively Olt (77.1%) and F 376 (79.5%), and that is because grains humidity was of 18.5 % for these hybrids.

Mass of 1000 grains. The mass of 1000 grains is significantly different on hybrids and it is determinate by grain mass on ear, number of grains on ear, grains humidity and climatic conditions in the grain formation period.
The highest mass of 1000 grains was recorder for the hybrids P0216 (412.5g), Florencia (395.2 g), and F376 (375.1g).
The lowest mass of 1000 grains was recorded in the case of hybrids PR35F38 (260.6g) and PR37Y12 (271.9g).

Grain humidity. The grain humidity is correlated to the hybrid precocity and the climatic conditions in the cultivated area. For the eleven tested hybrids in the experimental field, grains humidity is variable from 16.5% for PR37Y12 hybrid to 18.5% for Olt and F376 hybrids. The foreign maize hybrids for Romania had the ability to lose grain humidity fast at plant maturity.

Standard yield of grains at the humidity 15%. The average standard yield for the hybrids tested in Romanian plain conditions in 2014 year was 9.3 t/ha.
The highest standard yield were recorded for the maize hybrids P0216 (11.1 t/ha), Florencia (10.9 t/ha), and F376 (10.5 t/ha), which significantly exceed the average yield per experiment. Lower yields, significantly distinct from the average yield were recorded for the hybrids Rapsodia (7.5 t/ha) and PR37Y12 (7.5 t/ha).
The higher temperatures and rainfall deficit in July and August affected the full potential yield of the tested hybrids.

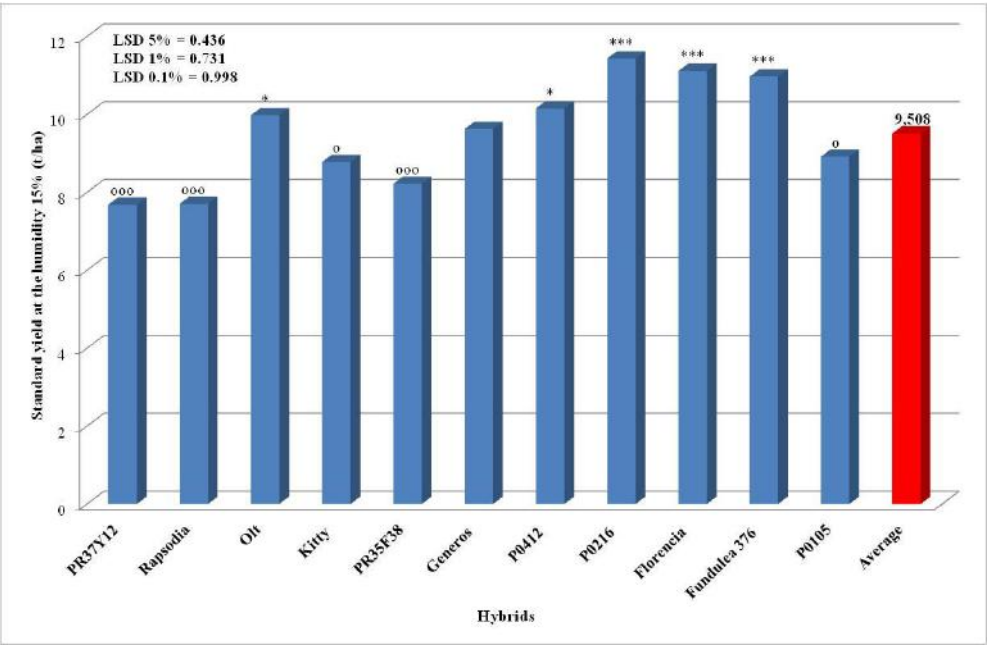

Figure 4. Standard yield of grains at the humidity 15%

Conclusion

The maize hybrids react considerably function of their precocity, plant density, fertilization strategy, weed control and rainfall distribution during vegetation phases.

The aggressive temperatures in the context of rainfall deficit in July and August have a considerable influence on the yield components regardless of the tested hybrids in the climatic conditions specific of the 2014 year in South Romanian Plain.

Farmers growing maize must consider crop technology management for a maximum use of pedoclimatic resources and for the decrease in effect of limitative factors on yield components.

Due to the large biomass production at maize, it is of interest to manage the crop residues after harvesting and by the new technology that can be used to produce pellets or briquettes for heating units with considerable economic effects.

INFLUENCE OF SPRING AGROTECHNICAL CARE TECHNIQUES ON FESCUE LAWN GRASS STAND QUALITY

Iana V. SUBBOTINA*, Iurii N. ZUBAREV

Agriculture Department, Perm State Agricultural Academy named after Academician D.N. Prianishnikov, Perm, Russia
*Corresponding author: zemledel@pgsha.ru

Abstract

Creation of landscape composition on the plot, the park or near administrative buildings only with trees, shrubs and flower beds will lead to the creation of an unfinished composition. Perennial ornamental grasses red fescue (*Festuca rubra*) and fescue (*Festuca pratensis*) in the climatic characteristics of Preduralie are excellent herbs for creating long-term lawns, both in pure form or in mixes. Sod formed from both fescues has great connectivity, density and elasticity, with dark green leaves that do not lose their coloring even in drought periods.

Application in spring harrowing or rolling grass herbage can improve quality, reduce the amount of lawn weeds in grass stands. Application of agrotechnical care methods (harrowing, rolling) during regrowth of lawns in spring allows improving the living conditions of the plants and form a dense grass stand of good quality.

It is also worth mentioning that having reached full development in the third year of life, the grasses respond better to rolling and harrowing-rolling combination during regrowth period.

The density of grass stand increases compared to the variants without treatment and harrowing with tooth harrows on average from 220 to 2227 shoots/m^2 over the years of research.

Sowing grass mixture 50% red fescue and 50% fescue, using rolling or harrowing combined with rolling in spring enables the lawns of good and excellent quality.

Keywords: *lawns, red fescue, meadow fescue, harrowing, rolling.*

Introduction

Landscape as an environment in which human operates permanently is of great importance. Lawn in landscape design is not only a decoration, it is a place for children to play, to have rest and picnics. Creation of landscape composition on the plot, the park or near administrative buildings only with trees, shrubs and flowerbeds will lead to the creation of an unfinished composition. Use of grasses that are adapted to climatic conditions of a region, resistant to temperature fluctuation allows lawns of satisfactory and good quality since the first year of plant life. Perennial ornamental grasses red fescue (*Festuca rubra*) cv. Sverdlovskaya and meadow fescue (*Festuca pratensis*) cv. Sverdlovskaya-37 in the climatic characteristics of Preduralie are excellent plants for creating long-term lawns, both in pure form or in mixes. Sod formed from the fescue has great connectivity, density and elasticity, with dark green leaves that do not lose their coloring even in drought periods (Lazarev, 2011). Application of harrowing and rolling in the spring period allows improving the quality of lawns, reducing the quantity of weed herbs in grass stand.

Since for the region of Preduralie there are no recommended plants and no developed agrotechniques for creating long-term lawns of good quality, the studies on the fescues are topical for further recommendations to landscape design companies.

Materials and methods

The investigations of agrotechniques for lawns are carried out in the experimental field of the Perm State Agricultural Academy, Perm, Russia, in particular, mono-sowings of red fescue

and mixture of red fescue and meadow fescue (50/50) in spring, during regrowth period (since the second year of life) agrotechnical methods of care: harrowing without harrows, rolling with star-wheel rollers and combination of these techniques.

Table 1

Experiment scheme «Influence of care technique on forming of sod from perennial grasses and lawn quality»

Without treatment	Harrowing	Rolling	Harrowing+ rolling
red fescue 100%			
red fescue 50% + fescue 50%			

The most common ornamental grasses in the region: meadow fescue (Sverdlovskaya-37) and red fescue (Sverdlovskskaya), perennial ornamental grasses of winter type of development were taken for the study. Meadow fescue and red fescue possess good winter hardiness and cold resistance (Kobozev et al, 2002). Meadows dominated by numerous radical vegetative shoots, which respond well to regular cuts, forming dense durable plant (Subbotina, 2006; Tiuldiukov, 2002)

The area of plot is 24 m^2, planted four times, completely randomized placing. Soil of the plot is sod-podsolic (typical for Preduralie), organic matter content 2.3 – 2.4%; pH=5.0; P2O5=120-185 mg/100 g; K2O=145-160 mg/100 g. Seeding rate in its pure rate with 100% germination: red fescue 13.3 g/m^2; meadow fescue 18 g/m^2. Sowing was carried out in the third decade of May manually. Shearing was carried out with a lawn mower at intervals of 14 days. The quantity of plants and shoots was calculated twice a vegetation period by monolith methods (quantitative calculating of plants) (Kobozev et al., 2002).

Results and discussion

In the first year of life, lawn shoots were not simultaneous, and by the end of the vegetation period the number of shoots on the experience, on average, was approximately 4000 per square meter with projective covering 60-65% (Table 2). For the second year of life, quality of lawns herbage has improved greatly and on studied options on average amounted to 5008-6659 shoots/m^2 with projective covering 75-84%. Red fescue seeding in pure stand from the second year of life helps form the lawns of satisfactory quality with 6350-6842 shoots/m^2 and projective covering 83-86%. The combination of red fescue and meadow fescue with 50/50 provides 4775-5475 shoots/m^2 with projective covering 70-81%.

Starting with the third year of life, the quality of grass stands was much better in the versions with sowing red fescue (*Festuca rubra*) + fescue (*Festuca pratensis*), the number of shoots per square meter in the options above at 586-1407 pieces/m^2 with roughly the same projective covering 72-76%. By the fourth year of life the studied lawns projective coverage amounted to 81-83% and 7001-7758 shoots per square meter in red fescue in pure stand and red fescue and fescue, respectively.

Lawn coverage made of fescue mixture forms on the 132-1400 shoots/m^2 more both when harrowing is applied during spring or rolling of herbage growing and without processing.

Table2

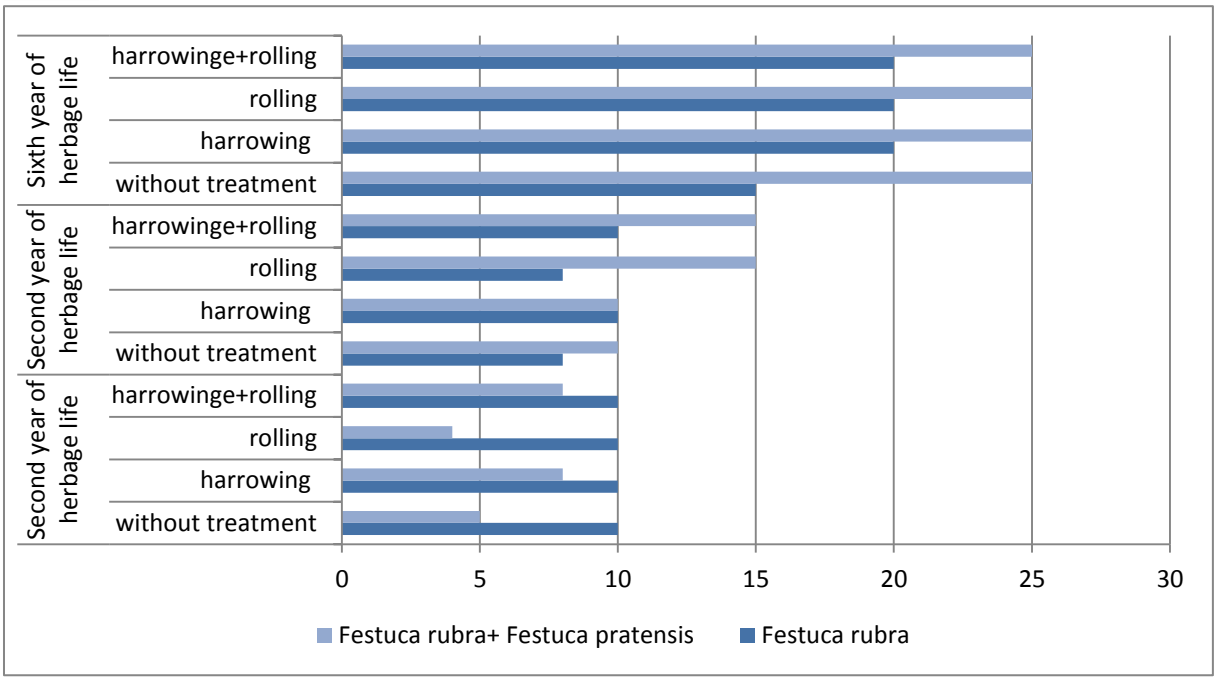
Influence of spring agrotechnical care techniques on fescue lawn quality

Year of herbage life	Care techniques in the regrowth period	*Festuca rubra*		*Festuca rubra+ Festuca pratensis*	
		quantity of shoots, pieces/m^2	projective covering, %	quantity of shoots, pieces/m^2	projective covering, %
Second	without treatment	6625	83	4775	81
	harrowing	6350	86	5225	70
	rolling	6842	82	4558	75
	harrowinge+rolling	6817	85	5475	75
Average		***6659***	***84***	***5008***	***75***
Fourth	without treatment	6891	80	7023	82
	harrowing	7112	82	7554	82
	rolling	6998	80	8398	84
	harrowinge+rolling	7002	83	8055	84
Average		***7001***	***81***	***7758***	***83***
Sixth	without treatment	8698	97	10157	97
	harrowing	9254	98	10349	99
	rolling	10598	95	12576	100
	harrowinge+rolling	9427	99	10886	100
Average		***9494***	***97***	***10992***	***99***

In following years of research, thanks to systematic grass density cuts is constantly increasing and the quality of the grass coating remains good with projective covering up to 100% and the number of shoots to 12576 pieces/m^2. In the sixth year of lawns life, red fescue in pure form and mixture of red fescue and fescue are highlighted in the treatments with the use of rolling in the spring regrowth period. Red fescue formed to the sixth year of life 10598 shoots/m^2 and projective coverage 95%, mixed with fescue, number of shoots formed was much higher - 12576 shoots/m^2 and 100% of the projective cover. Also it may be noted that conducting agrotechnical measures affects the quality of the lawn in different years of herbage. Methods of care are applied since the second year of lawns life to make grasses fairly well root, to avoid damaging them. Red fescue seeding in its pure form in all the years of research responded positively to the application of all treatments: harrowing, rolling, and harrowing-rolling combination. Red fescue and fescue mixture responds positively to spring harrowing, starting since the third or fourth year of life.

In general, the lawns of satisfactory quality were obtained from the second year of life both red fescue planted in its pure form, and fescue and red fescue planted in a mixture of 50/50.

Upon further examination of the herbage it was observed that to the sixth year of life the use of red fescue in pure form allows creating good quality lawns; mixture of red fescue and fescue50/50 improves the quality of lawn to excellent (Picture 1).



Picture 1. Influence of spring agrotechnical care methods on fescue lawn grass stand quality

Conclusion

According to the research results on possibility to create longstanding lawns of red fescue in pure form and in mixture using agrotechnical methods in spring period following conclusions can be drawn:

The optimum is to use a mixture of red fescue (*Festuca rubra*) variety Sverdlovskaya and fescue (*Festuca pratensis*) variety Sverdlovskaya -37.

Application of agrotechnical methods of care during regrowth of grass herbage allows increasing the density of red fescue grass by 107-1900 shoots/m^2, in mixture of fescue and red fescue by 192-2419 shoots/m^2thanks to of more intensive root stock in the fourth to sixth year of the studies.

AGROECOLOGICAL IMPORTANCE OF FIELD CROP ROTATIONS IN PERM REGION SOIL AND CLIMATIC CONDITIONS

Antonina KOSOLAPOVA, Marina VASBIEVA, Ecaterina MITROFANOVA, Denis FOMIN, Venera YAMALTDINOVA, Igor TETERLEV*

[1]Agricultural chemistry and husbandry Department, Perm Agricultural Research Institute 614532, Lobanovo, Perm region, Russia

Abstract

Typical grain-fallow crop rotations and ones, highly filled with legumes, were studied in stationary field experiment during 1998-2014 years on sod-podzolic soil (*Umbric Albeluvisols Abruptic*) on the backgrounds: without fertilizers, organic, mineral and organic-mineral fertilization systems. Crop rotations with green-manured fallow, annual legumes and perennial legume grasses proved their importance for promotion of high total yields and soil fertility raising. The same effect of typical grain-fallow crop rotations was achieved only with extremely high rates of FYM and mineral fertilizers.

Positive effect of joint application of manure and mineral fertilizers was noted in the experiment. Stabilization of soil fertility in typical crop rotation was achieved in treatment with manure application 60 t ha^{-1} in combination with NPK, in rotations with legumes – in the treatment with 40 t ha^{-1} and $N_{60}P_{60}K_{60}$. Organic-mineral fertilizer system provides not only the formation of positive balance of humus, but also its quality improvement.

Crop rotations with green-manured fallow and legumes provide stable high crops productivity. Application of 40 t ha^{-1} FYM and $N_{60}P_{60}K_{60}$. permitted to raise average crops productivity up to 3140 feed units (FU) t ha^{-1}, grain yields – 3,0 t ha^{-1}`, the energy ratio – 2,59. The supplements compared with typical rotations varied from 480 to 1190 FU per hectare.

Keywords: *crop rotation, green-manured fallow, perennial legume grasses, farmyard manure (FYM), mineral fertilizers*

Introduction

Sod-podzolic soils are most common in Perm region and are characterized by low level of natural fertility. They are featured by high soil acidity, low organic matter content, unfavourable physical and chemical properties. Using crop rotations with green-manured fallow, annual legumes and perennial legume grasses is the most available way for increasing fertility of these soils. It provides activation of fertility biological factors, reduces the use of organic and mineral fertilizers, increases the biocenosis productivity.

Crop rotations are important part of sustainable agriculture, which allows to optimize the functioning of agro- biocenosis based on rational use of natural, biological and anthropogenic factors (Kozlov and Abashev 2004, Thompson and Whitney, 2000). Scientifically founded crop rotations, adapted to the specific landscape, are most available means of soil fertility recovery (Lykov, 1982). Using of green-manured fallows, annual legumes and legume perennial grasses in crop rotations allows to activate fertility biological factors, reduce the use of mineral fertilizers and pesticides, while maintaining the productivity of arable land at high level, according to Loshakov (2012) and others.

Crop rotation eliminates soil degradation, which is associated with soil depletion of macro- and micronutrients, enzyme activity decreasing, accumulation of nematodes and other phytopathogenic microorganisms in soil (Naumkin et al., 2010; Loshakov, 2012; Bartels, 2006; Leithold and Volk, 2007).

Modern situation in Russian agriculture and, particularly, in Ural region, demands scientifically founded crop rotations, adapted to the specific soil and climatic conditions. Therefore, the purpose of given research is the assessment of different field crop rotations aimed at raising of arable crops productivity, soil fertility preservation and ecological safety.

Materials and methods

The experimental work was fulfilled in 1995-2014 in long-term stationary field experiment on the experimental farm of Perm Scientific Research Institute. The experimental plots located on sod-podsolic heavy loam soil with humus content 2.13-2.21 %, pH – 5.4, P_2O_5 – 100 mg kg^{-1}, K_2O – 150 mg kg^{-1}. (1969, before experiment foundation).

Experimental scheme: factor A – crop rotations: 1. Typical eight-course field rotation with bare fallow, rotation scheme: bare fallow, winter rye, spring wheat as shelter crop for clover (*Trifolium pretense* L.) and timothy (*Phleum pretense* L.) mixture, first year clover-timothy mixture, second year clover-timothy mixture, spring wheat, silage crops (sunflower with spring rape), spring wheat; 2. Eight-course field rotation with green-manured fallow, rotation scheme: green-manured fallow (mixture of spring vetch and oat), winter rye, spring wheat as shelter crop for meadow clover, first year clover, spring barley, spring wheat as shelter crop for meadow clover, first year clover, spring wheat. Factor B – fertilizers application: 1. No fertilizers (control); 2. Mineral fertilizers – NPK 30, 60, 90 kg ha^{-1}; 3. Farm-yard manure (FYM) 20, 40, 60 t ha^{-1}; 4. FYM 20, 40, 60 t ha^{-1} + NPK 30, 60, 90 kg ha^{-1}. Treatment placing is randomized, each treatment has four replications.

FYM were applied in bare and green manuring fallow, mineral fertilizers –for grain and fodder crops. Their afteraction was studied on clover and mixture of clover and timothy.

Soil and plant chemical analyses were fulfilled in analytical laboratory of Perm Agricultural Research Institute according national standards: humus content – GOST 26213-84 (Tyurin method); pH_{KCl} – GOST 26483-85 (potentiometrically); hydrolytic acidity - GOST 2 OST 26207-91 (Kappen method); total exchange bases – GOST 27821-88 (Kappen-Gilkovits method); content of mobile phosphorus and exchange potassium – GOST 26207-91 (Kirsanov method). Data processing included analysis of variance and correlation coefficients determination, using the program SPSS (v.18).

Results and discussion

Chemical parameters change of soil used in agriculture is significant aspect of their ecological assessment.

The agricultural use of soil without fertilizers application for eight years led to deterioration of soil absorbing complex parameters in plowing horizon in typical and green manuring crop rotations. Tendency of soil acidification in both rotations was noted, caused by pH_{KCl} decrease at 0.4-0.2, total exchange bases – at 28-30 mmol kg^{-1}

Concealed degradation processes were accompanied by increasing not only actual, but also potential acidity. Hydrolytic acidity increased by 2-3 mmol kg^{-1}. These processes were less expressed in green manuring crop rotation.

Degradation processes revealed also in decrease of humus content, average losses were 0.25 % in typical crop rotation and 0.02 % in green manuring crop rotation (table. 1). Less humus losses in green manuring rotation caused by green manure plowdown in fallow field.

Table 1. Effect of fertilizers and crop rotations on soil chemical properties.

Treatment	Typical crop rotation				Green manuring crop rotation			
	humus, %	pH_{KCl}	P_2O_5, mg kg^{-1}	K_2O, mg kg^{-1}	humus, %	pH_{KCl}	P_2O_5, mg kg^{-1}	K_2O, mg kg^{-1}

Content of phosphorus and potassium mobile forms decreased by 19 and 26 mg kg^{-1} (respectively) in typical rotation during five years. Losses of phosphorus and potassium by 6 and 8 mg kg^{-1} (respectively) were less in green manure rotation, compared to typical.

Comparative evaluation of agrochemical properties of plowing horizon in sod-podzolic soil revealed that accumulation of available nitrogen, mobile phosphorus and potassium (compared with the control treatment) was observed under systematic application of mineral fertilizers in rates of NPK 60 and 90 kg ha^{-1} for eight years. However, the positive effect of all rates of mineral fertilizers on soil absorbing complex was not noted. Process of acidification was enhanced compared with the soil before experiment foundation in both types of crop rotation.

Application of mineral fertilizers did not promoted the conservation of original humus content, that is coincide with the data obtained by Mineev and Shevtsova (1978). At the same time decreased of humus losses was noted due to adding to the soil more stubble and root residues compared with control treatment (no fertilizers).

Mineral and organic fertilizers use with low rates (NPK 30 kg ha^{-1} of FYM and 20 t ha^{-1}) provided conservation of humus, mobile forms of nitrogen, phosphorus, potassium, and has not stopped the process of soil acidification.

FYM application 40 t ha^{-1} slacked the decline process of organic matter and mobile forms of nitrogen, phosphorus and potassium. Increasing of FYM rate up to 60 t ha^{-1} provided stabilization of soil humus content and mobile forms of nitrogen, phosphorus and potassium as well.

Joint application of organic and mineral fertilizers in moderate rates provided humus conservation in typical crop rotation and its accumulation in green manuring rotation. Positive

changes of soil fertility properties are small en bloc, but are statistically significant as influenced by green manuring rotation.
The positive effect of joint application of organic and mineral fertilizers, even in moderate rates, expressed in raising of nitrogen, phosphorus and potassium mobile forms. Edmeades (2003) made the same conclusions as a result of data generalization of long-term experiments with fertilizers application.
FYM 20 t ha^{-1} and NPK 30 kg ha^{-1} application proved insufficient for soil fertility stabilization at the original level in both crop rotations types. Thus, irreversible changes in plowing horizon of sod-podzolic soil and reducing its fertility takes place under arable land irrational use and application of mineral and organic fertilizers low rates.
The stabilization of soil fertility is provided at the original level by FYM 60 t ha^{-1} in combination with NPK 60 kg ha^{-1} application in typical crop rotation, in green manuring rotation – 40 t ha^{-1} of FYM and NPK 60 kg ha^{-1}.
Results of our research works show that stubble and root residues incoming quantity significantly depends on crop rotation type. So, 53.4 t ha^{-1} of plant residues plowed down into the soil formed during rotation without use of fertilizers in green manuring rotation, 17.5 t ha^{-1} higher than in typical crop rotation. The application of mineral and organic fertilizers in moderate rates provided input increase of plant residues organic matter.
Improvement of agrochemical soil properties, humus content raising due to crop rotation and fertilizers promoted increase of soil biological activity and plants nutrients mobilization that had positive affect on yields level of arable crops.
Comparative general evaluation of field eight-course crop rotations revealed advantage of green manuring rotation (table 2).

Table 2. Effect of crop rotation type on average crops productivity and energy-efficiency of crop rotation

Treatment	Productivity, FU ha^{-1} per year			Energy-efficiency coefficient	
	crop rotation		supplements	crop rotation	
	typical	green manuring		typical	green manuring
No fertilizers	1950	2680	730	2.64	3.12
$N_{60}P_{60}K_{60}$	2220	3020	800	2.24	2.64
$N_{90}P_{90}K_{90}$	2340	3090	750	2.12	2.44
FYM 40 t ha^{-1}	2350	3110	760	2.54	3.07
FYM 40 t ha^{-1} + $N_{60}P_{60}K_{60}$	2400	3140	740	2.15	2.59

FYM 60 t ha^{-1} + $N_{90}P_{90}K_{90}$	2400	3060	660	1.82	2.20
LSD_{05} – 250					

Notes:
FU - feed units
LSD - least significant difference

The highest grain crop yields (2.47-3.09 t ha^{-1}) and average crops productivity (2680-3240 FU ha^{-1}) were obtained in green manuring rotation. The positive effect of FYM on grain crops yield observed for all application rates. However, the yields were higher at 10-69 % in green manuring rotation compared with typical. The highest productivity 2530 FU in typical crop

rotation was noted with application of FYM 60 t ha^{-1} and NPK 90 kg ha^{-1}, in green manuring rotation – 3190 FU with application of FYM 40 t ha^{-1} and NPK 60 kg ha^{-1}. Some other treatments (for instance, $N_{90}P_{90}K_{90}$, FYM 40 t ha^{-1}) provided approximately the same productivity, the difference between these treatments has not exceeded LSD_{05} value.

Joint application of organic and mineral fertilizers at moderate rates also promoted crop yields raising. High rates application of organic (60 t ha^{-1}) and mineral (90 kg ha^{-1}) fertilizers caused lodging of crops and as a result, reduced yields due to losses during harvesting.

Conclusion

Irrational use of arable land leads to soil degradation and, as a result, forming low crop yields. The highest negative balance of humus 0.25 t ha^{-1} per year was noted in typical crop rotation.

Stabilization of soil fertility at the original level was achieved under FYM application 60 t ha^{-1} in combination with NPK in typical crop rotation, in rotation with green-manured fallow – with FYM 40 t ha^{-1} and NPK 60 kg ha^{-1}.

Energy inputs were paid off by crop returns in both rotation types. The energy-efficiency coefficient varied from 1.82 to 3.07 depending on treatment.

Rotation with green-manured fallow with FYM application 40 t ha^{-1} and NPK 60 kg ha^{-1} provided average crops productivity 3140 FU ha^{-1}, grain crop yields 3.0 t ha^{-1}, energy-efficiency coefficient 2.59 and increased organic matter accumulation by 0.16% compared to basic level.

Abstract

Peculiarities of yield capacity formation of pea and barley grain in mixed sowings were studied in various component ratios and nitrogen fertilizer doses in the conditions of Middle Preduralie of Russia. The authors pointed out that on sod-podzolic heavy loamy, highly provided with phosphorus and potassium soil in years favorable for development of spring grain and unfavorable for legumes, the maximum yields of barley 5.36 t/ha were received at component ratio 12.5%+87.5% during sowing and nitrogen application 60 kg/ha. Crop yield in average over the research years was closely related to quantity of productive stems, which increased in average by 19-84 pcs/m^2, as well as to the increase of grain quantity in ear by 0.7-2.0 pieces and mass of 1000 grains by 1.0-6.5g. Application of nitrogen 60 kg/ha leads to sustainable reduction of pea productivity 4.5 times. This is due to a decline in all indicators of productivity. When applying nitrogen in a dose of 60 kg/ha, total nitrogen contents in barley leaves in the shooting phase reached an optimal level 4.36-4.43%. A direct relationship between the content of total nitrogen in leaves and grains of barley was revealed. Application of nitrogen 60 kg/ha provides crude protein content in barley 14.8-15.0%, and enables coarse grains with the digestible protein 105 g/fodder unit. The content of available energy in mixture grain is higher than 11 MJ/kg. Maximum energy 60.7 GJ/ha and protein crop productivity 646 kg/ha was observed at the component ratio 12.5% +87.5% and application of nitrogen under pre-sowing cultivation in a dose of 60 kg/ha.

Keywords: *pea, barley, mixed sowing, seeding rate, yield capacity.*

Introduction

At the moment increase of fodder production, amelioration of their quality and power ratio is the most important aim of the middle Preduralie regions' agriculture, because developing of cattle breeding and increase its productivity does not raise not only because of fodder shortage, but also because of protein unbalance, which became the reason of fodder considerable overspend and increased spend per unit of animal product. The main source of feed protein for animal is plant fodder. In connection with this the important requirement is liquidation of protein malnutrition and the rise of crude protein content in grain till 14 % and also increase the available energy till 11mJ per 1 kg of dry basis is the rise of fodder quality which is impossible without nitrogenous nutrition correct regulation of legume- grass compounds (Golovnya, Razumeiko, 2012; Shpakov, 2008; Proshkin, 2012).

As a consequence the great significance consists of scientifically based research of fodder deficit methods reducing which has well- balanced protein. One of the important things is organization of adaptive fodder production on the basis of highly productive mixed agrophytocenosis creation. This agrophytocenosis of cultivation was made by trial and error which uses more complete bioclimatic recourses of the region and provides acceptance of high quality fodder combined with recourse-saving and ecofriendly technologies of their cultivation.

The goal of the research is standard optimization of seeding, dose, methods of nitrogen fertilizer application for getting crop yield of pee-barley compound at the level of 4 t/ha with

the content of available energy at least 11 mJ/kg and prosperity of fodder unit digestible protein has at least 105g.
The following aims determined the next steps:
To elicit specialty crop yield seeds formation of pee-barley compound and its component depending on their correlation in the period of seeding and also to elicit the dose and method of nitrogen fertilizer application.
To determine the content of total nitrogen in barley leaves and estimates its connection with the quality of grain.
To make an agro-energy estimation of studying cultivation methods.

Material and methods

Experimental work was realized in 2011-2013 on the trial field of Perm State Agricultural Academy (Russia). The research was made on the sod-podzolic heavy loamy soil with average grade of organic matter (2.2 – 2.9 %), high content of potassium (138 – 150 mg/kg of soil) and phosphorus (293 – 398 mg/kg of soil), with average grade of ammoniac nitrogen (19.5 – 26.2 mg/kg of soil) and nitrate nitrogen (2.7 – 4.1 mg/kg of soil) which is typical for the middle Preduralie region (Mudrykh, Aleshin, 2011).
We applied common methods of establishment and held trail realization during the period of the research (Dospekhov, 1985; Fedin, 1985).
Object of research: common barley “Sonet”, field pea “Gubernator”. Experimental design – Factor A – seeding rate (components correlation (pea + barley) in the period of seeding, % from norm dropping in pure form): A1 – 25 + 75, A2 – 12.5 + 87.5; Factor B – method of nitrogen application: B1 – pre-plant, B2 – radical, B3 – foliage; Factor C – dose of nitrogen, kg/ha: C1 – 0, C2 – 15, C3 – 30, C4 – 45, C5 – 60. Disposition of variants is systematical with help of split-plot method and quadruple tier. Floor area of field is 75 m^2, accountable is 48 m^2. We used drill mixed planting method.
In our trial we used technology of pea- barley agrophytocenosis cultivating which is common for this region (Akmanaev, Zubarev, Eliseev, Renev, 2012). Fore-crop was winter wheat. The main cultivation of soil contained primary tillage LDG – 15B and plowing on the full depth enrichment horizon (PLN 4-35). In spring we made dragging of fell – plowed field BZTS 1.0 into two wheel-track with the following pre-plant wheel-track cultivation KPS-4.0+BZTS-1.0 at depth of 6 - 8 cm. Phosphorous and potassium fertilizers are used in dose of $P_{42}K_{104}$ which cover removal of food compounds with barley crop yield 4t/ha. They were applied under the pre-plant cultivation with spreader L – 116. Nitrogenous fertilizer in forms of calurea is used according to experimental design. The fertilizer was applied by hands under cultivation before seeding. The root application was made in phase of three leaves in barley with seed drill SZ – 3.6. On the stage of barley tillering was made foliar application as plant food with shoulder sprayer of 10% calurea solution. Norms of seeding of culture in pure sowing: pea 1.2 mio, barley 5.5 mio viable seeds per hectare. Planting method of components is mixed with help of row drill SSNP – 16. The depth of seed placement is 4 -5 cm. The single – phase harvesting with combine SK – 5M – 1 at the end of barley yellowing. The crop yield was reached 100% of purity and 14% of humidity.
The result of weather conditions’ evaluation in the period of the experiment shows that it was not typical as to distribution of precipitations and heat supply infrastructure. There was warm weather in May and June. The temperature was about +11.9 и +17.6 C^o, it means that it was higher than long-time average annual level. Also there was enough moisture content. The number of precipitations was 48 – 91 mm, which composed with 89 – 136 % from long-time average annual level.
Such conditions contribute the fast plants growing, especially for the barley in phase of tillering. There was very hot weather in July. The average temperature was +19.8C^o,

moreover there was the rise of the first and second decay till 25-30C^{o}. There was light precipitation (52% from long-time average annual level) which led to plant inhabitation such as pea, barley and reduction of their survival rate especially on the back of the rise nitrogen doses. This situation connected with well developing of nitrogen in phase of ear formation.

Results and discussion

It was defined that crop yield of pea-barley compound formed generally due to cereal component. The part of cereal component in harvest reached 95% (table 1).

We defined that the maximum of grain crop yield compound 5.36 kg/ha was reached with ratio of 12.5+87.5%, pre-plant of nitrogen application in quantity of 60 ha/kg, which is more 0.9 t/ha, than with ratio of 25+75% for 3-year average.

Pea-barley agrophytocenosis crop yield on average for the period of research connected primarily with expansion in the number of correlation barley yielding footstalk to gathering at an average 19 – 84 pcs/m^2, expansion in the number of grains is 0.7 – 2.0 pcs and mass of 1000 grains is 1.0 – 6.5 g. Using nitrogen fertilizer did not depend on the elements of pea crop yield structure, however there is a stable tendency of pea production cropper loss by means of beans quantity reduction on the plant to 0.4 – 1.4 pcs, the quantity of seeds in bean to 0.5 – 1.5 pcs and mass 1000 seeds to 7. – 49.7 g.

Every year in the period of research low crop yield of pea was determined by weak saving intensity of dry basis. The proportion of bean component in common biomass of compound to

barley milk stage did not exceed 3.5%. The quantity of active tuber on the pea root consists of 18 pcs per plant. The duration of their activities is 47 days.
Content of total nitrogen in barley leaves depends on method of application and dose of nitrogen (table 2). This content accomplishes the optimal level only after pre-plant of nitrogen application in amount of 60 kg/ha which consists 4.36-4/43%.
Low efficiency of pre-plant and foliar application appeared because the plant needed the nitrogen fertilizer in earlier period of growth and developing. Also the plant needed the period of realization foliage application. We observed the dry weather in all periods of research.
We revealed straight close relationship between containing of total nitrogen in leaves and grains of barley. The dose of nitrogen essentially influence on crude protein containing in barley grains. The maximum quantity was fixed after application of nitrogen in amounts of 6-kg/ha, on average 14.19%, which is more than other study amounts on 0.87 – 3.65%. As a result for getting fodder grain compound and barley with content of crude protein 14.8 – 15.0% it is necessary to apply nitrogen under pre-plant cultivation in amounts of 60 kg/ha minimum.

High concentration of crude protein in grains ameliorates its feeding value and provides higher digestibility. Calculations shows that compound of feeder grain reached the standard

prosperity of digestible protein to 105 gram per fodder unit. It can be possible only with 60 kg/ha dose of nitrogen fertilizer under pre-plant cultivation (table 3).
Contain of available energy in pea – barley compound grains reached 1.3 mJ/kg and did not depend on correlation of components and approach of nitrogen application. Compound grains without content nitrogen contain less available energy 0.1 mJ/kg. Consequently, it is important to apply the nitrogen under the pre-plant cultivation in amounts of 60 kg/ha for getting barley and pea-barley compound feeding grain in which there will be well balanced protein and contain minimum 11mJ/kg of available energy if the part of pea compound in the harvest is less than 5 %.
Energy output with harvest depends more on quantity and less on the quality. The maximum output of available energy in range of 60.7 gigajoule per hectare. We have got the next correlation of the components 12.5+87.5% and apply of nitrogen under pre-plant cultivation in range of 60 kg/ha however we fixed the maximum of protein seeding productivity on the level of 646 kg/ha.

Table 3. Content of digest protein in pea-barley grain compound depending on components correlation by seeding, method of applying and doses of nitrogen fertilizer, gram per feeding unit (the average to 2011-2013)

LSD05 r.d.F.A	F<F05	LSD05 m.e.F.A	F<F05
LSD05 r.d.F.B	7	LSD05 m.e.F.B	1
LSD05 r.d.F.C	4	LSD05 m.e.F.C	1

Conclusions

The pea-barley compound with component ratio under seeding 12.5+87.5% is forming crop yield of grains primary due to cereal component. The part in harvest consist of 95% on the sod-podzolic heavy loamy soil of the middle Preduralie region on the first humid and the second arid period of vegetation. The crop yield growth determined the density increase of productive crop 84 pcs/m^2, productivity of ear 0.24 g.

Content of total nitrogen in barley leaves depends on application methods and dose of nitrogen. The optimal level will be reached only with help of pre-plant application of nitrogen in amount of 60 kg/ha and will consist 4.36 – 4.43 % of stem elongation.
Peas and barley mixture sowing with correlation 12.5+87.5% with pre-sowing application of nitrogen dose 60 kg/ha provides crude protein content in barley grain 14.8-15.0 %. It allows getting a fodder with digestible protein level of 105 gram per fodder unit with available energy content in grain of mixture more than 11 MJ/kg, with a maximum output of available energy - 60.7 GJ/ha and collecting digestible protein 646 kg/ha.

Abstract

One of the oldest selective establishments in Russia is Nikita Botanical Garden (NBG), where in 1824 it started to select abundant and multi-blooming garden rose varieties, tolerant to climate of Southern Russia. Over 300 domestic sorts of 7 garden groups (Floribunda, Grandiflora, Hybrid Tea, Kordesii, Large-flowered Climber, Miniature, Shrub) were bred here applying various methods including a new system of complex selection of garden roses.
Reproduction of this assortment is carried out in 3 nurseries of NBG, located in different soil and climatic belts of the Crimea: Steppe, South Coastal and close to Sivash lake zones. Capacity to propagate by method of grafting on a seedling stock *R. canina* L. and green and ligneous cutting was investigated in terms of the research. The following was determined: the most favorable periods for cutting and grafting within different zones of the Crimea and methods of cuttings establishment and their growing. Container method for growing cuttings of garden roses, which favors a high seedling output (up to 91-97%), was developed.
Key words*:* *variety, garden roses, breeding, vegetative propagation, cuttings*

Introduction

NBG is one of the oldest breeding institutions of Russia, where in 1824 breeding of garden roses was initiated for the first time. Breeding researches were aimed at breeding of abundant and multi-blooming cultivars, tolerant to hot southern regions of Russia characterized by high air and soil aridity. Over 300 domestic cultivars of 7 garden groups (Floribunda, Grandiflora, Hybrid Tea, Kordesii, Large-flowered Climber, Miniature, Shrub) (Klymenko et al., 2012; Klymenko, 2012) were bred for 200 years applying different selective methods (hybridization, clonal selection and experimental mutagenesis). System of complex breeding of garden roses was developed and adopted to stimulate breeding of garden roses. This system permitted to extend spectrum of form-building processes of garden roses and considerably shorten selection terms of roses while breeding high-ornamental cultivars with transgression of the following parameters: remontantness and disease-resistance (Klymenko, 2012).
Domestic assortment of garden roses differs either by selection methods or by applying distant hybridization for various wild cultivars, what effected on these sorts capacity to propagate.
Moreover in different climatic zones of the Crimea quantitative and qualitative differences of seedlings took place. Being cultivated in these regions they had different degree of frost-resistance.
That`s why objective of this research was to develop and determine the optimal propagation methods and terms of domestic rose assortment in different climatic zones of the Crimea.

Materials and methods

Objects of this study were 350 garden rose cultivars and hybrid forms of domestic and foreign selections at collection plot NBG (Fig.1). They were investigated applying generally accepted methods for study, assessment and propagation of rose varieties (Bylov, 1971; Bylov, Nazarenko, 1968; Vasil´eva O.Y. 2006.; Vasil´eva O.Y. 2008.; Vasil´eva O.Y. 2009; Ambros Ye.V., Vasil´eva O.Y 2013; Uljanov et al., 1987). Green and ligneous cuttings of 2-3 or 4-5 buds were prepared with foliage conservation for further cutting. To intensify establishment of green cuttings they were treated by growth regulators in the following solutions: beta-indolebutyric acid (IBA) with concentration of 25-50 mg/l or beta-indoleacetic acid (IAA, heteroauxin) 50-100 mg/ or alfa-naphthylacetic acid (NAA) 12-25 mg/l. After treating green cuttings were planted into beds equipped by arched film cover and fog-forming system. During the period before root emergence (the first 15 days after cuttings were planted for establishment) fog-forming system is used since 9:00 till 21:00 with interval of 5 minute, water dispersion lasts 12-15 second. In phase of mass establishment (15-25 days after cuttings were planted) fog-forming system works keeping the previous regime. During the phase of total establishment (25-35 days after cuttings were planted) fog-forming system works since 10:00 till 19:00 with 5 minute interval, water dispersion lasts 7-8 second. In 35-40 days cuttings were planted for establishment, time of fog-forming system operation shortens 1 hour every other day. Then before total establishment of cuttings they are watered 1-2 times a week applying water dispersion for 30-40 minute. After cuttings were totally established film cover is taken down, abscissed leaves are removed and mineral fertilizers are used for extra nutrition.

Results and discussion

Using of different breeding methods gave us possibility to obtain assessment of garden roses characterized the by resistance to fungal diseases being cultivated under conditions of South Coast of the Crimea (Fig. 1). Majority of bred varieties of garden groups Floribunda, Grandiflora, Hybrid Tea, Miniature, are notable for not only high ornamental characteristics, but repeated, remontant and continuous blooming till 200 days (Fig. 2).

Propagation of domestic rose varieties is carried out in 3 nurseries of NBG, located in different soil and climatic belts of the Crimea: in north regions of the Crimea - Steppe and close to Sivash lake zones, and south region – South Coast of the Crimea. It was determined that majority of modern garden rose cultivars, based on warm-requiring varieties from the South East Asia being cultivated in north regions of the Crimea are more frost-resistant if to graft them on the local seedling stock, but not to establish scion-rooted plants as a result of cutting. Thereby for Steppe and close to the Sivash lake zones rose propagation on the seedling stock is more preferable, but for South Coast of the Crimea cutting is appropriate as well.

During industrial cultivation capacity of garden roses to different ways of vegetative propagation was investigated and it was found out for some cultivars cutting is the main way to product planting stock, while combination with grafting can be successful for others. According to biological peculiarities of cultivars and demands of economics both propagation ways complementing each other provide high efficiency in production of rose seedlings. Especially high percentage of establishment due to cutting method was marked out for cultivars of the following garden groups: Floribunda, Large-flowered Climber, Miniature.

According to study results method of green cutting is the most prospective method of garden rose propagation on South Coast of the Crimea. This method assumes establishment of cuttings in special beds equipped by artificial fog-system. Special substrate is used for cuttings establishment. It must be quite water and air-penetrating with heat capacity, free of seeds and weeds, pests and agents of diseases. This substrate should consist of two layers:

bottom layer of 15-20 cm thick is a nutrient solution (humus, peat and sand or upper peat, valley peat and pearlite in equal shares) and the upper layer (2-3 cm) is sand.
During research the following was determined: optimal periods of cutting within Steppe Crimea and South Coast of the Crimea, methods of cuttings preparation and treatment by growth regulators, optimal modes of operation for fog-forming system depending on a stage of cutting establishment. According to research data optimal term for green cutting on South Coast of the Crimea is a period (the first decade of May – the first decade of June) when rose shoots are half-lignificated with the phase of budding (phase of coloured bud), and during the mass blooming. After necessary agrotechnical treatment during summer and innovations forming on cut stools, they are used for repeated green cutting in the first decade of August.

Figure 1. Varieties of gardens' roses breeding of NBG

Under conditions of north zone of the Crimea optimal period for green cutting is June. Cuttings can consists of 2-3 or 4-5 buds, leaves are preserved. Cuts of grafts are treated by special powder containing growth regulators. After that green grafts are planted into beds equipped by artificial fog-system and film covering, which is removed in 30-40 days.
Later when cuttings established, mineral fertilizer is added (50g/1 m^2). The following dosing (nitrogen fertilizer) is in 3 weeks, after 3-4 weeks - potash fertilizer. Established cuttings are grown till standard size to produce scion-rooted seedlings of garden roses in the field

conditions for realization. Container method for growing rose established cuttings, which favors a high seedling output (91-97%), was developed in terms of this investigation.
Propagation of garden roses by ligneous cuttings in standard beds is carried out in autumn – September, beginning of October – either in north or in South Coastal zones of the Crimea. Established grafts are grown under field conditions or in containers during the next year and realized.

Figure 2. Long-flowering varieties of garden roses bred in NBG

It was determined that optimal period for grafting on seedling stock of *R. canina* L. in north regions of the Crimea is last decade of August, while on South Coast of the Crimea – the first decade of September. Realization occurs the next autumn.

Conclusions

System of complex breeeding of garden roses developed in NBG favored breeding of more than 300 highly ornamental cultivars of garden roses, which are propagated by two ways: cutting and grafting on stock seedling. It was determined that in north regions of the Crimea cultivation of garden rose is more preferable by grafting on stock-seedling, while for south regions green and ligneous cutting is comfortable as well.

Abstract

In the five economically most important cultivars of pears grown in Europe (‘Butirra Precoce Morettini’, ‘Carmen’, ‘Williams’, ‘Conference’ and ‘Abate Fetel’) flowering, pollen germination and pollen tube length were examined in 2012 and 2013 on Radmilovac locality. Pear flowering occurred in the second decade and at the beginning of the third decade of April. ‘Carmen’ cultivar was characterized by the earliest, and the ‘Williams’ cultivar the latest beginning of flowering. Flowering lasted on average 9.4 days and ranged from 8.5 to 11.0 days depending on the cultivar. These examined pear cultivars were statistically very different in terms of pollen germination and pollen tube length. Pollen germination ranged from 42.75% in ‘Williams’ cultivar to 73.54% in ‘Abate Fetel’ cultivar. The lowest length of pollen tubes was found in ‘Butirra Precoce Morettini’ cultivar (644.71 μm), and the highest in ‘Carmen’ (1068.04 μm) and ‘Abate Fetel’ (1009.35 μm). ‘Abate Fetel’ and ‘Conference’ cultivars which showed the highest pollen germination can be recommended as a potentially good pollenisers in new commercial plantations of pear.

Key words: *Pyrus communis, flowering, pollen germination, pollen tube length.*

Introduction

After the grapevine and apple, pear is the third most important continental fruit species that are grown in the world. Production of pears in the world is constantly increasing (Wojciechowski and Antkowiak, 2009). Although there are many cultivars of pears, world production is based on only a few cultivars, such as ‘Williams’, ‘Conference’, ‘Passe Crassane’, ‘Docteur Jules Guyot’, ‘Beurré Anjou’ and ‘Beurré Bosc’ (Bell, 1991; Deckers and Schoofs, 2008).

The main objectives of pear breeding are creating of cultivars with good fruit quality that can long be kept, high and regular productivity, as well as the development of cultivars resistant to climatic factors (frost and drought) and to disease pests (Milatović, 2009).

For good fruit set and achieve high yields, it is necessary to conduct a successful pollination and fertilization. These processes depend on more factors: the success of transfer of pollen, its quality, structure of stigma and style, pollen germination and pollen tube growth, the emergence of incompatibility and effective pollination period (Stösser et al., 1996). One of the very important factors in these processes is the quality of pollen, which varies between individual cultivars within one species. In addition, the quality of pollen depends on the time of taking, methods of collecting and storing conditions (Stanley and Linskens, 1974).

Knowledge of pollen quality is very important for breeding and production of pear. For breeders it is very important to know the functional ability of pollen before crossing, and for producers because of the choice of appropriate pollenisers when planting of pear orchards. This is especially significant at pear, considering to it, that in production beside diploid are cultivated a triploid cultivars, which have low pollen germination and can no used as pollenisers.

Therefore, the aim of this study was to examine phenophase of flowering, pollen germination and pollen tube length, in order to the cultivars with the highest pollen germination are recommended as a potentially good pollenisers when planting of pear orchards and choice of parents for breeding work.

Material and methods

Investigations were carried out at the experimental field "Radmilovac" Faculty of Agriculture, University of Belgrade (Serbia). The subject of this research was five cultivars of pear: 'Butirra Precoce Morettini', 'Carmen', 'Williams', 'Conference' and 'Abate Fetel'. The rootstock is quince BA 29, training system is 'Slender Spindle' and planting distance is 3.5 x 1.0 m. Researches were carried out during 2012 and 2013.

In the mentioned cultivars, phenophase of flowering, pollen germination and pollen tube length were investigated. Phenophase of flowering was monitored by the recommendations of the international working group for pollination (Wertheim, 1996). Beginning of flowering is registered as 10% of open flowers, full of flowering when 80% of flowers open, and the end of flowering, when it fell 90% petal. The duration of flowering is given as the number of days from the beginning to the end of flowering and abundance of flowering estimates from 0 to 5.

For examination of pollen germination branches with flower buds in the 'balloon' phase were taken and carried to the laboratory. In order to collect pollen from the flower buds anthers were isolated in Petri dishes. They are stored at room temperature (20±2ºC) for 24-48 h to dry and to release the pollen. Then, the pollen of each cultivar was sown with fine brushes in Petri dishes (9 cm diameter) on the previously prepared nutrient medium consisting of 15% sucrose and 0.7% agar-agar.

Petri dishes with a sowed pollen were observed under light microscope 'Leica DM LS' (Leica Microsystems, Wetzlar, Germany), for counting of germinated pollen grains. The experiment was done in three repetitions, each including at least 300 pollen grains. Pollen is considered as germinated if the length of pollen tube was larger than the diameter of the pollen grain.

Pollen tube length was measured from images taken under the microscope 'Leica DM LS' using 'Leica IM 1000' program. From each cultivar 60 pollen tubes were measured.

The obtained results were processed statistically with the help two factorial analysis of variance. Percentage data were subjected to arcsin square root transformation before the statistical analysis. Duncan's multiple range test (5% and 1%) was performed for means comparison. Data analysis was performed using the statistical software package 'Statistica' (StatSoft, Inc., Tulsa, Oklahoma, USA).

Results and discussion

Knowing flowering time of pear cultivars is very important for selecting the most appropriate pollenisers. Pear flowering occurred in the second decade and at the beginning of the third decade of April (Table 1). 'Carmen' cultivar was characterized by the earliest (11 April), and the 'Williams' cultivar the latest beginning of flowering (14 April). Beginning of flowering is very varied by years of research. All studied cultivars were beginning to flowering earlier in 2012 compared to 2013. Beginning of flowering in 2012 was an average of two weeks earlier (05 April) compared to 2013 (19 April). The differences between years can be linked to differences in air temperatures just before the beginning of flowering, which were higher in 2012 compared to 2013. Full of flowering is occurred on average two days after the beginning of flowering and this sub-phases is also registered earliest at cultivar 'Carmen' (12 April), and latest at cultivar 'Williams' (16 April). Consequently, the end of flowering is occurred earliest at cultivar 'Carmen' (20 April), and latest at cultivar 'Williams' (23 April).

Table 1. Flowering of investigated pear cultivars.

Cultivar	Year	Beginning of flowering	Full of flowering	End of flowering	Duration of flowering (days)	Abundance of flowering (0-5)
‘Butirra Precoce Morettini’	2012	05 April	07 April	15 April	15.0	2.0
	2013	19 April	21 April	26 April	7.0	2.0
	Mx	**12 April**	**14 April**	**21 April**	**11.0**	**2.0**
‘Carmen’	2012	04 April	05 April	15 April	11.0	4.0
	2013	18 April	19 April	24 April	6.0	5.0
	Mx	**11 April**	**12 April**	**20 April**	**8.5**	**4.5**
‘Williams’	2012	07 April	09 April	18 April	11.0	3.0
	2013	21 April	23 April	28 April	7.0	3.0
	Mx	**14 April**	**16 April**	**23 April**	**9.0**	**3.0**
‘Conference’	2012	06 April	08 April	17 April	11.0	3.0
	2013	20 April	22 April	27 April	7.0	3.0
	Mx	**13 April**	**15 April**	**22 April**	**9.0**	**3.0**
‘Abate Fetel’	2012	05 April	08 April	16 April	11.0	5.0
	2013	18 April	20 April	26 April	8.0	5.0
	Mx	**12 April**	**14 April**	**21 April**	**9.5**	**5.0**
Year	2012	05 April	07 April	16 April	11.8	3.4
	2013	19 April	21 April	26 April	7.0	3.6
	Mx	**12 April**	**14 April**	**21 April**	**9.4**	**3.5**

Flowering lasted an average of 9.4 days, with a variation between cultivars of 8.5 days (‘Carmen’) to 11.0 days (‘Butirra Precoce Morettini’). Data on the duration of flowering in pear agree with the allegations Mratinić (2000). The duration of flowering was shorter in 2013. The reason is that the flowering of cultivars in 2013 occurred later, when are higher air temperatures, which caused the faster flow of phenophase flowering in this year.

Abundance of flowering is a genetic trait of species ie cultivar of which depends largely on fruit set and yield (Mratinić, 2000). This trait is very varied among the pear cultivars in our experiment. ‘Abate Fetel’ cultivar had the highest, ie maximum score for the abundance of flowering (5.0). In addition to the cultivar ‘Abate Fetel’, high score for abundance of flowering had a ‘Carmen’ cultivar (4.5). On the other hand, the cultivar ‘Butirra Precoce Morettini’ is rated as the worst in terms of the abundance of flowering (2.0).

Test of pollen germination *in vitro* is one of the main indicators of functional pollen viability (Figure 1). The average pollen germination of all cultivars in the two-year period amounted to 53.09% (Table 2). Pollen germination is statistically very significant different among the pear cultivars. The highest pollen germination was found in ‘Abate Fetel’ cultivar (73.54%). Mratinić (2000) points out also for this cultivar that has a good germination of pollen. In addition to the ‘Abate Fetel’ cultivar, high pollen germination was characterized by the ‘Conference’ cultivar (61.79%). On the other hand, pollen germination rate was the lowest in the ‘Williams’ cultivar (42.75%). Stančević (1980) states that the pollen germination of diploid pear cultivars varies from 30% to 100%. Pollen germination of the cultivars tested in our work was at the mentioned interval. Sharafi (2011) found that the pollen germination of some indigenous of pear cultivars in Iran ranged from 28.4% to 80.8%. However, Jovančević (2002) established that the genotypes of wild pear (*Pyrus communis*) are characterized by an extremely high pollen germination (average 94.76%).

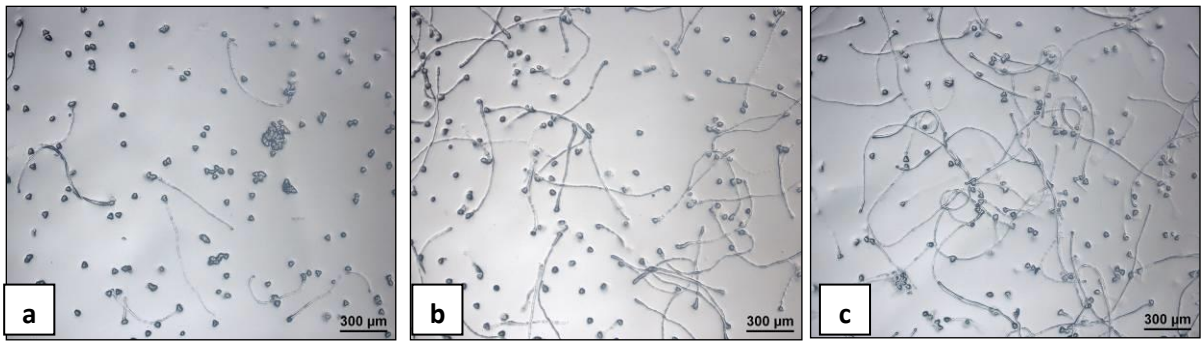

Figure 1. Pollen germination in pear cultivars: a) ‘Carmen’, b) ‘Conference’, c) ‘Abate Fetel’.

Apart among the cultivars, pollen germination is very significantly different between the investigated years. It was on average about 20% higher in 2013 compared to the year 2012. This can be explained by the influence of different temperatures between years at pollen germination, which is in line with the results of Deckers and Porreye (1984). It was found that despite the low, high temperatures during anther development affecting the poorer pollen germination (Pressman et al., 2002).

Table 2. Pollen germination of investigated pear cultivars (%).

Cultivar/Year	2012	2013	**Mx**
‘Butirra Precoce Morettini’	25.95	60.55	**43.25 c**
‘Carmen’	24.63	63.60	**44.12 c**
‘Williams’	24.67	60.83	**42.75 c**
‘Conference’	57.21	66.38	**61.79 b**
‘Abate Fetel’	79.28	67.80	**73.54 a**
Mx	**42.35 b**	**63.83 a**	**53.09**

In addition to pollen germination, pollen tube length is a very significant different between the pear cultivars (Table 3). In the ‘Carmen’ and ‘Abate Fetel’ cultivars was determined the highest of pollen tube length (1068.04 µm and 1009.35 µm). In contrast, the pollen tube length was the lowest in ‘Butirra Precoce Morettini’ cultivar (644.71 µm). The pollen tube lenght in our work was significantly higher than the indigenous pear cultivars which examined by Sharafi (2011) in Iran. This is due to genetic differences between the two groups of cultivars.

Table 3. Pollen tube length of investigated pear cultivars (µm).

Cultivar/Year	2012	2013	**Mx**
‘Butirra Precoce Morettini’	418.85	870.58	**644.71 c**
‘Carmen’	611.15	1524.92	**1068.04 a**
‘Williams’	453.06	1098.36	**775.71 b**
‘Conference’	768.68	1171.81	**970.25 a**
‘Abate Fetel’	913.75	1104.95	**1009.35 a**
Mx	**633.10 b**	**1154.12 a**	**893.61**

Similarly pollen germination, pollen tube length is very significant different between the years of research. It was an average for all cultivars two times higher in 2013 (1154.12 μm) compared to 2012 (633.10 μm).

Conclusion

Based on the research results of flowering, pollen germination and pollen tube length of five the most important pear cultivars in the Belgrade area was determined following:

Pear flowering occurred in the second decade and at the beginning of the third decade of April. ‘Carmen’ cultivar was characterized by the earliest, and the cultivar ‘Williams’ the latest beginning of flowering.

Phenophase of flowering in the cultivars studied in this paper is quite coincided, so according to this criterion all cultivars can be used as mutual pollenisers.

These examined pear cultivars were statistically very different in terms of pollen germination and pollen tube length. ‘Abate Fetel’ and ‘Conference’ cultivars which showed the highest pollen germination can be recommended as a potentially good pollenisers in new commercial plantations of pear.

Abstract

Pollen germination and pollen tube growth *in vitro* in eight quince cultivars (‘Leskovacka’, ‘Vranjska’, ‘Morava’, ‘Pazardzijska’, ‘Hemus’, ‘Asenica’, ‘Portugal’ and ‘Triumph’) were studied in the three-year period (2010-2012). Agar-plate method with three different concentrations of sucrose (10%, 15% and 20%) was applied. Statistically significant differences between quince cultivars were found in terms of pollen germination and pollen tube length. The highest germination rate was found in 15% sucrose (78.72% in average). Slightly lower germination was found in 20% sucrose (78.52%), while the lowest germination was determined in 10% sucrose (73.76%). Among quince cultivars, the highest germination rates were found in ‘Triumph’ and ‘Asenica’, and the lowest in Leskovacka. Increasing the concentration of sucrose increased the pollen tube length (from 1435.8 μm in 10%, followed by 1790.7 μm in 15% to 2077.5 μm in 20%). Pollen tube length in 20% sucrose concentration ranged from 1770.3 μm (‘Vranjska’) to 2574.4 μm (‘Asenica’). Based on obtained results, the sucrose concentrations of 15% and 20% can be recommended as optimal for pollen germination of quince cultivars.

Key words: *Cydonia oblonga, sucrose, pollen germination, pollen tube length*.

Introduction

Pollen germination and pollen tube growth are the most important characteristics that determine the quality of pollen. The quality of pollen is a very important factor for successful fertilization, fruit set and yield in quince (*Cydonia oblonga* Mill.).

Pollen viability varies between individual cultivars within the same fruit species (Stösser et al., 1996). In addition to the cultivar, pollen viability depends of rootstock on which the cultivar is grafted (Kidman et al., 2014). Besides these factors, pollen viability varies depending of microclimate, locality, character of last year's vegetation, vigour, age, nutrition and health status of fruit trees (Pejkić, 1980). Pollen viability can be affected by the presence of heavy metals: Cd, Cu, Hg and Pb (Gür and Topdemir, 2008; Kiliç et al., 2009), boric acid (Imani et al., 2011; Mondal and Ghanta, 2012; Liu et al., 2013), plant growth regulators (Bolat and Pirlak, 2003; Tosun and Koyuncu, 2007) and the fungicides (Yi et al., 2003; Kargar and Imani, 2011). Also, the quality of pollen depends on the time of taking, methods of collecting (Stanley and Linskens, 1974), the length and mode of its storage (Aslantas and Pirlak, 2002; Perveen and Khan, 2008). The germination of pollen varies depending of temperature (Pirlak, 2002; Sorkheh et al., 2011; Milatović and Nikolić, 2014).

One of the most important factors affecting to the pollen germination is sucrose concentration (Dalkiliç and Mestav, 2011; Sutyemez, 2011). The optimum concentration of sucrose for testing the pollen germination varies between different fruit species and it is ranging from 10 to 20% (Mahanoğlu et al., 1995; Milatović and Nikolić, 2007; Mert, 2009; Dalkiliç and Mestav, 2011; Sutyemez, 2011). However, the concentration of sucrose over 20% may have an inhibitory effect on pollen germination (Bolat and Pirlak, 1999).

Knowledge of pollen functional ability is a very important parameter in fruit breeding for the choice of male parent in hybridization. In addition, this parameter is very significant in the production practices for the selection of appropriate pollenisers when planting of quince orchards, because pollenisers, among other parameters need to be distinguished by good pollen germination.
The aim of this study was to determine the pollen germination and pollen tube length in eight quince cultivars, in order to evaluate suitability of these cultivars as potential pollenisers. Also, testing of nutrient media with different concentrations of sucrose aimed to determine the optimal concentration for testing pollen germination and pollen tube length.

Material and methods

Investigations were carried out in the collection orchard of quince at the Experimental Station 'Radmilovac' of the Faculty of Agriculture in Belgrade during a three-year period (2010-2012). The orchard was established in the spring of 1999, with the planting space of 4.5 x 3 m. The study comprises eight cultivars of quince: 'Leskovacka', 'Vranjska', 'Morava', 'Pazardzijska', 'Hemus', 'Asenica', 'Portugal' and 'Triumph'. The examined cultivars were grafted on the rootstock 'Quince MA'.
For examination of pollen germination branches with flower buds in the 'balloon' phase were taken and carried to the laboratory. In order to collect pollen from the flower buds anthers were isolated in Petri dishes. They are stored at room temperature (20±2ºC) for 24-48 h to dry and to release the pollen. Then, the pollen of each cultivar was sown with fine brushes in Petri dishes (9 cm diameter) on the previously prepared nutrient medium consisting of three different sucrose concentration (10%; 15% and 20%) and 0.7% agar-agar.
Petri dishes with a sowed pollen were observed under light microscope 'Leica DM LS' (Leica Microsystems, Wetzlar, Germany), for counting of germinated pollen grains. The experiment was done in three repetitions, each including at least 300 pollen grains. Pollen is considered as germinated if the length of pollen tube was larger than the diameter of the pollen grain.
Pollen tube length was measured from images taken under the microscope 'Leica DM LS' using 'Leica IM 1000' program. From each cultivar 60 pollen tubes were measured.
The data were statistically analyzed using three-factor analysis of variance (ANOVA). In the results expressed in percentages, the arcsin square-root data transformation was performed. The significance of differences between the mean values was determined using the Tukey's test for significance level $p < 0.05$. Data analysis was performed using the statistical software package STATISTICA, Version 8 (StatSoft, Inc., Tulsa, Oklahoma, USA).

Results and discussion

Test of pollen germination *in vitro* is one of the main indicators of pollen functional ability (Figure 1). The average pollen germination for all cultivars in the three-year study period was quite high and amounted to 77.00% (Table 1). It has significantly varied between the examined cultivars and ranged from 65.12% ('Leskovacka') to 84.74% ('Triumph'). Pollen germination at a concentration of 10% sucrose was highest in 'Triumph' cultivar (82.40%) and lowest in 'Leskovacka' cultivar (62.61%). 'Leskovacka' cultivar had lowest pollen germination at sucrose concentrations of 15% (64.62%) and 20% (68.12%), while the 'Asenica' cultivar had highest pollen germination in sucrose concentrations 15% (86.43%) and 20% (87.58%). In addition to 'Asenica' and 'Triumph' cultivars, high pollen germination had 'Pazardzijska' and 'Morava' cultivars, which is consistent with the findings of Stančević (1986) and Stančević (1990). Pollen germination between quince cultivars examined in our work was much less varied in relation to the one established by Sharafi (2011a) in Iran, in which the pollen germination ranged from 45.4% to 82.3%. This is due to genetic differences between tested cultivars.

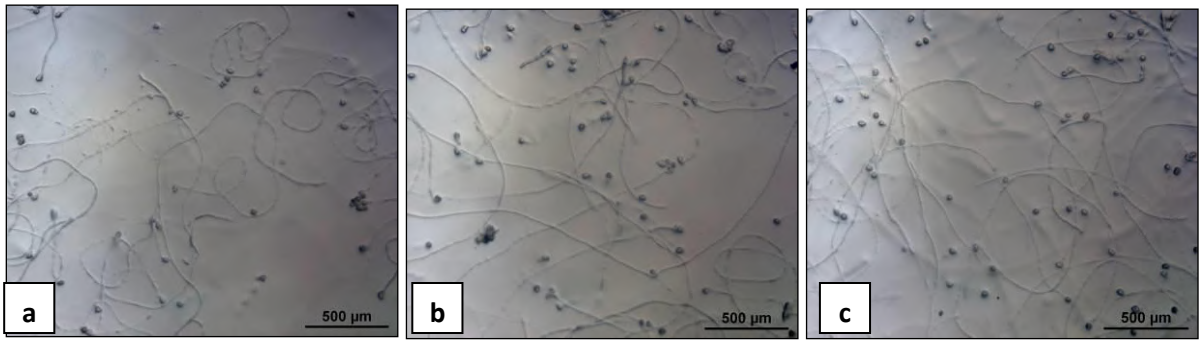

Figure 1. Pollen germination of Triumph cultivar at three different sucrose concentrations: a) 10%, b) 15%, c) 20%.

In addition to the cultivars, pollen germination differed significantly between investigated concentrations of sucrose, which is in accordance with the results Dalkiliç and Mestav (2011). The highest germination rate was found in 15% sucrose (78.72% in average). Slightly lower germination was found in 20% sucrose (78.52%), while the lowest germination was determined in 10% sucrose (73.76%). These results partially agree with those obtained by Çetin and Soylu (2006), where the highest pollen germination in quince cultivars was found in 10% and 15% sucrose solution. Pollen germination rate also varied depending on the concentration of sucrose in the Japanese pear (Okusaka and Hiratsuka, 2009), apricot (Mahanoğlu et al., 1995; Milatović and Nikolić, 2007; Asma, 2008), sweet and sour cherry (Bolat and Pirlak, 1999; Sutyemez, 2011) and walnut (Mert, 2009).

Table 1. Pollen germination (%) of investigated quince cultivars (average 2010-2012).

Cultivar/Year		Sucrose concentration			Mx
		10%	15%	20%	
‘Leskovacka’		62.61	64.62	68.12	**65.12 d**
‘Vranjska’		68.75	71.86	75.45	**72.02 c**
‘Morava’		74.41	82.60	80.61	**79.21 b**
‘Pazardzijska’		74.14	80.76	78.75	**77.88 b**
‘Hemus’		76.76	80.47	77.27	**78.17 b**
‘Asenica’		79.38	86.43	87.58	**84.46 a**
‘Portugal’		71.64	77.22	74.36	**74.41 c**
‘Triumph’		82.40	85.81	86.02	**84.74 a**
Year	2010	80.26	83.13	83.00	**82.13 b**
	2011	80.61	85.79	84.69	**83.70 a**
	2012	60.41	67.24	67.87	**65.17 c**
Sucrose concentration		**73.76 b**	**78.72 a**	**78.52 a**	**77.00**

The pollen germination in our study was significantly different between years, but it was a more balanced in the first two years, amounting to over 82%. However, it was about 15-20% lower in 2012 and amounted to 65.17%. It can be connectted with the influence of low temperatures on the pollen germination in this year.

Pollen tube length was significantly different among quince cultivars, sucrose concentrations and years of study (Table 2), which is in line with the results Milatović and Nikolić (2007). An average length for all cultivars was 1768.0 µm, and it varied between cultivars from 1577.5 µm (‘Hemus’) to 2015.8 µm (‘Asenica’). At a sucrose concentration of 10%, pollen

tube length ranged from 1236.1 μm (‘Hemus’) to 1674.2 μm (‘Portugal’). ‘Hemus’ cultivar had shortest pollen tubes (1411.9 μm) in 15% sucrose solution, and the longest pollen tube lenght had ‘Asenica’ cultivar (2072.0 μm). At a sucrose concentration of 20% lowest pollen tube lenght had ‘Vranjska’ cultivar (1770.3 μm), and highest ‘Asenica’ cultivar (2574.4 μm). Pollen tube lenght in our work was significantly higher compared to the results obtained by Sharafi (2011 a, b), at the quince cultivars in Iran, what is result of genetic differences between these two groups of cultivars.

Table 2. Pollen tube length (μm) of investigated quince cultivars (average 2010-2012).

Cultivar/Year		Sucrose concentration			Mx
		10%	15%	20%	
‘Leskovacka’		1543.2	1898.5	2011.9	**1817.9 ad**
‘Vranjska’		1375.0	1797.2	1770.3	**1647.5 bcde**
‘Morava’		1371.5	1593.9	1926.2	**1630.5 cde**
‘Pazardzijska’		1528.0	1839.6	2154.0	**1840.5 ab**
‘Hemus’		1236.1	1411.9	2084.5	**1577.5 e**
‘Asenica’		1401.0	2072.0	2574.4	**2015.8 a**
‘Portugal’		1674.2	1735.2	1957.2	**1788.9 bcd**
‘Triumph’		1357.3	1977.1	2141.5	**1825.3 ac**
Year	2010	1774.0	2121.5	2300.4	**2065.3 b**
	2011	1964.5	2407.4	2798.8	**2390.2 a**
	2012	568.8	843.1	1133.2	**848.4 c**
Sucrose concentration		**1435.8 c**	**1790.7 b**	**2077.5 a**	**1768.0**

Increasing the concentration of sucrose increased the pollen tube length (from 1435.8 μm in 10%, followed by 1790.7 μm in 15% to 2077.5 μm in 20%). This trend was evident in all cultivars except the ‘Vranjska’ cultivar, in which the pollen tube length was the highest at a concentration of 15% sucrose. However, Bolat and Pirlak (1999) were determined the highest pollen tube length at sucrose concentrations of 10% and 15% at some cultivars of apricot, sweet and sour cherry. This indicates that the optimal concentration of sucrose for testing of pollen tube growth depends of fruit species.

Depending on meteorological conditions, the pollen tube length has differed by years. It was the highest in 2011, and the lowest in 2012. The occurrence of late spring frosts in April 2012 reduced the pollen tube length two to three times compared to the previous two years. This effect was present in all tested cultivars, except for ‘Asenica’ cultivar at sucrose concentrations of 15% and 20%.

Conclusion

Based on the results of three year trials, it can be concluded that the pollen germination and pollen tube length differed significantly depending on the cultivar, year and the concentration of sucrose. ‘Triumph’ and ‘Asenica’ cultivars were characterized with highest and ‘Leskovacka’ cultivar with lowest pollen germination. All studied cultivars had high pollen germination, so they can be recommended as a potentially good pollenisers in new commercial plantations of quince. Based on obtained results, the sucrose concentrations of 15% and 20% can be recommended as optimal for pollen germination of quince cultivars.

Abstract

Recently, various technologies have been developed in order to achieve maximal utilization of by-products of wine production as well as greater productivity. One of the most potential by-products of wine production is grape pomace, which is still very rich source of anthocyanins. It is well known that these natural colourants have high antioxidant activity.

The aim of this research was optimization of anthocyanins extraction from grape skin of black grape variety *Cabernet Sauvignon*. The extraction was carried out with water and water/ethanol in different ratios. The extraction efficacy and kinetics as well as the application of ultrasound (40 kHz) were examined.

The content of total anthocyanins and total polyphenols were determined by pH differential and the Folin-Ciocalteu method, respectively.

The results indicate a significant influence of ethanol and ultrasound on the anthocyanins extraction efficiency. In addition, the time needed for the extraction maximum was significantly decreased (90 minutes) compared to water extraction. The best results have been achieved with 70% ethanol solution exposed to ultrasound, where a three times higher contents of anthocyanins and total polyphenols were obtained than in water extracts.

The grape skin of black varieties, especially *Cabernet Sauvignon*, could be important source of natural colourants and bioactive compounds. Furthermore, it should represent replacement for artificial colourants in numerous food products in the current worldwide market.

Key words: *extraction, grapeskin, anthocyanins, colourants, polyphenols*

Introduction

Utilization of by-products from the food industry is an increasing economic and ecological issue. There are trends of developing novel technologies, in order to achieve maximal exploitation of by-products and greater productivity with minimal environmental contamination (Schieber et al., 2001; Galanikis 2012).

Anthocyanins are well known as a valuable bioactive compounds and their addition in food product has a great potentials (Liang et al., 2008; Iriti and Faoro, 2011). Problem with applying of these components in food is low stability during the processing and storage of food or in the gastrointestinal tract. The effectiveness of these components depends on preservation of their stability, bioactivity and bioavailability which are limited by external influences.

In order to obtain the extracts of better quality, different types of extractions and traditional extractions (maceration, with the use of enzymes) are increasingly being replaced by modern, such as ultrasonic extraction. With this type of extraction, which is actually modified by maceration, extraction of anthocyanins and other polyphenolic compounds is improved by using ultrasound. The effect of ultrasound on the extraction of bioactive compounds from

different plant material is attributed to: cavitation effects (affect the destruction of the cell wall), hydration of material, particle size reduction, and the acceleration of the mass transfer.
In our research authors compared the efficacy and extraction kinetics of water and water/ethanol extractions with and without the application of ultrasound (40 kHz) during 360 minutes.

Material and Methods

In this study grapeskin of black grape variety *Cabernet Sauvignon* was used. This grape variety was grown at the experimental school estate of Faculty of Agriculture – "Radmilovac", Serbia.
Chemicals: Potassium chloride and ethanol were procured from Centrohem (Belgrade, Serbia). Citric acid and sodium hydrogen phosphate were purchased from Hemos (Belgrade, Serbia). Potassium dihydrogen phosphate was provided by Fisher Chemical (Lougborogh, UK). Gallic acid, Folin-Ciocalteu's phenol reagent, ammonium hydroxide, hydrochloric acid, sodium acetate trihydrate and sodium carbonate were purchased from Merck (Darmstadt, Germany).

Extraction

Milled grapeskin was extracted with water, 50 %v/v and 70 %v/v ethanol solutions during 360 minutes. The samples were extracted by shaking (200 rev/min) with and without the application of ultrasound. The ultrasonic bath (Elma) with frequency 40 kHz was used. Ethanol was chosen as the solvent based on its environmentally friendly characteristics and its ability to enhance the extraction of phenolic constituents and anthocyanins from grapeskins, respectively, compared to mono-component systems (Spigno et al., 2007). Pinelo et al. (2005) also pointed out the advantages of using ethanol instead of methanol and water.

Determination of total anthocyanins

The content of total monomeric anthocyanins was determined by pH differential method that is based on the structural transformation of anthocyanins in change in pH (Lee et al., 2005). The monomeric anthocyanins are subject to structural transformation of the reversible as a function of pH, wherein at pH = 1 are in the form of intensely stained flavilijum cation, and at a pH = 4.5 taking the form of a colorless hemiketal. Anthocyanins' content is determined by measuring the change in absorbance at two different pH values (pH = 1 and pH = 4.5), whereby the difference in absorbance of a pigment at a wavelength of 520 nm is proportional to the concentration of the pigment. The concentration of the monomer is expressed in anthocyanin cyanidin-3-glucoside according to the equivalents of the following formula:

$$\textit{anthocyanin content(cyanidin-3-glucoside equivalents, mg/L)} = A \times MW \times DF \times 10^3 / \mathcal{E} \times l,$$

where $A = (A_{520nm} - A_{700nm})_{pH1.0} - (A_{520nm} - A_{700nm})_{pH\ 4.5}$; MW (molecular weight) = 449.2 g/mol for cyanidin-3-glucoside (cyd-3-glu); DF = dilution factor established in D; l = pathlength in cm; $\mathcal{E}$ = 26 900 molar extinction coefficient, in $Lmol^{-1}cm^{-1}$, for cyd-3-glu; and 10^3 = factor for conversion from g to mg.

Determination of total polyphenols

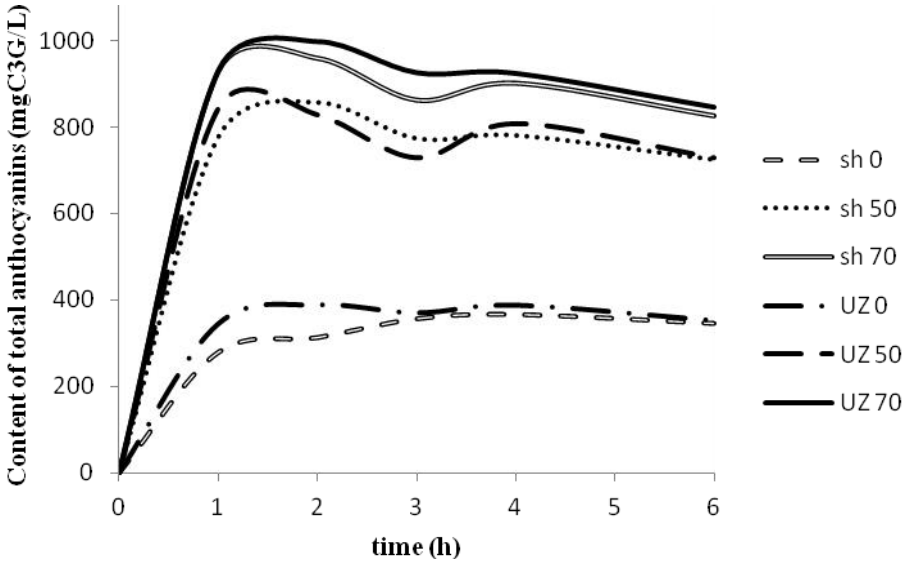
The total phenolic content of samples was determined according to the Folin-Ciocalteu spectrophotometric method by using UV-Vis Double beam spectrophotometer (HALO-DB/2S Dynamica) (Singelton and Rossi, 1965). All samples of extracts were mixed with distilled

water in order to get dilutions of appropriate concentration. 125 µL of the diluted samples and 1.25 mL of 10-fold diluted Folin-Ciocalteu's phenol reagent were mixed and allowed to react for 4 min. One milliliter of saturated sodium carbonate (75 g/L) was added to the mixture and then shaken. After 120 minutes of reaction at room temperature in the dark, the absorbance at 760 nm was determined. The measurement was compared to a calibration line of prepared gallic acid (GA) solution, and the results were expressed as milligrams of gallic acid equivalents per liter of extract (mg GAE/L).

Results and discussion

Determination of total anthocyanins

In this study six different extracts of grape skin were obtained. As can be seen from the Graph 1 the best extraction has been achieved with 70 %v/v ethanol solution exposed to ultrasound.

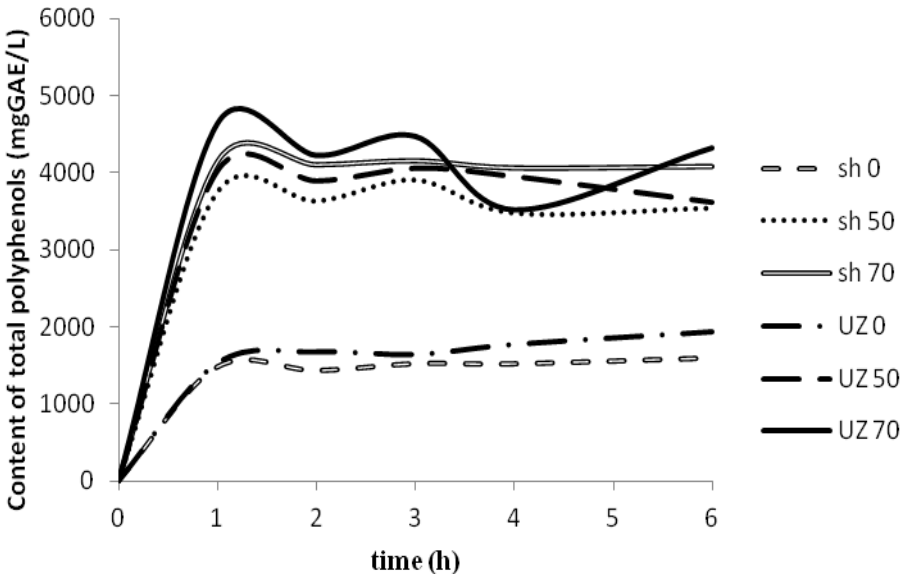


Graph 1. Extraction kinetics of total anthocyanins
(sh-shaking, UZ-ultrasound, 0-water extraction, 50-ethanol/water ratio 50/50, 70- ethanol/water ratio 70/30)

Ultrasound showed better results in each sample (with all three types of solvents), but not significantly different. However, the influence of ethanol was very important. The difference between samples extracted with and without alcohol has been statistically significant (about 900 mg C3G/L compared to 350 mg C3G/L).

Determination of total polyphenols

Addition of ethanol to water significantly improved the extraction rate of total polyphenols (Graph 2). Phenols extracted with different ethanol content in solutions showed similar results, but still the highest result has been achieved with 70 %v/v ethanol solution.



Graph 2. Extraction kinetics of total polyphenols
(sh-shaking, UZ-ultrasound, 0-water extraction, 50-ethanol/water ratio 50/50, 70- ethanol/water ratio 70/30)

The results represented in Corrales et al (2008) and Kalušević et al (2015) studies also confirmed very significant effect of the ultrasound application on grapeskin phenols and anthocyanins extraction in comparison to control extraction.
As can be concluded from both graphs the time needed for the maximum of extraction of polyphenols and anthocyanins has been decreased and achieved in the first 90 minutes of the extraction. Kalušević et al (2015) have presented the same optimum time (90 minutes) for water extraction with ultrasound from Prokupac grapeskin, compared to 180 and 270 minutes in samples without application of the ultrasound.

Conclusions

The extracts of black varieties' grapeskin could be a significant source of natural colourants and bioactive compounds, thus potential additives for some functional products. The potential applications of the ultrasound for bioactive compound extraction must be studied on the basis of the matrix characteristics, solvent choice, liquid–solid ratio, temperature, and time. Due an economical issue is crucial one for the industrial implementation the combination of effective extraction and low-cost raw materials represent and environmental and economical solution in comparison to conventional extraction methods where large amounts of organic solvents and long extraction times are required. The use of the novel processing technologies will reduce food processing wastes and facilitate the production of natural valuable products which will guarantee food sustainability and also, meet consumer demands.

Abstract

In contrast to the mechanism of action, the mode of actions of certain chemicals in the plants is defined as the totality of the effects that these chemicals cause the effect on metabolism, growth and development of plants. In this sense, we studied the effect of the broad concentration range of 24-epibrassinolide on germination of two maize hybrids (ZP434& ZP704), whereby the monitoring of effect mentioned brassinosteroid phytohormone on germination, and some thermodynamic and biochemical parameters in the seeds during germination. Then we are exposed plants of the maize hybrid (ZP505), grown in different light environments (light vs. shadow) or at different volumes of pot (in which we cultivated plants), to the effects of 24-epibrassinolide or propiconazole (an inhibitor of the synthesis of brassinosteroids). During trial we registered some parameters of growth and photosynthesis. And finally, we conducted a mini field trial treating two maize hybrids (ZP434& ZP341) with the broad range of doses of 24-epibrasinolide, as well as with two doses of propiconazole. We checked the final yield and some characteristics of growth of maize plants in the field, as well as the chemical composition of the grain after harvest. The results are discussed from the perspective of a 24-epibrassinolide effects on maize plants of different ages.

Key words: *mode of action of 24-epibrassinolide, germination, whole plant physiology*

Introduction

Brassinosteroids (BRs) are known to have a crucial role in development of a plants (Clouse and Sasse, 1998). But, the main goal of contemporary investigations of action of these phytohormones are concentrated on mechanisms of their action. In contrast to the mechanism of action, the mode of actions of certain chemicals in the plants is defined as the totality of the effects that a chemicals cause the effect on metabolism, growth and development of plants. In this sense, we studied the effects of 24-epibrassinolide (24-EBL; concentration range: 5.2 X 10^{-7} – 5.2 X 10^{-15} M) on the different maize hybrids in a developmental stages.

Material and methods

Seeds of two maize (*Z. mays* L.) hybrids (ZP434& ZP704) were germinated 7 days in a phytotron (light/dark period: 12/12 h, 30/20 ^{0}C; PAR~100 μmol $m^{-2}s^{-1}$), according ISTA rules. The seeds were germinate on solutions of 24-EBL („Epin-Extra“®, Russia) of different concentrations (5.2 X 10^{-7} - 5.2 X 10^{-15} mol, and control). After that procedure we checked the percentage of germinated seeds, and absolute and relative fresh weight of young plant parts (plumule, radicle& rest of seed) and weights after drying them at 60, 105 and 130 ^{0}C. Measured values used for calculations of thermodinamic parameters (Sun, 2002) of

germination proceses. Photosynthetic pigments are determined according to Lichtenthaler (1987). Samples for sugar determination was prepared, and extracted in a conventional manner, and then quantified by ion chromatography method. Maize plants (ZP505) were grown in half-shade (PARmax≈ 500μmol photon $m^{-2}s^{-1}$) 1 month, in the pots of V=5 l (2/3 so called (s.c.) “5 plants”) and V=11 l (1/3 s.c. “11 plants”), until the beginning of September 2013, when ½ of 5 l plants grown were replanted in V=11 l pots (s.c. “5→11 plants”). Then samples for analysis of dry matter partitioning and plant growth (De Groot et al., 2002) and thermodynamic calculations (Sun, 2002) were taken, while the remaining plants were transferred to full daylight (PARmax1500 μmol photon $m^{-2}s^{-1}$). After 7 days of light acclimation, 1/3 of plants were treated with 24-EBL (≈10^{-7} mol) solution, other 1/3 with PZR (propikonazole, an inhibitor of BRs synthesis (Hartwig et al., 2012); ≈10^{-6} mol) solution and 1/3 were control (K) plants. Treatment was repeated after 7 days. The parameters of Chla fluorescence (Maxwell and Johnson, 2000; Lichtenthaler and Miehe, 1997) were measured and calculated. After 2 weeks experiment was finished. During experiment, outside temperature was mainly suboptimal (t=14-19°C) for maize growth. In addition, we conducted the field trials, where we investigated the effect of foliar treatment with solutions of different concentrations (5.2 X 10^{-7}, 5.2 X 10^{-9}, 5.2 X 10^{-11}, 5.2 X 10^{-13} and 5.2 X 10^{-15} mol, and control) of 24-EBL, and two different solute concentration of PZR (≈10^{-6} mol and ≈10^{-7} mol), about a month after sowing (late April 2014) of maize (ZP434 and ZP341), as two weeks later. At the end August we sampled ears of corn, to assess the yield (per elementary plot (≈25 m^2) and per 1 ha) and its parameters, as well as the chemical composition of the grain (quantified by standard spectrophotometric and AAS methods).

Results and disscusion

Changes of allocation of dry mass between maize seedlings organs (plumule, radicle, the rest of the seed) indicate that the concentrations of 24-EBL from 5.2 X 10^{-12} M to 5.2 X 10^{-10} M most affected by the status of the radicle in both genotypes, as well as the status of plumule, but on different manner (Table 1). In contrast, the highest concentration of 24-EBL of 5.2 x 10^{-7} M has the most influence on the relative weight of the rest of the seeds in both maize genotypes (Table 1), so we can say that the allocation of dry weight from the rest of the seed to the plumula and the radikula of maize seedlings at that concentration 24- EBL is inhibited. In contrast to this uniform response of allocation of mass between organs and growth of maize seedlings, differential enthalpy, as a thermodynamic measure of the synthetic process, i.e. the thermodynamic potential of the system, are highly variable in both genotypes, depending on the temperature at which the organs of seedlings were dried (Table 1). As we know, enthalpy is defined as a thermodynamic potential of a system, i.e. as a measure of chemical potential of a system. In living systems reeling chemical reaction depends primarily on the water as a universal solvent. The most negative values of differential enthalpy testify to the fullest exothermal processes in certain organs of maize seedlings (Table 1), and various temperature at which the weight of seedling organs associated with various caps fractions of water in them (free (apoplastic) water, cytoplasmatic water, chemically bound water; Sun, 2002). According our data, changes of enthalpy of free, apoplastic water (dH105-60) affects the optimal 24-EBL impact on biochemical reactions at concentrations of 5.2 x 10^{-13} and 5.2 x 10^{-14} mol in radicle and plumule, while the least likely unwinding of biochemical reactions at concentrations of 24-EBL from 5.2 X 10^{-9} mol in ZP434 genotype (Table 1). In the case of changes of enthalpy of cytoplasmic (dH130-60) and chemically bonded (dH130-105) water of ZP434 maize plants, the concentration at which optimally convenient for 24-EBL influence on biochemical reactions are completely different (Table 1). In the case of changes of enthalpy of free water of plumule of ZP704 maize situation is oposite (data not shown).

Table 1. Average values (mean of 4 measures) of germination (%), relative fresh weight (RFW; g g^{-1}) and enthalpy (J mol^{-1} K^{-1}) of 25 maize (ZP434) seedlings parts (exposed at different concentrations of 24-EBL)

What is the cause of the observed differences in germination, the redistribution of mass and ability to perform biochemical reactions (differential enthalpy: dH) in various organs of the maize varieties, with the influence of the different concentrations of 24-EBL? Therefore, we analyzed the content of photosynthetic pigments in fresh, as well as some sugars (Table 2) and polyphenols (data not shown) in dried tissue of plant organs of maize seedlings. Low values of ratio's of photosynthetic pigments (Table 2) testify poor competence of the photosynthetic apparatus of plumule, which is not surprising for such an early stage of development of seedlings (Babani and Lichtenthaler, 1996). However, this means that most assimilates (i.e. and sugar), necessary for growth and development of plumule and radicle comes from the rest of the seed (Thomas and Rodriguez, 1994). We analyzed trehalose, sugar important in plant resistance to stress (Paul et al., 2008), followed by arabinose, an sugar moiety present in cellulose in cell wall of grass (Carpita, 1996), as well as in some important glycoproteins (Fincher et al., 1983), followed by glucose and fructose, sugars significant both

in primary metabolism, as well as necessary monomers of important plant polysaccharides (Duffus and Duffus, 1984), as well as sucrose, a main transport sugar in higher plants (Komor, 2000). Overall, the build-up of the aforementioned sugars is more pronounced at higher concentrations 24-EBL, and less at lower concentrations of mentioned phytohormone (Table 2). We think that the lower the concentration of 24-EBL accelerate biochemical processes and metabolic processes in plumule and radicle, which grow rapidly (germination!), but the plant does not suffer from osmotic stress (low concentration of trehalose!). A specificity of the metabolic processes in different organs of maize seedlings testifies by work of Waisi et al. (2015) that are water soluble polyphenols primarily related to radicle, and lypophylic polyphenols primarily related to plumule.

In the next experiment, we monitored the effect of 24-EBL (≈10^{-7} mol), and propiconazole (≈10^{-6} mol) (an BRs biosynthesis inhibitor in plants; Hartwig et al., 2012) on growth,

allocation of dry weight in plant, thermodynamic changes during accumulation of dry weight, and parameters of photosynthesis in maize plants exposed to root manipulation during the trial (Table 3). Indeed, PZR treatment affected the root volume of “5 plants” (Table 3). However, if the change in free energy was considered in whole maize plant (ΔG_{105tot}) we note that this parameter is higher in “5 plants”, whereas PZR treatment (Table 3) increases change of free energy in the “5→11 plants”. So the “5 plants” have higher free energy values, indicating their higher susceptibility to the stress, but the reaction is modulated by the inhibition of BRs synthesis. It is notable that during the experiment the LMR was reduced and RMR rose of “5 plants”, regardless the way of BRs content manipulation in plants (Table 3). In “11 plants” or “5→11 plants”, we noted a slight LMR and SMR increase and RMR decrease; where treatment with PZR slightly emphasizes this trend (Table 3). In control and plants treated with 24-EBL, ΔG_{105} values of leaves and stems of “5 plants” and “5→11 plants” are lower than in “11 plants”, but in the case of root ΔG_{105} situation is reversed. In the plants treated with the PZR situation is inverted, meaning that the inhibition of BRs synthesis affects the change of free energy in different organs of maize plants (Table 3).

Table 3. Average (of 6 measurements) values of parameters of maize (ZP 505) plant growth and matter partitioning and thermodinamic changes during manipulation of root status and plant content of BRs

How applied treatments affect the photosynthesis of maize estimated by fluorescence of Chla? The “5 l plants” have high values of RC PS_2 activity indicators (Fv/Fm,Fv/F_0), except in PZR treated plants, while the values of the parameters are same in the “11 plants” (Table 4). It is similar situation in the case of parameters of photochemical efficiency (ΦPS_2, qP). All NPQ values (photoprotective processes indicator) were high, indicating that the plant fight stress (low temperature), regardless of treatment. Finally, two different indicators of overall photosynthesis (ETR, RFD_{730}) point that maize plant struggles with stress and the handling of brassinosteroids content had negative effect on “11 plants”. If we compare the above mentioned parameters we find that the thermodynamic parameter $\Delta G_{105\ tot}$ (J mol^{-1} K^{-1}) is significantly positively associated with the regression parameters of Chla fluorescence NPQ (R^2 = 0.2193) and RFD_{730} (R^2 = 0.2262) (data not shown). Furthermore, the dry root mass ratio (RMR; g g^{-1}) is significantly positively associated with regression thermodynamic parameters $\Delta G_{105\ root}$ (R^2 = 0.8416) and $\Delta G_{105\ tot}$ (R^2 = 0.3708), and Chla fluorescence parameters Φ PS_2 (R^2 = 0.1877), Fv/F_0 (R^2 = 0.1617), RFD_{730} (R^2 = 0.3741), NPQ (R^2 = 0.4091), and ETR (R^2 = 0.2063) (all results not shown). In contrast, the accumulation of total fresh weight (TFW; g) is in the negative regression related to thermodynamic parameters $\Delta G_{105\ root}$ (R^2 = 0.2425) and $\Delta G_{105\ tot}$ (R^2 = 0.3864), as well as the parameters of Chla fluorescence Φ PS_2 (R^2 = 0.4924), Fv/F_0 (R^2 = 0.0583), RFD_{730} (R^2 = 0.1807), and ETR (R^2 = 0.4472) (all data not shown). In a similar negative regression concerning there is a parameter accumulation of dry weight ln TDW (g) towards the thermodynamic parameters $\Delta G_{105\ root}$ (R^2 = 0.0658) and $\Delta G_{105\ tot}$ (R^2 = 0.0866) (Figure 4), and Chla fluorescence parameters Φ PS_2 (R^2 = 0.4910), Fv/F_0 (R^2 = 0,0079), RFD_{730} (R^2 = 0,0430), and ETR (R^2 = 0.4364) (data not shown).

In a field trial conducted in 2014 was not observed significant differences in yield (t/ha) between experimental treatments, except that it is somewhat (≈15%) was reduced in plants treated with 5.2 X 10^{-7} M 24-EBL (data not shown). Medium yield was 14.56 t/ha (18% grain moisture), ie. 13,977 t/ha (14% grain moisture), which is more than good. However, if we look at some yield components and some reserve matter content of grain (total protein, starch), the situation is somewhat different. In both hybrids, we see that only the treatment of 5.2 x 10^{-7} M 24-EBL reduces the number of rows in the piston (highly heritable trait), with from 14-16 to 12 (ZP341), ie. from 16 to 14 (ZP434), which is not observed in other treatment concentrations of 24-EBL (data not shown). We believe that this is due to a disorder of growth of maize plants treated with 5.2 x 10-7 M 24-EBL, which led to a change in these characteristic highly heritable trait. As for the characteristics of the number of kernels per row we see that in both maize hybrids that number in the control plants is about 38, among those treated with 5.2 x 10^{-7} M 24-EBL about 33, and in all other treated plants from 39 to 40 (data not shown), which means that treatment with 24-EBL has a positive effect on the characteristic. In addition, in hybrids ZP434 higher concentrations of 24-EBL increased content of biochemical parameters, but the implementation PZR as biosynthesis inhibitor of BRS, increases content of elements (Table 5). The situation is also similar in the hybrid ZP341 (data not shown). These facts are consistent with the literature data (Hola et al, 2010).

Abstract

Twenty honey bee colonies selected from the apiary of the Institute for forage crops in Kruševac (Serbia) were used for the experiments. The colonies were transported to and placed on the location where the red clover bred for seed was grown (Lukovo and Vrbnica). All colonies were inspected and their strength and food supplies determined. Bees were counted in five days in three different terms. All the bees that have left the hives (scouts) and those who were returning with a load of pollen (foragers) were counted. Counting lasted 3 minutes per colony per term of day. The activity of scouts and foragers differed depending on the red clover cut. The coefficient of variation for scouts was slightly higher in the second cut (10.7% in the second and 8.0% in the third cut). Similar results were obtained for foragers, where the coefficient of variation as the second cutting was 14.4% and 11.2% in the third cut. The largest number of scouts in the second cut was 465, and the third cut 373. Regarding foragers, in the second cut, the most counted foragers was 315, while the third cut, the largest number of foragers was 182. Percentage of honey bees in relation to other pollinators in the second cut was 75.0%, and at the third cut was 61.7%.

Keywords: *honey bee, red clover, pollination, variability*

Introduction

Red clover is one of the most important forage crops in Serbia and is a short-lived plant species which lives two to three years. It has a good tolerance to less favorable soils, which are not suitable for alfalfa, and also gives high yields of good quality forage (Mousset-Declos, 1993)

Red clover is almost entirely cross-pollinated forage crop (97- 98%). Self-sterility of this plant is caused by gamete incompatibility. Considering flower morphology, red clover is entomophile plant, and the most significant pollinators are honey bee (*Apis mellifera* L.), bumble bees (*Bombus* spp.) solitary bees and others, (Taylor and Smith, 1979). A lot of authors consider red clover a “bumblebee crop”, but there are those that give primary role to honey bee (Palmer-Jones, 1967; Jevtić et al., 2010). In red clover there is no naturally occurring side opening whereby bees can obtain nectar without tripping the flowers as may occur sometimes when honey-bees are collecting nectar from alfalfa flowers (Morrison, 1962).

The pollination of red cover depends on many factors, including the proximity of honey bee colonies to the red clover fields (Jevtić, 2010).

Rao and Stephen (2009), in their research, have found that in the isolation cages with bumble bees, red clover gave 661 kg ha^{-1} of seed, while in cages with honey bee 640 kg ha^{-1} of seed was obtained. Seeds yield of red clover can vary much and depends on the exploitation year and can reach a maximum of 700-1000 kg ha^{-1}. Seed yield in research of Lugić et al. (1996) depended on the seed norms and interrow distance.

The amount of nectar in the flower tube has the main influence on the honey bee visits to the red clover. Miladinović (1968) found that in the second cut 71% of flower tubes had more than 2 mm of nectar, and the 29% had nectar level less than 2 mm. The diploid cultivars of red clover (2n=14 chromosomes) are easier to pollinate than tetraploid cultivars (4n=28), since these have a deeper floral tubes, and so the seed production is considerably lower. Due to this, the increased interest in the honey bee for the pollination of red clover is quite justified.

The aim of this study was to determine whether the cutting of the red clover (second or third cut) had impact on the visitation by pollinators and thus the pollination of red clover.

Material and methods

Honey bees from the apiary of the Institute for forage crops in Kruševac city were used. Colonies were in LR hives, and 20 colonies were used for the research. The research was conducted in 2012. Before sampling, colonies in the apiary were inspected and colonies with similar strength and food supply were selected for further research. Selected 20 colonies were transported to the areas where red clover for seed production was grown. Selected sites were Lukovo in Boljevac district and Vrbnica in Aleksandrovac district. Red clover in Lukovo was in second cut, while the red clover in Vrbnica was in the third cut.

To determine the number of foragers (worker honey bees which bring pollen back to the colony) and scouts (worker bees which scout for nectar or pollen sources), bees were counted for 3 minutes, three times a day. The visitation to the flowers of red clover was determined by counting all pollinating insects that visited red clover flowers on 1 m^2. These countings were done on three separate lots (3 x 1 m2) in the same time. Countings lasted for 10 min and were repeated three times a day.

Statistical analysis was done using computer program Statistica 8.0 (StatSoft, 2008)

Results and discussion

There were differences in the number of counted honey bees depending on the cut of red clover. Total number of scouts in the second cut was 56101 and of foragers 26924, while in third cut total of 36954 scouts and 13855 foragers were counted. The largest number of scouts in the second cut was 465, and in the third cut 373. Regarding foragers, in the second cut, the most counted foragers was 315, while the third cut, the largest number of foragers was 182.

This is similar to the results of Rao and Anderson (2010) of their research of pollinator abundance during red clover bloom. According to their research, honey bee abundance dropped during late bloom and they speculated that this is due to honey bee preference for alternative pollen sources present in the area. Similar observations have been reported from other areas (Petersen et al 1960).

After the statistical analysis, it was determined that the activity of scouts and foragers differed depending on the red clover cut. The coefficient of variation for scouts was slightly higher in the second cut (10.7%) than in the third cut (8.0%). Similar results were obtained for foragers, where the coefficient of variation in the second cut was 14.4% while in the third it was 11.2%. In both cuts, honey bees were prevalent pollinators compared to solitary bees and bumblebees. Percentage of honey bees in relation to other pollinators in the second cut was 75.0%, and at the third cut was 61.7%.

a, b, ab – homogenous groups

There were three homogenous groups in both cuts for both scouts and forager honey bees. The colony number 1 have proved to be the one with the highest activity of both scouts and foragers in the second cut, while in the third cut it had the highest activity of scouts. The best activity of foragers in the third cut was found in the colonies number 7 and 13 (Table 1).

Conclusion

According on the results of this research, the pollination of red clover by honey bees depends on the cut. Higher activity of honey bees, both scouts and foragers, was determined in the second cut, while in the third cut it was diminished.

Honey bees were the dominant pollinators in both cuts, which might be a result of deliberate setting of the honey bee colonies on the red clover fields.

There were honey bee colonies which shoved better scout and forager activity, and those can be used for further selection of honey bees for more effective pollination of the red clover.

Abstract

In Serbia, shortage of water limits soybean [*Glycine max* (L.) Merr.] production. Current irrigation practices aim at maximizing seed yield, but achieve lower return for the water consumed. Maximizing water use efficiency (WUE) may be more suitable in areas where water, not soil, is the most limiting factor. The aim of this study was to investigate the effect) of water stress on yield, WUE and irrigation water (IWUE) use efficiencies of soybean (*cv*. Nena) growing on a calcaric Chernozem in temperate environment. Field experiments were conducted at the experimental field of the Maize Research Institute “Zemun Polje”, in the vicinity of Belgrade (Serbia) during 2007 and 2008 growing seasons. The crop was subjected to three irrigation levels (rainfed and supply at 50 and 100% of field capacity, FC). Treatments were arranged in a randomized complete block design with four replicates. Rainfed (non-irrigated) and deficit irrigation treatment (50% of FC) significantly reduced seed yield. The full irrigated treatment (100% of FC) had the highest yield (3.06 t ha^{-1} average), while the rainfed treatment had the lowest yield (2.26 t ha^{-1} average), a 27% seed yield reduction. Deficit irrigation treatment produced 9% less seed yield then the full irrigated treatment. Both WUE and IWUE were significantly reduced as amount of irrigation water was increased. Seasonal crop evapotranspiration increased with increased amounts of irrigation water supplied. In conclusion, higher amounts of irrigation resulted in higher seed yield, whereas WUE and IWUE values decreased when irrigation amount increased.

Keywords: s*oybean, water stress, yield, water use efficiency, irrigation water use efficiency.*

Introduction

In the Vojvodina region, northern part of the Republic of Serbia, soybean is cultivated under both irrigated and nonirrigated conditions. In the period between 1993 and 2004 soybean was grown on 43,583–146,000 ha (Hrustić and Miladinović, 2008). According to Kazi et al. (2002), soybean crop seldom attains its full yield potential because limitations on physiological processes imposed by environmental stresses. The average yield was 2.1 t ha^{-1}, ranging from 1.2 to 2.8 t ha^{-1} and the yield levels depended primarily on the amount and distribution of precipitation within season. The introduction irrigation can potentially stabilize and increase yields, as well as increasing the use efficiency of water received both from precipitation and from irrigation. Under irrigated conditions, yields steadily exceed 3 t ha^{-1} and reach over 4 t ha^{-1} (Bošnjak and Dragović, 1998). In Vojvodina, irrigated yields were 22 % (average) higher, compared to those of nonirrigated soybean (Pejić et al., 2012). Cox and Jilliff (1986) reported that water stress reduced seed yield from 27 to 87% when the crop was subjected to a moisture deficit ranging from 18 to 70%. Kadhem et al. (1985) found that yield and other agronomic responses are sensitive to the water stresses during whole growing period. Burriro et al. (2002) studied the response of soybean to soil moisture stress in the environment oh the Pakistan. They found that the water use was affected by water stress. Considering paramount importance of proper use of irrigation for high yields, the present

studies were designed to investigate the effect of soil moisture stress on yield and water use efficiency in soybean crop in a temperate climate (Vojvodina).

Materials and methods

The field experimental (2007–2008) studies were carried out in Zemun Polje (44°52' lat. N; 20°20' long. E, 30 m a.s.l) at the experimental farm of the Maize Research Institute "Zemun Polje". The soil is a Calcareous Chernozem, silty clay loam – silty loam soil. It has field capacity (FC) of about 35% and wilting point (WP) at 16% by volume for the top 60 cm soil profile. Total plant available soil water is 173 mm m^{-1}. Mean bulk density varies from 1.17 to 1.41 g cm^{-3} (Tapanarova, 2011). The average annual rainfall was 638 mm (considering 20-year-long term period) and air temperature was 11.9°C. The climatic parameters during the crop growing seasons are summarized in Table 1.

The experiment was conducted using a randomized complete block design with four replications, and adapted to technical specifications of the sprinkling irrigation system. Each experimental plot size was 5 m^2. There was a 2.0 m space between each plot in order to minimize water movement between treatments. Soybean cultivar *Nena* was sown on 19 April in 2007 and 06 May in 2008. The sowing density amounted 445 000 plants ha^{-1}.

Common cropping practices were applied during vegetation. The following amounts of mineral fertilisers were used: 136 kg N ha^{-1}, 68 kg P_2O_5 ha^{-1} and 68 kg K_2O ha^{-1}. Weeds, pests and diseases were adequately controlled. The crop was harvested manually on 18 and 15 October in 2007 and 2008, respectively.

The crop was subjected to three irrigation levels (rainfed and supply at 50 and 100% of field capacity, were maintained on volumetric basis). Irrigation was applied when approximately 50% of the available soil moisture (the difference in soil water storage between FC and WP) was consumed in the effective root zone (to 0.60 m*)*. The irrigation rate and time were determined according to the soil water content at the effective root zone depth. Irrigation water was extracted from a deep well. Irrigation was started on 10 July 2007 and 04 July 2008.

Soybean evapotranspiration (ETa, mm) was estimated using the water balance method:

$$ETa = P + I + C_r - R_f - D_p \pm \Delta S \quad (1)$$

where P is the precipitation (mm), I is the irrigation water applied (mm), C_r is capillary rise to the root zone (mm), R_f is the surface runoff (mm), D_p is the drainage water (percolation) (mm), and ΔS represents the change in root zone water storage over a given time interval (mm).

Water use efficiency (WUE, kg ha^{-1} mm^{-1}) and irrigation water use efficiency (IWUE, kg ha^{-1} mm^{-1}) were estimated as Howell et al. (1995), (2, 3):

$$WUE = Y/ETa \quad (2)$$

$$IWUE = (Ym - Ya)/I \quad (3)$$

where Ym is the maximum harvested yield (under irrigation, non limiting conditions – 100% FC, kg ha^{-1}), Ya is the actual harvested yield (non-irrigated, kg ha^{-1}), ETa is the actual evapotranspiration (mm), I is the irrigation water amount (mm).

Grain yield in t ha^{-1} at 14% moisture was processed by the statistical method of the analysis of variances, while differences among individual treatments were analysed by the Fisher's test

(LSD) at the probability levels of 5% and 1%. The relationship between crop yield and total amount of water (precipitation + irrigation) was evaluated using regression analysis.

Results and discussion

Weather conditions, irrigation water applied and seasonal water consumption (ETa)

Total monthly precipitation and mean air temperature data during the soybean growing period are presented in Table 1.

Table 1 Mean air temperature and total monthly precipitation in 2007–2008 and between 1981 and 2002 at Zemun Polje.

Months	Temperature (^{o}C)			Precipitation (mm)		
	2007	2008	1981–2002	2007	2008	1981–2002
April	13	13	12	31	27	60
May	19	18	17	42	40	56
June	23	22	20	63	36	95
July	24	23	22	19	46	57
August	24	23	22	52	20	62
September	15	17	18	73	55	55
Total				279	225	384

In general, weather conditions were warmer and drier during the 2007 and 2008 growing seasons than to the long-term series. In both years, the average monthly temperature in the growing period was higher than the long-term temperatures, by 0.9^{o}C in 2007 and by 0.7^{o}C in 2008 (Table 1). During the summer months, there were particularly large deviation from the average temperature, and the soybean was then in the generative stages of growth when it was very sensitive to high temperatures and low relative humidity. High air temperatures, especially in the summer period 2007 (25.2^{o}C and 25.3^{o}C in third decade of July and August, respectively, Table 1) affected the amount of water used for evapotranspiration and irrigation frequency. The growing seasons from 2007 to 2008 were dry and very dry with 73 and 58% of the long-term mean precipitation (384.1 mm), respectively (Table 1). Because of the uneven seasonal distribution of precipitation irrigations had to be performed each year.

The irrigation rates depended on weather conditions during the investigation period. The amount of irrigation water applied in the growing season of 2007 was 135 mm and 50 mm for 100% FC and 50% FC, respectively. In 2008, irrigation rates were 235 mm and 95 mm for 100% FC and 50% FC, respectively.

Similar to irrigation water applied, seasonal water consumption (ETa) also depended on weather conditions during the investigation period. In the study period, ETa in non-irrigated conditions ranged from 226–308 mm and in the irrigation conditions in the range from 427–450 mm. The results observed in this study were in agreement with Pejić et al. (2012).

Yield

Table 2 provides information that the yield of soybean was significantly affected under irrigation treatments. The average yield at 100% FC (3.10 t ha^{-1}) was the highest, and significantly different compared to 50% FC (2.82 t ha^{-1}) and non-irrigated (rainfed) (2.26 t ha^{-1}). The average increases brought by supplemental irrigation were 0.84 and 0.56 t ha^{-1} or 37.2 and 24.8% under 100% FC and 50% FC conditions, respectively. Under the rainfed conditions, the yields of soybean depended primarily on the amounts and distribution of

rainfall during growing seasons. Our results are agrees with the results of Vučić and Bošnjak (1980) who had reported that the average increase of soybean yield by irrigation was 30%. Accordung to Pejić et al. (2012), the average yield increase of soybean due to irrigation practice was 0.82 t ha^{-1} on average, ranging from 2.5 t ha^{-1} in years with limited precipitation and higher than average seasonal temperatures (2000) to 0 t ha^{-1} in rainy years (1996, 1997, 1999). Carison et al. (1982) observed yield reduction due to water stress which varied from 20 to 50%.

Table 2 Yield (Y), water (WUE) and irrigation water (IWUE) use efficiency of soybean in grain production as affected by year and irrigation.

	Y (t ha^{-1})		Ave-rage	WUE (kg ha^{-1} mm^{-1})		Ave-rage	IWUE (kg ha^{-1} mm^{-1})		Ave-rage
	Years			Years			Years		
Variants	2007	2008		2007	2008		2007	2008	
Rainfed	2.88c†	1.63b	2.26	9.35ab	7.21b	8.28	–	–	–
50% FC	3.09b	2.55ab	2.82	9.48a	7.75a	8.62	4.20b	9.68a	6.94
100% FC	3.50a	2.69a	3.06	8.20b	5.98c	7.09	4.59a	4.51b	4.55
Cv‡	7.2	8.9		7.1	6.5		4.3	5.8	

†Means within columns not followed by the same letter are significantly different at the $P < 0.05$ level. ‡Coefficient of variation.

Contrary to our findings, Vučić and Bošnjak (1980), Bošnjak (1988) and Maksimovic et al. (2005) reported that irrigation variants with 70 and 80% of FC did not produce significantly different yields. Likewise, no significant differences could be found between the irrigation variants with 70 and 60% of FC (Maksimovic et al., 2005). Bennett and Albrecht (1984) reported that excessive soil water caused by unexpected precipitation following irrigation can affect soybean response to irrigation, resulting in lower yield. According to Mkasimovic et al. (2005), under conditions of high soil moisture, soybean develops large vegetative mass and it uses water excessively, so that the assimilation curve remains unaltered in spite of the increased water consumption.

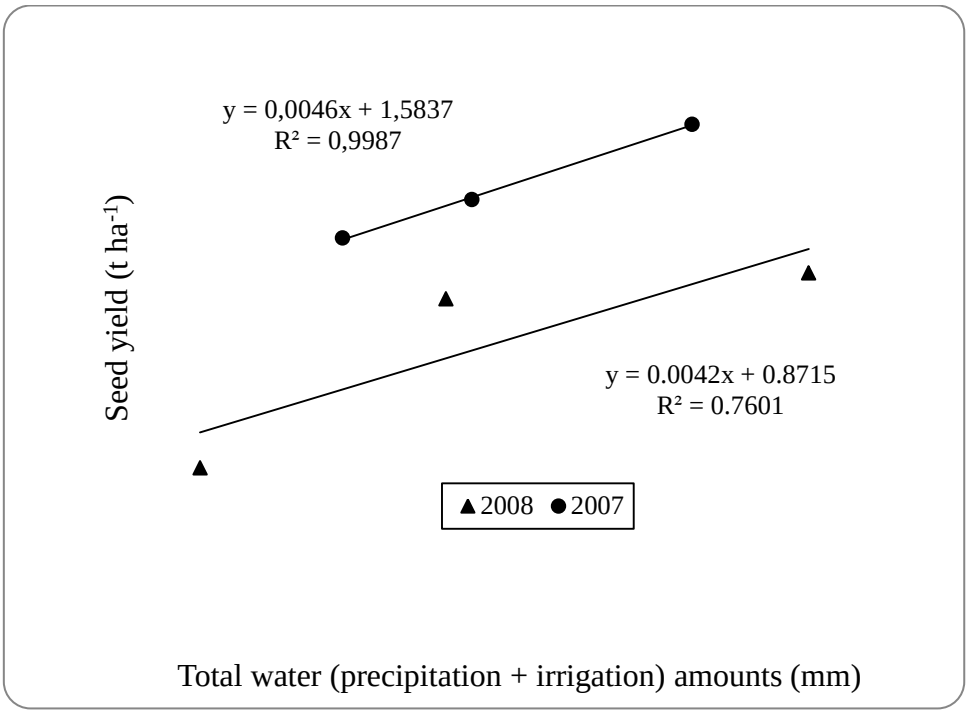
Water use efficiencies

Table 2 shows that the effects of deficit irrigation at vegetative period on the WUE and IWUE were significantly different. Irrigation treatments of 50 and 100% FC showed significant difference compared to rainfed (as a control). In this research, water use efficiency (WUE) of soybean ranged from 5.98 to 9.48 kg ha^{-1} mm^{-1} with an average value of 8.00 kg ha^{-1} mm^{-1}, while irrigation water use efficiency (IWUE) varied from 4.20 to 9.68 kg ha^{-1} mm^{-1} with an average value of 5.75 kg ha^{-1} mm^{-1} (Table 2). This agrees with the results of Pejić et al. (2012) in rainfed and irrigated soybean in Vojvodina.

In a 1-year experiment on the WUE of soybean growing on Ultisol soil, Bustomi Rosadi et al. (2007) found values of WUE of 0.037–0.187 kg m^{-3} (0.37–1.87 kg ha^{-1} mm^{-1}). Howell (2001) reported that irrigation can be an effective means to improve WUE through increasing crop yield especially in semiarid and arid environments. Even in subhumid and humid climate, irrigation is particularly effective in overcoming short-duration droughts. According to Pejić et al. (2012), irrigation by itself may not always produce the highest WUE possible.

The obtained IWUE values are in agreement with those given by Garcia y Garcia et al. (2010) who reported IWUE values of 0.55 kg m^{-3} and 1.14 kg m^{-3} in Georgia, USA. Demirtas et al. (2010) reported a lover values of IWUE (0.39-0.45 kg m^{-3}) in western Turkey as a consequence of very high seasonal evapotranspiration (684–771 mm) and comparative high

seed yield (3.57–4.00 t ha^{-1}). Scott et al. (1987) and Bhardwaj (1986) reported the average WUE soybean of 0.6 kg m^{-3} for USA and 0.63 kg m^{-3} for India, respectively.
The relation between total amount of water (precipitation + irrigation) and grain yield have been evaluated for each year (Graph 1). The relationship between total amount of water and grain yield was linear for each experimental year. Their relationship was significant at $P < 0.05$. A linear relationship between total amount of water and yield for soybean has been reported by other researchers (Garcia y Garcia et al., 2010).



Graph 1. Relationship between seed yield (t ha^{-1}) and total amount of water received during the growing season (precipitation + irrigation, mm).

Conclusion

Based on the results of the 2-year experiment on the effect of deficit irrigation on the yield and water use efficiency of soybean grown under temperate climate of the Vojvodina region, it was concluded that the supplemental irrigation practice brought highly significant yields compared with those obtained in the non-irrigated control. The average increase soybean yield due to irrigation ranged from 0.84 to 0.56 t ha^{-1} or 37.2–24.8%. IWUE decreased with increasing irrigation amount, with similar trends observed during both years; while WUE tended to increase in 2007 as irrigation amount increased, the opposite was in 2008. The finding of this study showed that variant 100% FC could be used for soybean grown in Vojvodina regions under no water scarcity. However, severe deficit in irrigation water amounts will cause significant declines in crop yield.

Abstract

Researches included two Traminer cultivar forms: White Traminer and Traminer 11 Gm. The variety, as well as its clones and subvarieties, is described by many researchers, and all of them pointed out to its great variability in quantitative and qualitative traits. The study was done in the collection vineyard of the Center of Viticulture and Enology of Niš city (Serbia). The investigation lasted three years, and it included fertility, grape yield of the examined Traminer cultivar forms, resistance to *Botrytis cinerea* and wine quality. This paper also gives a detailed ampelographic description Traminer cultivar forms, according to International Organization of Vine and Wine (OIV) descriptors. The purpose of this paper is to determine growth, fertility, yield, and grape and wine quality of the examined Traminer cultivar forms in the viticultivar subregion of Niš. Average grape yield varied depending on conditions of the particular year. White Traminer recorded higher yield. Traminer 11 Gm wine has been awarded the average organoleptic grade of 18.17 points, which classifies it in the category of top-level white wines. Wine tasting grade awarded to White Traminer wine is 17.39 points, which classifies it as a quality wine. These researches contribute to the familiarization with the total variability of Traminer cultivar, as well as the importance of forms examined for the production of quality and top-level wines within climatic of the southern Serbia.

Introduction

The occurrence of biotypes, forms within old grapevine cultivars is a well-known fact (Kaserer et al., 2003). Traminer is a very old and widespread cultivar with many biotypes characterized by diversity of genetic and phenotypic properties (Scienza et al., 1990). The first written data on Traminer cultivar was recorded in XV century (Goethe, 1887). The true origin of the cultivar is impossible to determine due to an extremely unstable genome. Traminer is much older cultivar than other grapevine cultivars, which is indicated by the high variation level (Imazzio et al., 2002). It is considered to originate from a Tyrolese place Tramin, Italy, wherefrom it has been cultivated in numerous European countries (Goethe, 1887). An important variability has been recorded within this cultivar. It is a heterogenous cultivar with numerous forms and clones. There have been attempts to proclaim certain forms for cultivars. White Traminer is grown in many European countries such as France, Austria, Switzerland, Germany (Santiago et al., 2007).

This Traminer form has been described by several authors (Galet, 1958; Foex, 1981; Ambrosi et al., 1994; Boidron et al., 1995).

White Traminer is by mistake frequently identified as a traditional Spanish cultivar Albarino Blanc (Santiago et al., 2007). Imazio et al. (2002) claim that Sauvignon Blanc is synonymous with White Traminer, which complies with Galet's (1990) ampelographic researches, according to which Sauvignon, i.e. White Traminer is one of Traminer cultivar forms. From a

population Traminer cultivar form Traminer 11 GM singled Helmut Becer (1979) at the Institute Geisenheim in Germany. In Serbian vineyards, Red Traminer dominates with numerous forms, which are more fertile than the cultivar population, yet at the same time of less intense fragrance which is especially valued in Traminer (Zirojević, 1974; Cindrić et al., 2000). The purpose of this paper is to apply standard ampelographic methods in order to record differences between the forms examined, to determine fertility, yield and quality of grapes and the wine produced under the ecological conditions of the subregion of Niš. This would contribute to the familiarization with biological properties, especially fertility of buds and shoots, as well as grape and wine quality that could be achieved in the ecological conditions of the subregion of Niš. These researches contribute to the familiarization with the total variability of Traminer cultivar, as well as the importance of forms examined for the production of quality and top-level wines within the climatic conditions of the southern Serbia.

Material and Methods

The investigation has been carried out during the period 2004-2006 in the collection vineyard of the Center for Viticulture and Enology at Niš. This grape varieties' collection is located in vinegrowing subregion of Niš, characterized by moderately continental climate with average annual air temperature of 11.8^{o}C and average vegetational air temperature of 18.1^{o}C. The absolute minimum of air temperature during the study was -18.2^{o}C. The average annual precipitation amount in the observed period was 750 mm, 422 mm of which fell during vegetation. Soil type was eutric cambisol. The vineyard was established in 1995, with planting distance of 3x1.2 m (2777 vines per ha), which was universal value for the all varieties at this collection vineyard. Bud load per vine was 20 buds or 6.6 buds per m^2. The trial was set in random complete block design with four replications, and the data were processed by analysis of variance. Ampelographic description has been done according to the descriptor list of OIV. Resistance to Botrytis cinerea was estimated by means of OIV descriptor, Code 459: 1 – 3 very low resistance, 5 – medium resistance, 7 – 9 high or very high resistance. Must quality, presented through the average content of sugar and total acid, was determined on representative samples during the vintage. Oechsle scale was used to measure sugar content, while titration with N/4 NaOH was applied in order to measure the total content of acid. Microvinification and chemical analysis of wine were carried out in the enological laboratory of the Viticulture and Wine Production Center of Niš. The quality of the wine produced was determined based on the results of the chemical analysis and organoleptic assessment made by the wine tasting commission of the Faculty of Agriculture, University of Belgrade. The all observed parameters were determined by standard ampelographic procedures.

Results and Discussion

Ampelographic description was carried out according to the OIV descriptors i.e. according to the Codes System which stipulates International Union for the Protection of New Varieties of Plants (UPOV) for a description of new genetic resources of grapevine.

The examined Traminer forms did not show considerable differences based on the acquired data on ampelographic and botanical description of the tip of a young shoot, a leaf, a blossom, a flower, and a mature shoot (Table 1).

Table 2. The number of developed and fertile shoots

Forms	The number of developed shoots				The number of fertile shoots			
	2004	2005	2006	Average	2004	2005	2006	Average
White Traminer	18.42	16.50	18.33	17.75	16.00	13.83	16.08	15.31
Traminer 11 GM	18.67	16.42	18.00	17.69	16.33	12.25	14.08	14.22
Average	18.54	16.46	18.16	17.72	16.16	13.04	15.08	14.76
Lsd 0.05	Years 0.57		Forms 0.65		Years 1.18		Forms 1.36	

The number of developed and fertile shoots was not considerably varied between the examined forms of Traminer cultivar (Table 2).

Out of the total number of White Traminer shoots left at pruning, about 17.75 shoots, of which 15.31 fruit bearing ones, developed. As for Traminer 11 GM, 17.69 shoots, of which 14.22 fruit bearing ones, developed out of the 20 shoots left. In the examination years, meteorological conditions considerably influenced differentiation of fertile buds and the development of fertile shoots. In both forms, there were approximately as much developed and fertile shoots per vine as in the first and the third year, i.e. considerably more than in the second year of examination.

Table 3. Grape yield of the examined Traminer cultivar forms

Form	White Traminer				Traminer 11 GM				Lsd_{005}	
	2004	2005	2006	X	2004	2005	2006	X	Years	Forms
GYE (g)	145.6	107.9	148.6	133.99	134.6	90.5	111.5	112.24	17.32	20.00
GYDS(g)	156.1	131.1	160.5	149.27	144.2	110.6	123.9	126.28	18.95	21.88
GYFS(g)	178.5	155.6	180.4	171.53	163.2	148.4	155.9	155.88	15.62	18.04
GYV (g)	2912	2157	2969	2679.8	2692	1810	2231	2244.6	346.39	399.98
GYH (kg/ha)	8088	5992	8245	7441	7477	5027	6197	6233		
BW (g)	109.60	107.96	105.90	107.82	102.92	120.62	111.16	111.56	11.46	13.23

GYE – grape yield per bud, GYDS – grape yield per developed shoot, GYFS – grape yield per fertile shoot, GYV – grape yield per vine, GYH – grape yield per hectare, BW – bunch weight .

Yield parameters (yield per bud, grape yield per developed shoot, grape yield per fertile shoot, grape yield per vine, grape yield per hectare, bunch weight) varied significantly ($P<0.05$) between the examined forms and highly significantly between the examination years (Table 3). Average values of all yield parameters in White Traminer were significantly ($P<0.05$) higher than in Traminer 11 GM, excluding the grape yield per fertile shoot and the bunch weight. The highest yield per vine in White Traminer (2969 g) was in the third (2006) year, and the lowest (2157 g) in the second (2005) examination year. Traminer 11 GM had the highest yield per vine (2692 g) in the first (2004) year, and the lowest (1810 g) in the second (2005) year. The data obtained clearly indicated that the lowest yield in both forms was in the second year, namely much lower than in the other two years of examination. Grape yield per hectare varied in the same manner as grape yield per vine. White Traminer, with the average number of 25 bunches per vine, produced the average bunch weight of 107.82 g. On the other hand, Traminer 11 GM, with the average number of 20 bunches per vine recorded the bunch weight of 111.56 g. Cindrić et al. (2000) reported the average bunch weight of the forms examined under the conditions of Fruška Gora: Traminer 11 GM 130 g, and White Traminer 142 g. In our examinations, Traminer cultivar forms had smaller bunch weight than the one recorded by the above-mentioned authors. Differences in the bunch weight between the examined forms, and examination years as well, were not significant.
Bearing in mind that yield is mainly dependent upon the number of bunches and the average bunch weight, in our researches the yield was more dependent upon the number of bunches than on the average bunch weight. Taking into account biological features of Traminer forms, we can say that the yields there of during the research period were regular and low.

White Traminer showed a high level of resistance (7.0), while somewhat lower resistance was registered in Traminer 11 GM (6.3). The highest resistance level was registered in the first and third year (7.0), while the strongest *Botrytis cinerea* attack was registered in the second (2005) examination year (6.0).

Table 4. Resistance of Traminer forms to *Botrytis cinerea* (OIV Code 459)

Form	Examination year			
	2004	2005	2006	Average
White Traminer	7	7	7	7
Traminer 11 GM	7	5	7	6.3
Average	7.0	6.0	7.0	6.6

Data on the resistance level obtained in our researches are similar to the earlier reported data for Traminer cultivar.

Table 5. Content of sugar and total acid in must of Traminer cultivar forms

Form	Sugar content in must (%)				Total acid content (g/l)			
	2004	2005	2006	X	2004	2005	2006	X
White Traminer	23.59	21.18	22.41	22.39	7.48	7.88	7.50	7.62
Traminer 11 GM	22.11	19.54	20.64	20.76	8.18	8.60	8.80	8.52

A high content of sugar (22.39%) was registered in the must of the White Traminer form characterized by a high average yield (Table 5). Traminer 11 GM recorded less sugar content (20.76%). The lowest grape yield in the second year did not cause the increase of the sugar content in must. Traminer forms had a high content of acids in must, (8.07 g/l in average).

Table 6 data indicate that the alcohol content in wine is appropriately expressed, analogously to the sugar content. A higher alcohol content was obtained in White Traminer wine (13.33%). Content of the total extract varied from 17.25 g/l in White Traminer wine to 20.45 g/l in Traminer 11 GM wine. Content of the total acid varied within the limits of 6.5 g/l in White Traminer wine to 6.8 g/l in Traminer 11 GM wine. Traminer 11 GM wine has been awarded the average organoleptic grade of 18.17 points, which classifies it in the category of top-level white wines.

Table 6. Chemical composition and organoleptic assessment of wine

Form	White Traminer	Traminer 11 GM
Specific gravity	0.9893	0.9918
Alcohol (%)	13.33	12.23
Total extract (g/l)	17.25	20.05
Reducing substances (g/l)	1.0	1.05
Sugar-free extracts (g/l)	17.25	20.45
Titratable acidity (g/l)	6.5	6.8
Volatile acids (g/l)	0.35	0.34
Total SO_2 (mg/l)	69.5	83.0
Free SO_2 (mg/l)	10.0	13.5
Ash (g/l)	1.64	1.85
Phenolic substances (g/l)	0.16	0.18
Organoleptic assessment	17.39	18.17

Wine tasting grade awarded to White Traminer wine is 17.39 points, which classifies it as a quality wine.

Conclusion

Based on the three-year examination results of White Traminer and Traminer 11 GM forms under the conditions of the subregion of Niš, the following conclusions have been drawn:

According to the ampelographic and botanical description, between two examined Traminer grapevine forms (White Traminer and Traminer 11 GM) were not found big differences.

Yield of the examined grape forms depended more on the number of bunches than on the bunch weight. Average values of parameters of the White Traminer yield were significantly higher than those of the Traminer 11 GM yield, excluding the grape yield per fertile shoot and the bunch weight. The highest yield per vine in White Traminer (2969 g) was in the third (2006) year, and the lowest (2157 g) in the second (2005) examination year. Traminer 11 GM had the highest yield per vine (2692 g) in the first (2004) year, and the lowest (1810 g) in the second (2005) year. Grape yield per hectare varied in the same manner as grape yield per vine. White Traminer showed a high level of resistance to *Botrytis cinerea* (7.0), while somewhat lower resistance was registered in Traminer 11 GM (6.3).

Chemical composition of wines of the examined Traminer cultivar forms showed that they had high content of alcohol and a favourable content of the total acids. Organoleptic

assessment of the wine fluctuated between 17.39 points (White Traminer) and 18.17 (Traminer 11 GM), which could be considered highly satisfactory.

Abstract

The crops of red clover (*Trifolium pratense* L.) are generally established on acid soils in which some of the trace elements are heavily accessible to the plants. In such conditions, the proper mineral nutrition can positively affect the yield of perennial legumes. The aim of the study was to analyze the effect of foliar treatment with cobalt on the forage yield of red clover on acid soil. The field experiment with varieties of red clover K-39, K-17, Una and Viola was set up in 2019, 2010 and 2011 in Čačak on alluvial soil type with pH(H_2O) 4.8. The experiment was designed using a randomized block design with four replications, with the plot size of 5x1 m. Sowing was carried out at 20 cm of inter-row distance and with seed rate of 18 kg ha^{-1}. The analyses were carried out on the first growth during the second year of cultivation, which in combined production forage-seed is mainly used for forage production. Foliar application of cobalt ($Co(NO_3)_2$ in concentration 0.033 g L^{-1}) was performed in the phase of intensive growth in the first growth in the second year of cultivation. The highest forage and hay yield in the control treatment was recorded in 2010, and the lowest in 2012, while on the variant with foliar application of cobalt there was no significant difference in the forage yield between 2011 and 2012. In the control treatment in all of the years, the variety Una had a significantly higher forage yield as compared to the varieties K-39 and Viola, while on the treatment with cobalt, the variety Una had a significantly higher forage yield only as compared to the variety Viola.

Key words: *red clover, cobalt, yield, forage, hay.*

Introduction

Given the economic and agro-tehnical importance of red clover *(Trifolium pratense* L.*)*, in the combined production of forage-seed, it is necessary to apply appropriate agro-tehnical practices to the potential for forage and seed yields a maximum realized. Proper mineral nutrition can have a positive effect on yield of perennial legumes, especially on acid soils (Dear and Lipsett, 1987). According to Taylor and Quesenberry (1996), acid soils are characterized by a high presence of easily accessible forms of aluminum, iron and manganese and reduced content of easily accessible phosphorus, calcium, and molybdenum. On acid soils, Al and H inhibited the growth of the root system, reducing its capacity for uptake of mineral nutrients and thereby reduces the resistance of plants to drought (Horst, 1991).

Growth and metabolism of plants to a large extent depend on the concentration of cobalt in the rhizosphere and soil (Palit and Sharma, 1994). Cobalt plant supply is essential for normal range of physiological reactions in the process of photosynthesis (Lipskaya, 1972), respiration (Palit et al., 1994; Aleshin et al., 1987), cell growth (increasing the amount of active form of auxin) (Lipskaya, 1970), which affects the rapid growth of plant organs (Ahmed and Evans, 1960; Mathur et al., 2006; Jayakumar et al., 2007; Jayakumar and Jallel, 2009). The positive effect of cobalt supply to plants is manifested through increased chlorophyll content (Lipskaya, 1972; Ozanne et al., 1963), increased thickness of palisade tissue, increased number and size of chloroplasts (Lipskaya, 1972). Cobalt significantly increases nitrogen

fixation by *Rhizobium*-all kinds, and thus the growth of legumes (Collins and Kinsela, 2011). Cobalt is a component of vitamin B_{12} that a component of enzymes and coenzymes involved in the process of nitrogen fixation in legume nodule (Bond and Hewitt, 1962; Kasimova et al., 1971; Palit and Sharma, 1994; Mathur et al., 2006). However, the high concentration of cobalt in plants is undesirable and it can have a detrimental effect on physiological and biochemical functions of the plant (El-Sheekh et al., 2003; Jayakumar and Jallel, 2009).
The aim of this study was to investigate the effect of foliar application of cobalt on acid soil on the forage and hay yield of red clover in the first cut in the second year of cultivation, which in combined production forage-seed is mainly used for forage production.

Material and Method

A field experiment was set up at a trial field of the Veterinary Extension Service in Čačak (43°54'39.06" N, 20°19'10.21" E, 246 m a.s.l.) in 2009, 2010 and 2011. The trial was established on alluvial soil (pH 4.8), which contained 3.18% organic matter, 0% $CaCO_3$, 22.1 mg P 100 g^{-1} soil and 30.0 mg K 100 g^{-1} soil. The preceding crop was natural meadow. In autumn, prior to seeding, 45 kg ha^{-1} N, 45 kg ha^{-1} P_2O_5, and 45 kg ha^{-1} K_2O were incorporated into the soil by primary tillage.
The mean annual air temperature in 2010, 2011 and 2012 was 12.57ºC, 12.37 ºC, and 13.12 ºC respectively, and the sum of annual rainfall 669.4 mm, 374.5 mm and 463.5 mm respectively. The average annual air temperature for multy year period (1992-2002) was 11.97 ºC, and the average sum of annual rainfall 680.3 mm.
The experiment involving four red clover varieties and two treatments with cobalt (control, foliar Co) was laid out in a randomized block design with four replications and with a plot size of $5m^2$ (5x1m). Red clover varieties K-17, K-39 (Institute of Forage Crops Krusevac, Serbia), Una (Institute of Field and Vegetable Crops Novi Sad, Serbia) and Viola (a Polish variety) were planted at a row spacing of 20 cm and a seeding rate of 18 kg seed ha^{-1}. The crop was foliarly treated with Co (as $Co(NO_3)_2$), at a concentration of 0.033 g L^{-1} and a water rate of 1000 L ha^{-1}, applied once in the intensive growth phase during the first growth in the second year of cultivation. Mechanical weed control was performed twice in the first year of cultivation. No irrigation was employed.
The analyses were performed on the first cut in the second year of cultivation (2010, 2011, 2012) which in combined production forage-seed is mainly used for forage production. Mowing was done in the budding stage. Forage yield was determined by measuring the total weight of the plot immediately after cutting and recalculated to forage yield in t ha^{-1}. After drying at 65° C, the measured sample (500g) was used to calculate hay yield (t ha^{-1}). The obtained results were subjected to a mixed-design analysis of variance model (year as a random effect, varieties and foliar fertilization as fixed effects) using SPSS (SPSS 1995). Differences between means were tested by LSD test.

Results and Discussion

In the treatment without cobalt, the highest forage yield of the red clover varieties was recorded in 2010, significantly lower in 2011 and the lowest in 2012 ($P \leq 0.05$) (Table 1.). Considering that the crop was grown without irrigation, yield differences are mainly the result of differences in the amount of rainfall per year. At the variant with the foliar application of cobalt, the forage yield of the varieties in 2010 and 2011 did not differ significantly, while the yield in the both of the years was also higher, as compared to 2012 (interaction year/foliar fertilization). The extremely low amount of rainfall was recorded in 2012, during the growing season. At the treatment without application of cobalt, the varieties had a significantly higher hay yield in 2010 and 2011 as compared to 2012. In the variant with foliar application of cobalt, the largest hay yield was recorded in 2011, significantly lower in 2010, and the lowest

in 2012 ($P \leq 0.05$) (interaction year/foliar fertilization). Hanson (1991) reported that the forage yield of perrenial legumes reduces if soil moisture is inadequate. According to Bošnjak (1993) the average increase of forage yield of alfalfa in dry years with the implementation of irrigation amounted to 56-61%, whereby the effect of irrigation at the start of vegetation was somewhat more modest. According to Duncan and Woodmansee (1975), the correlation between precipitation and forage yield at grasses and legumes was significant during the phase of intensive growth, especially if in this stage is expressed the lack of soil moisture. Bošnjak et al. (1995) found at alfalfa the existence of full corellation ($r=0.99$) between the forage yield and the annual precipitation.

Considering that in the treatment without foliar application of cobalt was recorded a significantly higher forage yield of the varieties in 2010 in relation to 2011 and that on the treatment with foliar application of cobalt, the forage yield did not significantly differ in these two years, the foliar treatment with cobalt achieved a positive impact on the forage yield of red clover varieties in 2011. The hay yield is in accordance with forage yield; at the treatment without cobalt the varieties did not differ in 2010 and 2011, while at the variant with cobalt, a significantly higher yield of hay was recorded in 2011 as compared to 2010. The results among others are the consequence of a somewhat higher water content in forage in 2010 as compared to 2011. According Vrany et al. (1978), Powrie (1964), Ozanne et al. (1963), foliar applications of cobalt resulted in a significant increase in the number of nodules on the root system, the amount of fixed nitrogen, which resulted in more intensive growth of red clover. Reddy and Raj (1975) also indicate that foliar application of cobalt in soybean affects better nodulation and increase in seed yield. According to Jayakumar et al. (2007), low concentrations of cobalt (less than 50 mg kg^{-1} soil) have a positive impact on growth of soybean plants, and adsorption of nutrients from the soil. Cobalt in the form of fertilizer increases the yield of peanuts (Joshi et al., 1987) and pea (Danilova et al., 1969) as a result of increasing the number of nodules per plant. Accordingly, Dilworth et al. (1979) stated that in absence of cobalt, the weight of nodules per lupine plant reduced to 50-80%. Application of cobalt in concentrations of less than 50 mg kg^{-1} soil in beans influenced significantly increase the number of nodules per plant, number of effective nodules per plant, weight of effective nodules per plant, dry matter accumulation in plants, increasing the number of pods per plant (Mathur et al., 2006) and yield per hectare (Pattanayak et al., 2000; Mathur et al., 2006). It should be emphesized that any method of application of cobalt (foliar or in soil) may increase its concentration in the feed. Reith and Burridge (1983) recorded the increase of the content of cobalt in forage of several species of clover and ryegrass, by the application of 0.5 kg ha^{-1} of cobalt in form of cobalt sulphate, especially on peat soils.

Irrespective of the year, on the treatment with cobalt, the varieties also behaved differently in terms of forage yield, in relation to the treatment without cobalt. In the variant with foliar application of cobalt, in all of the years, the variety Una had a significantly higher yield compared to varieties K-39 and Viola, while on the treatment with cobalt the variety Una had a significantly higher forage yield only as compared to the variety Viola (interaction cultivar/foliar fertilization). According to Radović et al. (2004), red clover cultivars showed better results in agroecological conditions in which they were selected. According to the same authors, native varieties of red clover have an advantage over foreign varieties, as a result of better adaptability to existing environmental conditions.

Table 1. Forage yield - FY (kg ha^{-1}) and hay yield - HY (kg ha^{-1}) cultivars of red clover in the first cut in the second year of cultivation depending on the foliar treatment with cobalt: Ø – control, without cobalt; Co – cobalt (interaction year/foliar treatment; cultivar/foliar treatment and year/cultivar/foliar treatment).

Conclusion

On the treatment without cobalt, the varieties realize the highest forage yield in 2010 with the highest rainfall, and the lowest in 2012 when the rainfall was the lowest. However, on the variant with foliar application of cobalt, forage yield of the varieties did not significantly differ between 2010 and 2011, and in both of the years the forage yield was higher as compared to 2012. The achieved results indicate that foliar treatment with cobalt achieved a positive impact on forage yield of the varieties of red clover in 2011, because on the variant with foliar application of cobalt the forage yield of the red clover cultivars did not differ significantly between 2010 and 2011. The hay yield results are consistent with the results of forage yield, because on the treatment without cobalt the varieties did not differ significantly in 2010 and 2011, while on the variant with cobalt a significantly higher hay yield was recorded in 2011 as compared to 2010. On the variant with foliar application of cobalt in all of the years, the variety Una had a significantly higher forage in relation to the varieties K-39 and Viola, while on the treatment with cobalt the variety Una had a significantly higher forage yield only in relation to the variety Viola.

Abstract

In a field trial set up on the research field of Agricultural station in Sombor, the effect of different fertilization systems and mulching on yield of pepper (varieties) and mineral nitrogen (N) dynamics in soil were studied. Trial was conducted during 2012 and 2013 cropping seasons. Pepper was grown with and without plastic foil as a ground cover, and on both mulching systems it was applied 240 kg N ha^{-1} in total, through different fertilization systems. Four organic fertilizers were applied: mature cattle manure (MCM); composted pig manure (CPM); vermicompost (V) and organic fertilizer *Fertor* (F). Each organic fertilizer was applied in two different amounts which contained 120 and 240 kg N ha^{-1}. On the same plots, mineral N fertilizers were added to fulfill target value for N application (240 kg N ha^{-1}). The monitoring of NO_3-N in soil during the pepper growing season has shown that the mineralization of organic fertilizers was most intense in the first half of vegetation, while in the second, during the yield formation, concentration of mineral nitrogen in soil was significantly reduced. Concentration of mineral N in soil under plastic mulch was significantly higher compared to plots without mulch. Yield of pepper in first and second term of harvest were positively correlated with concentration of mineral N in soil.

Key words: *soil, NO_3-N, fertilization systems, pepper, yield.*

Introduction

Vegetable cultures produce high yields during a short vegetation period so they have greater demands for nutrients, primarily nitrogen, which is an essential factor affecting yield.

In order to achieve high and stable good-quality yields in a short vegetation period of vegetable crops, not only mineral but also organic fertilizers need to be applied. Mineral fertilizers are fast-acting sources of nutrients. Organic fertilizers have a twofold effect on crops as they not only provide nutrients for the crops but they also positively affect the physical and biological properties of the soil. Organic fertilizers contain higher proportions of nutrients in an organic form, which is only after mineralization transformed into plant-available forms. It is therefore necessary to access the mineralization potential of organic matter in the fertilizer by following its nitrate dynamics so that the choice of an appropriate fertilizer and the time of its application can be coordinated with the demands of the crops (Čabilovski, 2009).

Nitrate dynamics in the soil is affected by numerous factors, the most important of which are temperature and humidity. Soil humidity directly affects the mineralization process and thus the mineral nitrogen content in the soil.

Low or excessive humidity can be stressful for microorganisms in the soil and it can inhibit their growth (Stanford and Epstein, 1974; Myers *et al*., 1982; Bogdanović *et al*., 2007; Ubavić *et al*., 2005), while alternating high and low levels of humidity increase the amount of fast-mineralizing material.

Temperature directly affects the decomposition of organic matter, while the microorganisms that are involved in the process have different temperature oscillations. Vegetable production in an open field occurs in the period of constant increase of soil temperature (10-15-25-30ºC) and, as intensive vegetable production is not possible without irrigation, this means that there

are favourable conditions for the mineralization of applied organic fertilizers and organic matter in the soil.
The rate of organic fertilizer mineralization is determined by the type of fertilizers, the degree of decomposition of organic matter, temperature, humidity and microbiological activity (Pansu and Truries, 2003). Due to intensive mineralization, an excessive application of organic fertilizers can lead to an increased accumulation of NO_3-N in the soil, harmful accumulation in the plants and pollution of the environment.
The objective of this research is to assess the effect of different systems of fertilizing pepper grown under polyethilene (PE) foil and without PE foil on NO_3-N dynamics in the soil and their effect on the yield.

Material and Methods

The dynamics of NO_3-N in pepper production was observed in field experiments set up using a split plot design with and without PE foil. The experiments are two-factorial, where factor A is the fertilization systems and B is the use of PE foil as mulch Pepper was grown with and without plastic foil as a ground cover, and on both mulching systems it was applied 240 kg N ha^{-1} in total, through different fertilization systems (Table 1). Each organic fertilizer was applied in two different amounts which contained 120 and 240 kg N ha^{-1}. On the same plots, mineral N fertilizers were added to fulfill target value for N application (240 kg N ha^{-1}).

Table 2. Agrochemical properties of soil in exspperiments before pepper planting

Year	Depth	pH		Percent			mg $100g^{-1}$		mg NO_3-N kg^{-1}	
		H_2O	KCl	$CaCO_3$	Humus	Total N	P_2O_5	K_2O	before planting	after planting
2012	0-30	7.60	7.0	4.59	3.12	0.16	21.9	22.1	36.0	27.0
	30-60	7.80	7.0	5.42	2.96	0.15	14.3	21.0	41.6	38.0
2013	0-30	8.01	6.85	3.82	2.48	0.12	17.8	21.3	46.4	30.0
	30-60	8.11	6.98	13.58	1.99	0.10	6.7	16.5	22.1	23.0

For the analysis of soil fertility standard methods were used. The first and the second harvests were performed during optimum technological maturity. The research results were processed by variance analysis for a two-factorial experiment.

Results and Discussion

NO_3-N dynamics in the soil under pepper with and without foil, dependent on applied fertilization systems, and fertilization treatments in 2012 and 2013 is given in Figure 1 and Figure 2. In both years a higher amount of NO_3-N was detected at all sampling times, with all systems and fertilization treatments in pepper under foil than in pepper without foil.

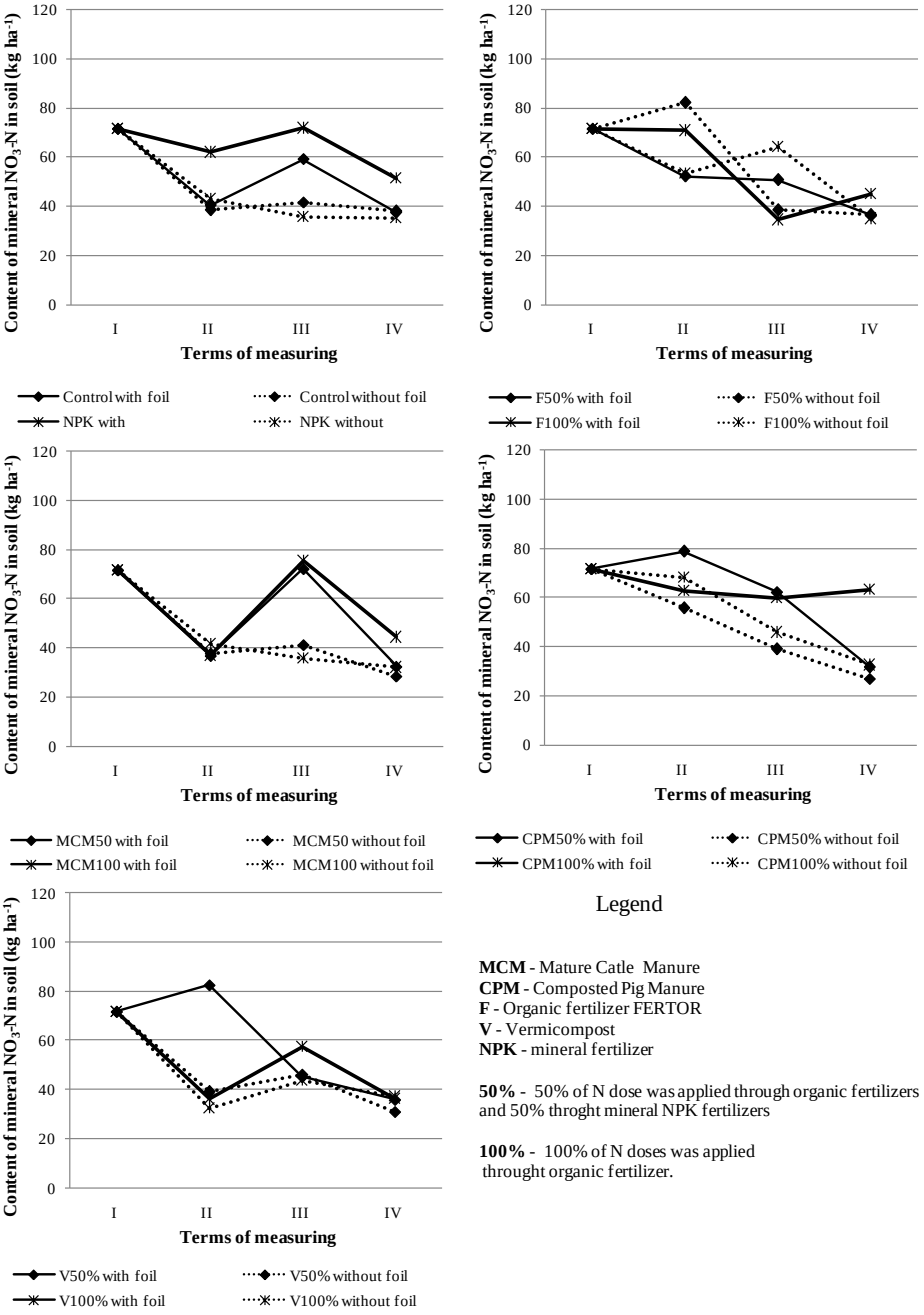

Figure 1. NO_3-N dynamics in the soil under pepper with and without foil, dependent on applied fertilization systems, and fertilization treatments in 2012.

Significantly higher amounts of NO_3-N were found in the soil under foil than in the soil without foil because of better mineralization conditions. The basic prerequisite for a better mineralization of organic fertilizers is a 3-4^oC higher temperature and a 1.5%-2.5% higher soil humidity in the experiment under foil when compared to the experiment without foil. The exception is the sampling made during intensive growth in 2012, in which the sample taken from the plot with pepper without foil had a significantly higher amount of NO_3-N with all fertilization treatments.

The highest amount of NO_3-N in the soil under foil was recorded in the experiment in 2012 with 100%. Fertor fertilization systems, and on the plots without foil with the application of N from vermicompost.

In the first harvest, the highest value of NO_3-N in the soil in 2012 was recorded with the treatment N from 100% MCM, and in the second harvest with the treatment N from 100% CPM under foil.

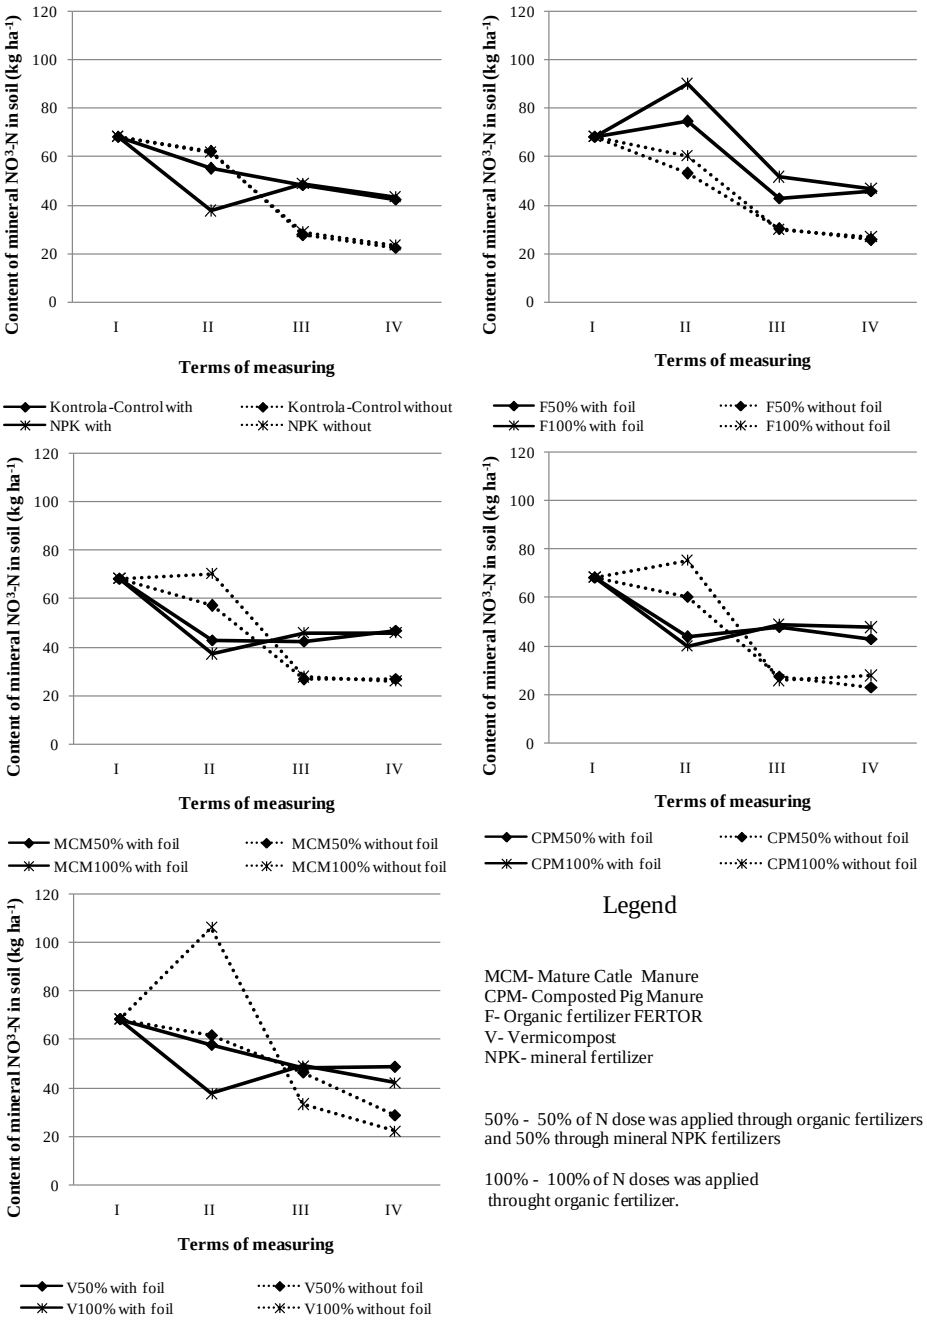

Figure 2. NO_3-N dynamics in the soil under pepper with and without foil, dependent on applied fertilization systems, and fertilization treatments in 2013.

The recorded values of NO_3-N under pepper with and without foil at different sampling times indicate that organic fertilizer N mineralization was more intensive in the first period of vegetation, during intensive growth, as compared to the second period of vegetation, when lowest values were recorded at the end of the second harvest.

The recorded amounts of NO_3-N at different sampling times represent a state of equilibrium between the mineralization of applied organic fertilizers and soil organic matter on one hand, and the immobilization of mineral nitrogen by pepper crops and microorganisms on the other (Bogdanović and Čabilovski, 2007; Bogdanović and Ubavić, 2008; Čabilovski *et al*. 2010).
NO_3-N dynamics in soil under pepper in the experiments with and without foil correlates positively with obtained yields in both years. The yields in the experiments with foil were significantly higher with all fertilization systems and treatments than those produced in the experiments without foil Figure 3 and Figure 4. Higher yields in the experiment without foil are directly dependent of the amount of NO_3-N measured in the soil, which area result of better conditions for organic fertilizer mineralization (humidity and temperature). Of all the applied organic fertilizers, the highest yields with and without foil were obtained with fertor (F) treatment, followed by composted pig manure (CPM), vermicompost (V), mature cattle manure (MCM), and the lowest with mineral fertilizers (NPK) (Figure 3 and 4).
The stronger effect that fertilizing with fertor had on pepper yields when compared to the other applied organic fertilizers stems from the production technology of this fertilizer and its content. Fertor is a pelleted organic poultry manure to which other organic plant materials are added and it contains all biogenic elements.
Furthermore, with CPM treatments higher yields were obtained with and without foil than with V, MCM and NPK treatments, which can be explained with significantly higher solubility and the presence of biogenic elements, primarily nitrogen from CPM, when it is compared to other fertilization systems**.** Research by Denić (2010) on maize and Bogdanović *et al*. (1995) on wheat shows that NO_3-N from liquid pig manure in the year of application had an effect on yield, identical to that of mineral fertilizers.

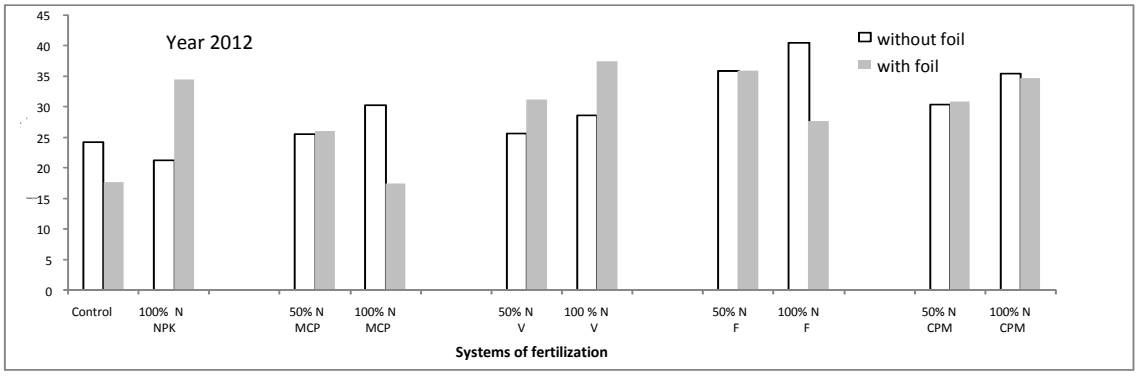

Figure 3. Pepper yield as dependent on fertilization systems and mulching in 2012.

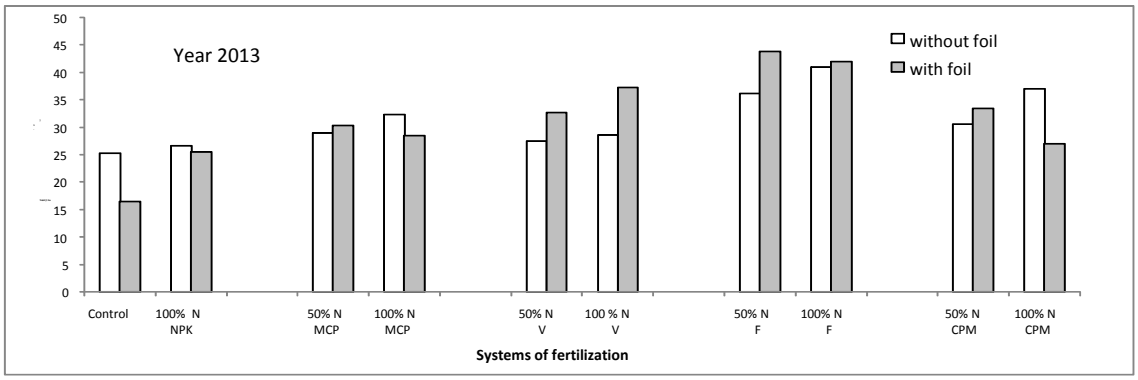

Figure 4. Pepper yield as dependent on fertilization systems and mulching in 2013.

Conclusion

Based on the observed dynamics of NO_3-N in the soil under pepper with and without foil, depending on the fertilization method and its effect on yield, the following conclusions can be drawn:

Mineralization of NO_3-N from organic fertilizers was more intensive in the first period of vegetation, during intensive growth, and considerably slower in the second period of vegetation at the times of the first and second harvest.

The highest amount of NO_3-N was recorded in the soil under pepper with foil in 2012, at the first harvest with N from 100% MCM treatment, and at the second harvest with N from 100% CPM treatment. In both years higher amounts of NO_3-N were found with foil than without it, at all sampling times, with all fertilization systems and treatments. Pepper yields under foil with all fertilization systems and treatments are significantly higher than those without foil.

Abstract

Variability of grain harvest index (GHI) and some components of yield (plant height, thousand grain weight) were studied in 20 winter wheat cultivars which selected in in different selection centers. Wheat cultivars were grown in the experimental field in 5 replication. Samples of 100 wheat plants (20 plants in 5 replications) were analyzed in full maturity stage during two seasons. Harvest index was computed as a ratio of grain yield and a total above ground part of the plant. The values of GHI varies depending from cultivars and environment. The obtained values for all analyzed traits were significantly different among wheat cultivars. The highest harvest index in first year had cultivar Lasta (41.3%) and the lowest had Zastava cultivar (35.1%). In second years, the highest HI had cultivar Pobeda (42.6%) and the least GHI had cultivar Ljubičevka (33.2%). Wheat cultivar Zastava had the highest height in both year of investigation, 98.32cm in the first year and 78.84cm in the second year of analysis. The lowest plant height had Gruža culivar in both year, 70.56cm in the first year and 57.10cm in the second year. Thousand grain weight (TGW) in the first year variate from 38.33g in Gružanka cultivar to 51.12g in Zadruga cultivar. In second year the highest value of TGW had Zadruga (52.85g) and the least value 38.84g had the Ljubičevka cultivar.

Key words: *wheat, cultivar, grain harvest index (GHI), stem height, thousand grain weight (TGW)*

Introduction

In the wheat breeding program breeders have aim to improve all characteristic, what is not simple because of different genetic control of traits, and very complex relationship among the traits. For the successful breeding process is necessary use the knowledge of characteristics of genotypes as well interaction of genotypes and environments. The breeding of wheat is directed to creation the cultivar for high grain yield or for any other desirable traits need to express genetic potential in different environment with low value of variance in different environmental factors of growing (Knežević, 2014). The genetic yield potential of a wheat cultivar may be dependent on favorable conditions and good agronomy for its expression. The traits as height of plants, length of spike, number of spikelets per spike are in positive correlation with grain yield (Zečević et. al, 2013). The harvest index (HI) of wheat plants can use as reliable parameters in wheat breeding which varies from 5-17% in the wild diploids to 51% in modern cultivars. GHI has increased over time due to breeding for higher yield which achieved 0.015 for Australian cultivars, and 0.02 percent per year for United Kingdom cultivars (Turner, 1997). The harvest index represents the ratio between economical yield and biological yield i.e. ratio between grain yield and yield of r straw + grain. In mostly modern cultivars, the proportion of total mass to grain yield is more than 2:1 which indicates excessive consumption of nutrients for straw formation instead of grain. The high HI value can achieve through decreasing vegetative part of wheat and increase grain filling by application of mineral nutrition and increasing efficiency of utilization and translocation

nutrient (Gorjanović et al., 2011) to grain especially at the grain filling phase. Numerous environmental factors have influence to the value of HI as well other yield components. The low or high temperature can cause damages on seed growth and at flowering phase and can influence to significant variation in harvest index. Frost after anthesis can cause reduction in HI and total grain yield as well quality (Allen et al., 2001). The variability of growing wheat plant influenced by N status in soil in conjunction with available water and vigorous growth can contribute to reduction of HI of wheat (Duggan et al., 2005). Diseases and pests have negative influence to grain filling and size what implicate to forming of grain yield. Investigation of McKirdy et al. (2002) showed that yellow mosaic virus have influence on expression shriveling of grain in wheat.

The aim of this work is investigation of variability values of harvest index, height of plants, thousand grain mass in genetically divergent wheat cultivars grown in different environment.

Materials and Metods

The variability of grain harvest index (GHI) and some yield components (plant height -PH, thousand grain weight-TGW) were studied in 20 wheat cultivars originated from different wheat breeding centers. For this investigation used cultivars: Balkan, NS Rana 2, Jugoslavija, Yantar, Rusalka, Šumadinka, Maris Freeman, Zadruga, Kompas, Gružanka, Apache, KG 78, Lepenica, Zastava, Gruža, Lasta, Libellula, Ljuičevka Partizanka and Pobeda. The experiment was performed in randomized block design in five replication on the experimental basic plot 5 m^2. For analysis of plant height, were used 100 plants in full maturity stage (20 plants/replication). The following parameters were computed: the average value (x); the variance (σ^2); the coefficient of variation (V) as an index of relative variability of the trait. The significant differences between the average value were estimated by F-test values. The differences of wheat cultivars was estimated on the base of analyzed parameters: harvest index, plant height, thousand grain weight.

Climatic conditions during growing seasons

The values of temperature and precipitation in two years experiment were different and compared with previous ten years average values (table 1).

Table 1. Monthly and mean temperatures and monthly and cumulative precipitation

Tem& Precpt	Period	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Xm	Total
^{0}C	2005/06	11.5	5.6	3.3	-1.7	1.5	5.5	12.7	16.4	19.7	8.3	74.4
^{0}C	2006/07	13.3	7.6	3.5	6.1	6.3	9.1	12.1	18.2	22.8	11.0	99.0
1990/2000		11.8	6.4	1.7	-0.1	2.6	5.9	11.6	16.4	20.4	8.5	76.7
(mm)	2005/06	49.0	54.8	47.1	27.9	38.1	116	86.3	29.6	84.8	59.3	533.7
(mm)	2006/07	16.7	13.7	51.9	45.3	32.1	62.9	3.6	118	25.3	41.1	369.9
1990/2000		61.0	44.3	44.6	30.0	29.9	33.2	52.9	52.6	69.3	46.5	418.5

Average temperatures were similar during ten years average value (8.5 ^{o}C) and first year (8.3 ^{o}C) of investigation, while in second year temperature value (115 ^{o}C) was higher in average about 2.5 5 ^{o}C than in the first (2005/06) and ten year period (1990/2000). Sums of precipitation were higher in 2005/06 (533.7mm) than in 2006/07 (369.9mm) year and ten year precipitation amount (418.5mm). According to long-term period, precipitations in 2006/07 vegetative period were lower for 115.9 mm, while 2005/06 amount of precipitation was higher for (47.9mm). In May 2006/07 precipitations were higher four time in relation to 2005/06 year and long-term period, but in April 2006/07 was only 3.6 mm.

Results and Discussion

Harvest index (HI). For small grains, harvest index (HI) is the ratio of weight of harvested grain to total shoot dry matter and represents plant efficiency in translocation nutritive matter from vegetative to generative plant part. Harvest index value can be used as a measure of efficiency of productivity. GHI depends to two distinctly quantitative traits contribute to high variability of cultivars. In the first year of investigation the GHI value ranged from $\bar{x}$ = 35.10% for cultivar Zastava to $\bar{x}$ = 41.30%, for Lasta cultivar. In second year harvest index value variate from $\bar{x}$ =33.20% in cultivar Ljubičevka to $\bar{x}$ =42.60% in Pobeda cultivar (tab. 2). Variability expressed by coefficient of variability in first year (V=5.23%) and in second year (V=5.84%).

Table 2. Average value of analyzed harvest index, plant height and thousand grain weight in wheat cultivars in period 2005-2007 years

Harvest index is reliable indicator of yield and significant correlation between harvest index and grain yield were found for 13 wheat cultivars of USA (Donmez et al., 2001), for 14 wheat cultivars of France (Brancourt-Hulmel et al., 2003) and for UK wheat varieties (Shearman et al., 2005). The negative correlation between harvest index and protein content in wheat were found Flood and Martin (2001) what is indicate difficulties to create cultivar with high yield and high quality. This could be connected with weather conditions, which causing shortening of stem, that was favorable for nutritive matter translocation. Predicting or modeling crop yield or harvest index responses to temperature extremes during the reproductive phase is problematic due to differences among genotypes, and difficulties to estimate damages of grain

by extreme temperature. The analysis of variance indicated that environmental conditions had significant influence on expression harvest index value. The efficiency with which wheat plant produce dry matter of grain is the first determinant of harvest index. For the most wheat cultivars the harvest index is below the 50%. The achieving high value of HI based on genotype capacity and value of adaptability to environmental factors as well variation of temperature, carbon concentration, soil fertility, water and nutrient availability.

Plant height. This trait is related to grain harvest index and grain yield in wheat cultivars. The plant height in the first year of investigation the ranged from $\bar{x}$ = 70.56cm for cultivar Gruža to $\bar{x}$ = 98.32cm, for Zastava cultivar. In second year plant height value varies from $\bar{x}$ =57.10cm to $\bar{x}$ =78.84cm (Table 2). Variability expressed by coefficient of variability in first year (V=5.12%) and in second year (V=4.46%) tab. 2. The differences are most likely caused by genetic diversity of studied wheat cultivars and environmental conditions in which field experiment was performed. Plant height controlled by genes and environment. The decreasing of plant height can contribute to increasing value of harvest index. *Rht* genotype had a significant effect on reduction plant height, coleoptile length, and yield. For the semi-dwarf wheat genotypes were found enhanced interaction with environment in comparison to tall cultivars (Dimitrijevic et al., 2000). The wheat cultivars with decreased stem height have increased efficiency of utilization mineral elements and grain filling. The genes *Rht-B1b, Rht-D1b* mainly have effect to plant height reductions about 20% and increasing of grain yield potential for 5-15%, while *Rht8* influence to stem reduction about 10% and decrease yield for about 5% (Robbins, 2009).

Thousand grain weight. In the first year, the highest average value of thousand grain weight had Zadruga cultivar (x=51.12g) the lowest average value of thousand grain weight expressed Gružanka cultivar (x=38.33g) and Šumadinka (x=38.80g). In second year of investigation the highest value of TGW had Zadruga cultivr (52.85g) and the least value of TGW had Lepenica cultivar (38.84g).Variability of thousand grain weight in analyzed cultivars, in average, was expressed and coefficient of variation had (V=3.08%) in the first year and (V=4.31%) in the second year (tab. 2). TGW have strong influence to spike productivity and yield value. For analyzed traits the environmental differences contributed more to total trial sum of squares than genotypic diversity. The biological yield, harvest index and TGW contribute to increasing of yield (Tsegaye et al., 2012) and that this trait, depends of phase of development variate under environmental factor (Khan and Dar, 2010) on the both phenotypic and genotypic levels (El-Moshen et al., 2012).

Conclusion

This study showed variability of harvest index, plant height and thousand grain weight and differences among the investigated wheat cultivars. Difference among analyzed wheat cultivars were significant and determined by genotype specificity and environmental factor. The highest grain harvest index in first year had cultivar Lasta (41.3%) and in the second year had cultivar Pobeda (42.6%). Other cultivars had different value of HI in two different environment. This difference values of HI in analyzed wheat cultivars indicated that remobilization of reserve into harvested organs varies among the cultivars. Cultivars expressed different reaction in plant height reducing, consequently that had the impact on HI, as well. Wheat cultivar Zastava had the highest height (98.32cm) in first and 78.84cm in second year and low values of HI in both year. The best wheat cultivar for TGW was Zadruga (51.12g) in the first year and 52.85g in the second year of investigation. The values of GHI, plant height and TGW was different among the investigated wheat cultivars as well for each cultivar depends of year of investigation, which indicated different response of genotype to environmental conditions in two experimental years.

Abstract

In this investigation used three maize hybrids that are belongs to different group of ripening: FAO 3, FAO 4 and FAO 6. The seed of those hybrids used for investigation of genotypic divergences for seed germination, energy of germination, content of abnormal emergence of seeds, content of dead seeds. Hybrid seed for analysis produced on the experimental field of the Institute of Maize in Zemun Polje, Belgrade. The viability of the maize hybrids seeds were determined in experimental analysis carried out in laboratory for quality of seed in the Maize Research Institute Zemun Polje, Belgrade. According to standard method on filter paper were estimated the values of seed germination. The three experiment of seed germination carried out: 2 months after harvest, 9 months after harvest and 18 months after harvest. In average for each test the highest percentage of seed germination were found for hybrid ZP FAO3: 92.75% for seed after 2 months of harvest, 92.00% for seed 9 monhts after harvest and 91.50% for seeds after 18 months of harvest. This hybrid had the lowest percentage of ungerminated seeds (2.75%) and the least content of dead seed (~5.00%). The lowest value of seed germination (86.33%) and the highest values of ungerminated seed (~3.00%) as well the highest content of dead seed (10.33%) had hybrid belongs FAO 4 group. The obtained results indicate differences of germination in analyzed maize genotypes.

Key words: *seed, germination, percentage, hybrid, maize*

Introduction

Value of seed germination is very important trait of genotypes and represent initial stage of plant development. The plant species potential for reproduction is determined with seed germination. Genetic potential for seed germination is different among cultivars and hybrids and expresed in interaction with environmental conditions. The process of seed germination require available water which is need for activating enzyme system and initiating growth and development of seedlings (ISTA 2010). Seed germination is the most important trait of quality and life cycle of seeds, depends of genotypes and environments, which determine efficiency of plant growth (Milošević and Malešević, 2004). In the aim to establish value of seed germination, developed different methodes for analysis of seed germination of different plant species as well as for maize (Milošević et al., 1994). The identification of quality of seed contribute to undestand its importance for economy. International seed trade represents one of the basic indicators of an economic status of a country. Seed production is among the most profitable activities in the field of agriculture, considering relation of areas under commercial seed production and high financial effect (Knežević et al., 2006). Methods for germination of maize seeds on filter paper and sand represent standard test under optimal humidity of supstrate, as well temperature and humidity of the environment. This methods used filter paper is very short and efficient for establishing of seed germintion. The standard test of germination healthy and unharmefull seeds under favorable laboratory condition give us useful information about seed germination capacity (Milošević et al., 2007). However,

standard tests, often do not show realistic behavior of the seed under field conditions are still used. In the case of high doses of treatment by pesticides can use larger fraction of seeds for testing in sand. In purpose to establish seed germination for planting in cold field conditions used different type of vigor tests. Germination percentage of seeds in laboratory will give information that seeds can planted in field conditions and develop into normal plants. The growing of maize hybrids in different environment can be associated with variations in seed germination ability under the influence of environmental limiting factors as well soil fertility, climate (Kovačević et al., 2011; Ranieri et al., 2012). Several ecological and evolutionary factors can affect the process of seed germination, as well seed size which have an important evolutionary effects on plant reproduction of many plant species (Moles et al., 2006), and have influence to germination time, germination percentage and seedling vigor (Yanlong et al., 2007).

The aim of this work is study of variability of seed germination hybrids belongs to different maturity group and established differences of percentages of germinated seeds in laboratory conditions.

Material and Methods

The three maize hybrids, originated from Institute of maize Zemun Polje, Serbia (ZP-FAO 3. ZP-FAO 4 and ZP-FAO 6) were utilized for investigation. Four replicates of hundred seeds of each hybrids were used in laboratory tests. The standard germination test was conducted in rolled paper towels placed in germinator at 20°C (16 hours) and then at 30°C (8 hours) according to the rules of the International Seed Testing Association (2010). The germinator was set to provide light during the high-temperature cycle (8 hours) and to remain dark during the low-temperature cycle (16 hours). An initial count of germination percentage was 5^{th} day and a final count 7^{th} day after beginning of germination test.

For data analysis was taken Kruskall-Wallis's test, which is a non-parametric alternative one way of analysis of variance with different patterns. Results are converted into ranks, and comparing the middle ranks of each group. Statistical analysis was performed using the "R programming language" (The R Project for Statistical Computing, version 3.1.3) (R Development Core Team, 2015).

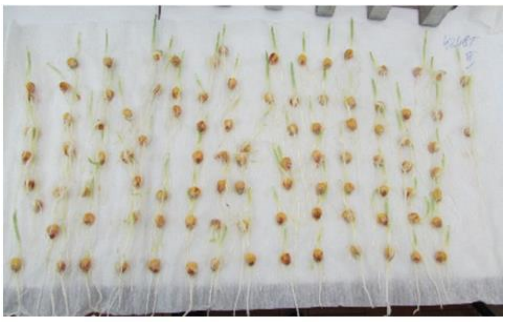
Results and Discussion

In this investigation obtained results showed variability of seed germination in laboratory conditions depends on hybrids and different length of storage time after harvest. The lowest value (86.10%) of seed germination energy, in average had the hybrid ZP FAO 4 and the highest germination energy (91.60%) had hybrid ZP FAO 3. Also in all test of grmination, the highest seed germination energy had ZP FAO 3 in test of two months after harvest - 92.25%, nine months after harvest-91.50% and 18 months after harvest 91.25%. The lowest energy of seed germination had hybrid ZP FAO 4, in test at two months after harvest - 86.75%, nine months after harvest-85.00% and 18 months after harvest 86.50%. Seed germination energy of hybrid ZP FAO 6 was in test at two months after harvest -86.50%, nine months after harvest-91.00% and 18 months after harvest 91.50% (table 1).

Table 1. Percentage of seed germination energy and percentage of seed germination

	Seed germination energy % after harvest			Average %	Value of seed germination % after harvest			Average %
Hybrid	2-months	9-months	18-months		2-months	9-months	18-months	
ZP FAO 3	**92.25**	**91.50**	**91.25**	91.60	92.75	92.0	91.50	92.08
ZP FAO 4	**86.75**	**85.00**	**86.50**	86.10	**87.50**	**85.75**	87.25	86.33
ZP FAO 6	**86.50**	**91.00**	91.50	89.66	**93.25**	**91.75**	90.25	91.75

The lowest value of seed germination (86.33%), in average had the hybrid ZP FAO4 and the highest value of germination (92.08%) had hybrid ZP FAO3. Also in all test of grmination, the highest percentage of seed germination had ZP FAO3, two months after harvest -92.75%, nine months after harvest-92.0% and 18 months after harvest 91.50%. The lowest seed germination had hybrid ZP FAO4, in test at two months after harvest -87.50%, nine months after harvest-85.75% and 18 months after harvest 87.25%. Seed germination energy of hybrid ZP FAO6 was in test at two months after harvest -93.25%, nine months after harvest-91.75% and 18 months after harvest 90.25% (table 1, picture 1.).
Data about differences between maize hybrids for seed germination reported in investigation of other genotypes (Milošević et al. 1994) depends of endosperm of seeds (Pajić et al., 1998) and in different environmental conditions (Meeks et al., 2013).



Picture 1. Test of seed germination in maize hybrids

Picture 2. Occurrence of abnormal seed germination and dead seeds

Table 2. Content of abnormal seeds and dead seeds of maize ZP hybrids

	Abnormal seed germination (%) after harvest			Average	Dead seed at germination % after harvest			Average
Hybrid	2-months	9-months	18-months		2-months	9-months	18-months	
ZP FAO 3	**2.75**	**2.75**	**2.75**	2.75	**4.50**	**5.25**	**5.25**	5.00
ZP FAO 4	**3.75**	**3.50**	1.75	3.00	**9.00**	**11.0**	11.0	10.33
ZP FAO 6	**2.25**	**2.25**	2.75	2.75	**4.50**	**6.00**	7.00	5.82

During the analysis of seed germination, abnormal germination of seed occured, and dead seed (picture 2). The value of abnormal seed germination was similar for the investigated maize hybrids, approximately 3% (table 2) However, the lowest percentage of dead seed had hybrid ZP FAO3 (5.00%) and ZP FAO6 (5.82%), while the highest content of dead seed had hybrid ZP FAO4 (10.33%) table 2.
The results of seed germination obtained by using standard method in the filter paper showed that the values obtained in three term after harvest are very few deviate for one hybrids, but there was differences between values obtained in the same test term after harvest for each analyzed hybrid of maize. For seed energy of germination and germination of seed were found differences between analyzed maize hybrids. The obtained values of χ^2 =1.96 for germination energy of seeds is with probability 0.5499 (figure 1), while for percentage of seed germination influence of genotype for computed χ^2 =0.11 is with probability 0.9465 (figure 2). On the base of obtained values of probability on the level of >0.05 differences between genotypes are not significnt.

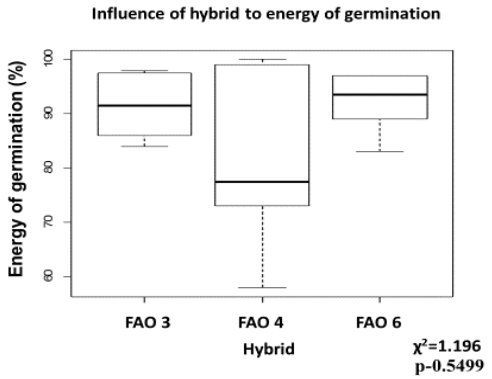


Figure 1. Effect of hybrids to germination energy

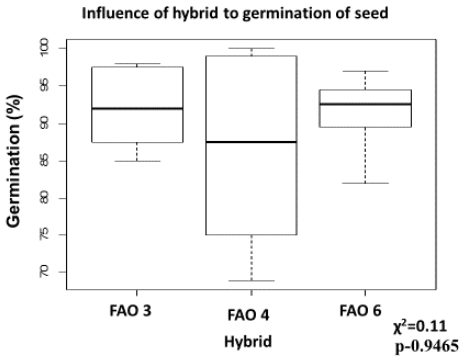

Figure 2. Influence of hybrids to germination

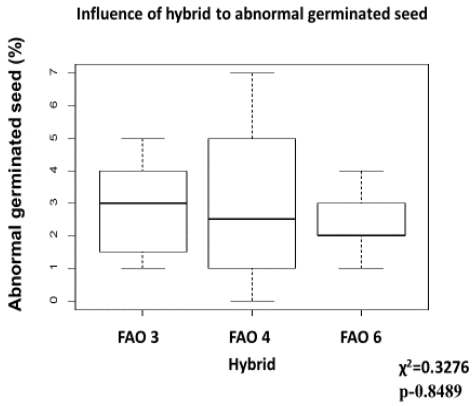

Figure 3. Effect of hybrids to occurence of abnormal seed germination

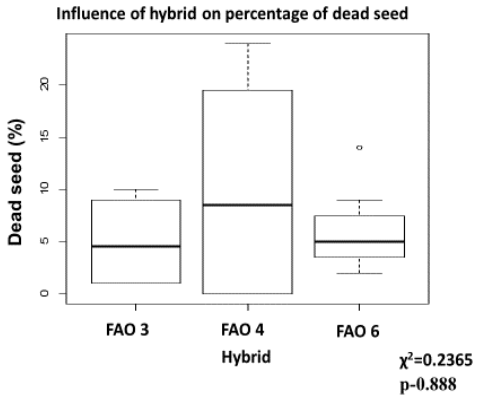

Figure 4. Influence of hybrids to occurence of dead seed

The differences between hybrids were not significant for occurence abnormal seed germination have probability 0.8489 for obtained values of χ^2 =03276 (figure 3) and for dead seed obtained values of χ^2 =0.11 was with probability 0.888 (figure 4).

Table 3. Kruskal-Wallis test for effect of seed storage time on traits of seed test germination in maize hybrids

Trait	χ^2	DF	p	Trait	χ^2	DF	p
Energy of germination	0,5888	2	0,745	Abnormal seeds	0,0378	2	0,9813
Percentage of germination	0,3464	2	0,841	Dead seed	0,4121	2	0,8138
χ^2-Chi square; DF-degree of freedom; p-probability							

The estimation of influence of different length of storage time after harvest on energy of seed germination, percentage of germination, content of abnormal germination of seeds and dead seeds presented in table 3. The obtained values of probability at level >0.05 for those traits indicate that included periods of storage seed after harvest do not have significant influence on seed germination. Storage time did not affect the values of seed germination, indicating that the seed is vital and that storage conditions were appropriate.

Conclusion

In this study were found differences among hybrids for seed germination energy, seed germination, occurence of abnormal seed germination and dead seed. In average the highest

germination energy (91.60%) and germination of seed (92.08%) had ZP FAO3, and the lowest germination energy-86.10%, and germination-86.33% had maize hybrid ZP FAO4. The occurence of abnormal seed germination was the lowest (2.75%) in hybrid ZP FAO3. The lowest content of dead seed established in ZP FAO3 (5.00%) and the highest in ZP FAO4 (10.33%). Included length of storage time after harvest of seed did not have significant influence on expressed differences of seed germination which were stored in appropriate conditions. Germination testing in the laboratory is done under very favorable, controlled conditions (humidity, temperature, light). Such results can be a good indicator of seed germination in field conditions where they are usually unfavorable factors as temperature and humidity, the structure of soil and soil pests.

INFLUENCE OF TEMPERATURE ON POLLEN GERMINATION AND POLLEN TUBE GROWTH OF PLUM CULTIVARS

Dragan MILATOVIĆ[1]*, Dragan NIKOLIĆ[1], Mirjana RADOVIĆ[2]

[1]Faculty of Agriculture, University of Belgrade, Serbia

Abstract

The temperature is an important environmental factor that affects pollen performance during the reproductive phase of fruit tree species. Pollen germination is one of the main factors for successful fertilization and fruit set in plum (Prunus domestica L.). The study was carried out to determine the effect of three different temperatures (5, 15 and 25°C) on the pollen germination and pollen tube growth in vitro of six European plum cultivars: ‘Cacanska Lepotica’, ‘Cacanska Rana’, ‘Jojo’, ‘Top’, ‘Toper’ and ‘Stanley’. Germination rate and pollen tube growth were determined on a culture medium containing 15% sucrose and 0.7% agar. Temperature significantly affected pollen germination of all studied cultivars. High germination rates (50–76%) were obtained at the temperatures of 15°C and 25°C. However, satisfactory germination rates (29–47%) were also obtained at the temperature of 5°C in some cultivars (‘Toper’, ‘Cacanska Rana’, ‘Cacanska Lepotica’ and ‘Top’). The influence of temperature was more prominent on the pollen tube growth. The length of pollen tubes was six to twelve times higher at 15°C and 25°C in comparison with 5°C. This has led to the conclusion that the temperature of 5°C, although it could be enough for pollen germination, is not enough for optimal pollen tube growth.

Keywords: *Prunus domestica*, pollen germination *in vitro*, pollen tube length.

Introduction

Pollen viability and its germination capacity is one of the main factors for successful fertilization in fruit trees. It is important for both breeding work and choice of the varietal composition in orchards.

Parfitt and Ganeshan (1989) studied seven different tests to evaluate pollen viability in several species of the genus *Prunus.* They concluded that two *in vitro* germination tests (hanging-drop and agar-plate) were the most reliable.

Temperature is the most important environmental factor affecting the success of fertilization and fruit set of stone fruit species. It affects different stages of a reproductive process, such as a stigmatic receptivity (Hedhly et al., 2003; Hedhly et al., 2005), pollen germination (Keulemans, 1984; Egea et al., 1992; Pirlak, 2002; Hedhly et al., 2004), pollen tubes growth (Cerović and Ružić, 1992; Hedhly et al., 2005; Milatović and Nikolić, 2014), and ovule viability (Stöser and Anvari, 1982; Postweiler et al., 1985; Cerović et al., 2000).

Keulemans (1984) examined the effect of six different temperatures (4, 6, 9, 12, 15 and 18°C) on pollen germination and pollen tube growth of six plum cultivars. The examined cultivars had different reaction on temperature. Cultivars ‘Czar’, ‘Opal’ and ‘Victoria’ were characterized by good germination and fast growth of pollen tubes at low temperatures.

The aim of this study was to determine the effect of temperature on pollen germination and pollen tube growth in six cultivars of European plum.

Materials and methods

Six plum cultivars: ‘Cacanska Lepotica’, ‘Cacanska Rana’, ‘Jojo’, ‘Top’, ‘Toper’ and ‘Stanley’ were used as a material for testing the pollen performance. Plant material was taken from a collection orchard of the Experimental farm “Radmilovac” of the Faculty of Agriculture in Belgrade. The orchard was planted in 2009. The rootstock was Myrobalan (*Prunus cerasifera* Ehrh.) seedlings, the crown form was Central Leader, and tree spacing was 4.5 × 3 m.

To collect pollen samples, twigs with flower buds in the “balloon” stage were taken from the experimental orchard. The twigs were transported to the laboratory where anthers were isolated from the flower buds. They were left to desiccate and release pollen in open Petri dishes for 24–48 h. Pollen was sowing using a fine brush in Petri dishes on previously prepared medium which consisted of 0.7% (w/v) agar-agar and 15% (w/v) sucrose. Petri dishes were then transferred to incubators ‘FOC 225I’ (Velp Scientifica, Usmate, Italy) at three different temperatures: 5, 15 and 25°C. After incubation of 24 hours, 40% (v/v) formaldehyde was added in Petri dishes to prevent further growth of pollen tubes.

Petri dishes with sowed pollen were observed under light microscope ‘Leica DM LS’ (Leica Microsystems, Wetzlar, Germany). The number of germinated and non-germinated pollen grains was counted and the percentage of germination was calculated. Petri dishes were divided into three parts, each part representing one repetition. In each repetition at least 300 pollen grains were analysed. Pollen was considered germinated if the length of the pollen tube was greater than the diameter of the pollen grain.

Pollen tube length was measured in pictures taken under the microscope ‘Leica DM LS’ using the ‘Leica IM 100’ programme. From all experiment variants (cultivars and temperatures) 60 pollen tubes were measured.

The experiment was conducted as two-factorial (cultivar, temperature), with three repetitions. The data were statistically analysed using the analysis of variance. Percentage data were subjected to arcsine square root transformation before the statistical analysis. Duncan’s multiple range test (5%) was performed for comparing means.

Results and discussion

Pollen germination ranged from 15.4% in the cultivar ‘Jojo’ at the temperature of 5°C to 76.3% in the cultivar ‘Cacanska Lepotica’ at the temperature of 25°C (Figure 1). In all studied cultivars pollen germination was significantly lower at the temperature of 5°C than at higher temperatures (15 and 25°C). Differences in pollen germination between temperatures of 15°C and 25°C were not statistically significant.

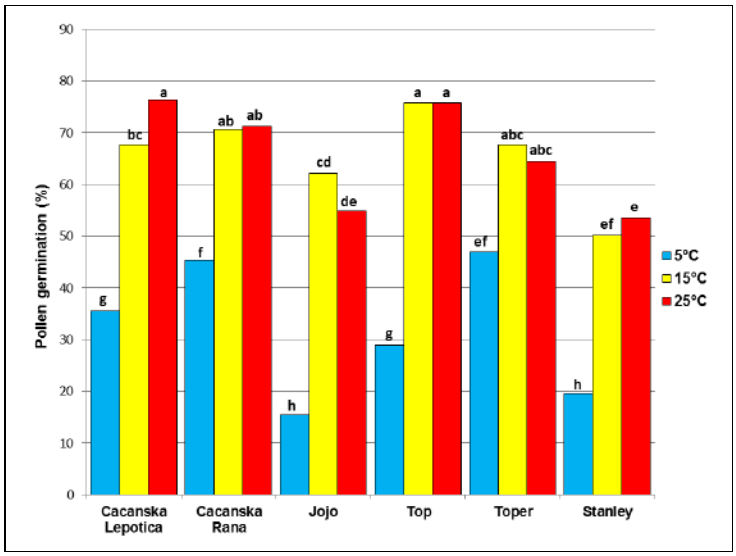

Figure 1. The influence of temperature on pollen germination of plum cultivars.

Differences between the cultivars were also significant (Table 1). Cultivars ‘Cacanska Lepotica’, ‘Cacanska Rana’, ‘Top’ and ‘Toper’ have higher germination rates (60-62% in average for all temperatures) comparing to cultivars ‘Jojo’ and ‘Stanley’ (41-44% in average).

Table 1. Analysis of variance for pollen germinatin and pollen tube length.

Source of variation	Pollen germination		Pollen tube length	
	df	Mean squares	df	Mean squares
Cultivar (G)	5	45.57**	5	2.12$^{n.s.}$
Temperature (T)	2	430.50**	2	437.91**
G x T	10	9.64**	10	1.55$^{n.s.}$
Error	36	17.07	36	125.477,4

**: statistically significant at 0.01 probability level; $^{n.s.}$ non-significant.

Cultivars ‘Toper’, ‘Cacanska Rana’, ‘Cacanska Lepotica’ and ‘Top’ had significantly higher germination rates at the temperature of 5°C compared to ‘Jojo’ and ‘Stenley’. This could point to their better adaptation to colder weather conditions during flowering.

Previous research has found that pollen germination depends on the genotype. Different authors have found great variation in the degree of pollen germination *in vitro* in European plum cultivars: Botu et al. (2002) 12-61%, Surany (2006) 25-64%, Koskela et al. (2010) 3-70%, Sharafi (2011) 46-72%, Nikolić et al. (2012) 30-67%. The results obtained in this study are within the specified values.

According to the states of Wertheim (1996) that pollen germination of 25% is considered as a threshold for satisfactory germination in plum, it can be said that the studied cultivars are characterized by good pollen germination rates. Therefore, they can be recommended as potential pollenizers for other cultivars.

The minimum length of pollen tubes was obtained in cultivar ‘Jojo’ at the temperature of 5°C and it was 127 µm, while the maximum length was obtained in ‘Stanley’ at 25°C and it was 1727 µm (Figure 2).

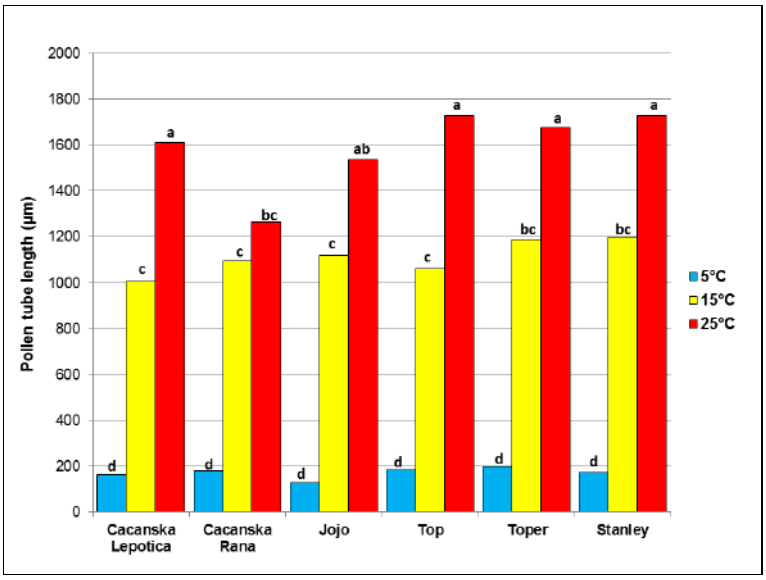

Figure 2. The influence of temperature on pollen tube length of plum cultivars.

The average values of pollen tubes length were the highest at 25°C (1589 µm), then at 15°C (1111 µm), while they were the lowest at 5°C (170 µm). The length of pollen tubes at temperature of 15°C was significantly higher than at the temperature of 5°C in all studied cultivars. Also, the length of pollen tubes at temperature of 25°C was significantly higher than at the temperature of 15°C in all cultivars, except ‘Cacanska Rana’. Differences between cultivars, as well as interaction Genotype × Temperature were not statistically significant (Table 1).

The average values of pollen tube length obtained in this study were higher than the values obtained by Sharafi (2011). Increasing of the temperature resulted in a significant increase in the length of pollen tubes, which confirms the results of previous studies (Cerović and Ružić, 1992; Pirlak, 2002; Hedhly et al., 2004; Milatović and Nikolić, 2014).

Conclusion

Temperatures of 15 and 25°C are optimal for pollen germination and pollen tube growth of European plums. However, the rates of pollen germination at 5°C were higher in some cultivars (‘Toper’, ‘Cacanska Rana’, ‘Cacanska Lepotica’ and ‘Top’) than in others (‘Jojo’ and ‘Stanley’). Therefore, these cultivars could be better adapted to the low temperatures during flowering.

The influence of temperature was more prominent on the pollen tube growth. The length of pollen tubes was six to nine times higher at 15°C and seven to twelve times higher at 25°C in comparison with 5°C. This leads to the conclusion that the temperature of 5°C, although it could be enough for pollen germination, is not enough for optimal pollen tube growth.

PHENOLOGICAL CHARACTERISTICS, YIELD AND FRUIT QUALITY OF INTRODUCED APRICOT CULTIVARS IN THE REGION OF BELGRADE (SERBIA)

Dragan MILATOVIĆ*, Dejan ĐUROVIĆ, Gordan ZEC

Faculty of Agriculture, University of Belgrade, Serbia
*Corresponding author: mdragan@agrif.bg.ac.rs

Abstract

The evaluation of ten introduced apricot cultivars originated from Romania, Bulgaria and Hungary was carried out in the region of Belgrade over a period of six years (2009–2014). Control cultivar for comparison was 'Hungarian Best'. Flowering of introduced cultivars was from two days before to two days after the control, while harvest was from 6 days before ('Neptun') to 13 days after ('Litoral'). The average yield per tree ranged from 5.7 kg in 'Kasna Drjanovska' to 12.2 kg in 'Mari de Cenad' and 'Roksana', while the average fruit weight ranged from 45.1 g in 'Umberto' to 82.0 g in 'Neptun'. Compared with the control cultivar, significantly higher yield was achieved in seven cultivars, while significantly higher fruit weight was found in six cultivars. The content of soluble solids varied from 14.2% in 'Cegledi arany' to 19.5% in 'Kasna Drjanovska'. Cultivars 'Roksana', 'Mari de Cenad', 'Gergana' and 'Neptun' stand out for fruit appearance, and 'Silistrenska kompotna', 'Kasna Dryanovska' and 'Mari de Cenad' for fruit quality. Among studied cultivars, for growing in this region 'Dacia', 'Gergana', 'Mari de Cenad', 'Neptun' and 'Roksana' can be recommended, predominantly for fresh fruit consumption. In addition, cultivars 'Silistrenska kompotna' and 'Kasna Drjanovska' can also be recommended, mostly for fruit processing.

Key words: *Prunus armeniaca*, flowering, maturing, yield, fruit, stone

Introduction

Extensive research is conducted worldwide on the creation of new apricot cultivars with improved characteristics, such as better adaptability to different environmental conditions, higher resistance to disease-causing agents, higher yield, and better fruit quality. In the last 20 years, more than 500 new apricot cultivars were created. The largest number of new cultivars was created in the United States, followed by France, Italy, Romania, China, Czech Republic and Spain (Milatović, 2013a).

Apricot cultivars have limited ecological adaptability. Thus, the leading cultivars are different in each region of production. Due to the limited adaptability, the best results in the apricot production are achieved with cultivars bred in the similar environmental conditions.

Romania is one of the leading countries in apricot breeding with more than 40 new cultivars released. Breeding has conducted in fruit research stations in Mărculești, Băneasa, Constanţa and Oradea (Cociu, 2006; Bălan et al., 2010; Topor et al., 2010). In Bulgaria, apricot breeding is conducted in Experimental Station Silistra and Fruit Growing Institute in Plovdiv (Tsoneva and Tsonev, 1995; Lyubenov, 2005; Zhivondov, 2012). In Hungary, 20 new apricot cultivars are bred, and the leading institutions are Fruit Research Station Cegled and Faculty of Horticulture, Corvinus University of Budapest (Szalay et al., 2005; Pedryc and Hermán, 2012).

The aim of this study was the evaluation of ten introduced apricot cultivars originating from Romania, Bulgaria and Hungary. The best performing cultivars will be recommended for growing in the region of Belgrade, as well as in other regions with similar ecological conditions.

Material and methods

The study was conducted in the apricot collection orchard at the Experimental Station "Radmilovac" of the Faculty of Agriculture in Belgrade during the period of six years (2009–2013). The orchard was planted in 2007. The rootstock is Myrobalan (*Prunus cerasifera* Ehrh.) seedling, training system is central leader, and planting distance is 4.5 x 3 m. All cultivars are represented by five trees.

The study included ten apricot cultivars: five from Romania ('Dacia', 'Litoral', 'Mari de Cenad', 'Neptun' and 'Umberto'), four from Bulgaria ('Gergana', 'Kasna drjanovska', 'Roksana' and 'Silistrenska kompotna') and one from Hungary ('Cegledyi arany'). 'Hungarian Best' cultivar was taken as a control.

Flowering was recorded by recommendations of the International Working Group for pollination: start of flowering – 10% open flowers, fool bloom – 80% open flowers, end of flowering – 90% of the petal fall (Wertheim, 1996). Trunk cross-sectional area (TCSA) was calculated on the basis of trunk circumference measured at the height of 30 cm above the ground level. Cumulative yield efficiency was calculated by dividing the cumulative yield over six years by the TCSA in the last year (2014). Fruit characteristics were measured on a sample of 25 fruits per cultivar. Fruit shape index was calculated using the formula: length × length / width × thickness. Soluble solids were determined by refractometer and total acids (expressed as malic acid) by titration with 0.1 N NaOH. Sensory characteristics of the fruit (appearance and taste) were evaluated by a five-member jury, scoring the cultivars using the scale from 1 to 5 points.

The obtained data were statistically analyzed using analysis of variance. The significance of differences between mean values was determined using Tukey's test at 0.05 level of probability.

Results and discussion

Average time of flowering of apricot cultivars was late March and early April (Table 1). Among studied cultivars small differences in flowering time were recorded. The start of flowering was from two days before the 'Hungarian Best' ('Litoral') to two days after the control ('Cegledi arany', 'Kasna Drjanovska', 'Umberto' and 'Silistrenska kompotna'). The longest duration of flowering was recorded in 'Neptun' and 'Roksana' cultivars.

Table 1. Phenological characteristics of apricot cultivars (average, 2009–2014).

Cultivar	Flowering dates			Duration of flowering	Harvest date	No. of days comparing to control
	Start	Full	End			
Cegledi arany	29.03.	31.03.	05.04.	7.0	10.07.	+8
Dacia	26.03.	29.03.	03.04.	7.8	28.06.	–5
Gergana	26.03.	28.03.	01.04.	6.5	05.07.	+2
Kasna Drjanovska	29.03.	30.03.	05.04.	6.4	15.07.	+12
Litoral	25.03.	27.03.	02.04.	7.8	16.07.	+13
Mari de Cenad	26.03.	28.03.	02.04.	7.2	07.07.	+4
Neptun	27.03.	30.03.	05.04.	8.7	27.06.	–6
Roksana	27.03.	30.03.	04.04.	8.0	07.07.	+5
Silistrenska kompotna	29.03.	31.03.	06.04.	7.6	13.07.	+10
Umberto	29.03.	31.03.	05.04.	7.2	14.07.	+11
Hungarian Best (control)	27.03.	29.03.	03.04.	7.0	03.07.	0

Compared to the results of Milatović (2005) obtained at the same location for the ten-year period (1995–2004) duration of flowering was shorter by 2.8 days on average. This

difference can be explained by higher temperatures during flowering season in the period of study (2009–2014).

Average time of maturity was from 27th of June (‘Neptun’) to 16th of July (‘Litoral’). Compared to the control cultivar (‘Hungarian Best’) time of maturity was from 6 days before to 13 days after. Average difference in the date of maturity between the year with the earliest harvest (2009) and the year with the latest harvest (2010) was 8 days.

The average yield per tree ranged from 5.7 kg in ‘Kasna Drjanovska’ to 12.2 kg in ‘Mari de Cenad’ and ‘Roksana’ (Table 2). Compared with the control cultivar significantly higher yields were achieved in seven cultivars.

Table 2. Yield, trunk cross-sectional area (TCSA), and cumulative yield efficiency (CYE) of apricot cultivars.

Cultivar	Yield (kg per tree)							TCSA (cm^2)	CYE (kg/cm^2)
	2009	2010	2011	2012	2013	2014	Average

* Mean values followed by the same letter within a column do not differ significantly according to Tukey’s test at $P \leq 0.05$.

In most cultivars the highest yield was obtained in 2014 when the weather conditions were favourable. The lowest yield was recorded in 2013 because of the cold weather during the flowering which resulted in low fruit set (Zec et al., 2013). The obtained results of yield are in accordance with the results of Vachůn (2002), who studied the productivity of 24 apricot cultivars during six-year period and found variation of yield from 3 to 20 kg per tree.

Trunk cross-sectional area in two cultivars (‘Silistrenska kompotna’ and ‘Kasna Drjanovska’) was significantly higher than in the control cultivar. Cumulative yield efficiency ranged from 0.26 to 0.85 kg/cm^2. With the exception of ‘Kasna Drjanovska’, in all cultivars it was higher comparing to the control.

The average fruit weight ranged from 45.1 g in ‘Umberto’ to 82.0 g in ‘Neptun’ (Table 3). Compared to the control, significantly higher fruit weight was recorded in six cultivars.

Stone weight ranged from 2.9 g (‘Dacia’) to 4.7 g (‘Mari de Cenad’), and its share in the fruit weight ranged from 4.3% (‘Neptun’) to 8.7% (‘Silistrenska kompotna’). According to the classification given by Milatović (2013b) seven cultivars had small share in the fruit weight (under 5.50%). Two cultivars (‘Umberto’ and ‘Kasna Drjanovska’) had medium share of the stone in the fruit weight (6.51–8.50%), while one cultivar (‘Silistrenska kompotna’) had high share (above 8.51%).

Table 3. Fruit characteristics of apricot cultivars (average, 2009–2014).

Cultivar	Fruit weight (g)	Stone weight (g)	Stone share (%)	Fruit dimensions (mm)			Shape index

* Mean values followed by the same letter within a column do not differ significantly according to Tukey's test at $P \leq 0.05$.

Fruit length of the studied cultivars varied from 44.4 to 57.2 mm, width from 41.9 to 53.4 mm, and thickness from 37.8 to 48.9 mm. Based on the fruit dimensions, the shape index was calculated, whose values ranged from 0.98 in 'Cegledi arany' (round flat shape) to 1.49 in 'Litoral' (elliptic shape).

Results of pomological fruit characteristics are in accordance with the previous findings for some cultivars (Cociu, 2006; Milatović et al., 2006; Korzin et al., 2010).

The content of soluble solids in tested cultivars varied from 14.2% in 'Cegledi arany' to 19.5% in 'Kasna Drjanovska' (Table 4). Cultivars 'Kasna Drjanovska' and 'Silistrenska kompotna' had significantly higher content of soluble solids than the control cultivar.

Table 4. Indices of fruit quality of apricot cultivars (average, 2009–2014).

Cultivar	Soluble solids (%)	Total acids (%)	Soluble solids /Total acids	Sensory evaluation (1–5)	
				Appearance	Taste
Cegledi arany	14.2 c	1.28 b	11.1	3.9 abcd	3.9 abc
Dacia	14.5 c	1.39 ab	10.5	3.9 abcd	4.0 ab
Gergana	15.5 c	1.25 b	12.4	4.2 abc	3.9 abc
Kasna Drjanovska	19.5 a	1.64 a	11.9	3.8 bcd	4.2 a
Litoral	14.9 c	1.66 a	8.9	3.5	3.4 c
Mari de Cenad	15.3 c	1.37 ab	11.2	4.4 ab	4.1 a
Neptun	16.1 bc	1.56 ab	10.4	4.2 abc	3.9 abc
Roksana	15.8 c	1.27 b	12.5	4.5 a	3.8 abc
Silistrenska kompotna	18.4 ab	1.35 ab	13.6	3.7 cd	4.3 a
Umberto	14.5 c	1.69 a	8.6	3.3	3.5 bc
Hungarian Best (control)	15.7 c	1.37 ab	11.4	3.6 cd	4.2 a

* Mean values followed by the same letter within a column do not differ significantly according to Tukey's test at $P \leq 0.05$.

The total acid content varied from 1.29% in ‘Gergana’ to 1.69% in ‘Umberto’. The ratio between soluble solids (consisting mostly of sugars) and acids contents indicates the sweetness of the fruit. It was the highest in cultivars ‘Silistrenska kompotna’ and ‘Roksana’ (more sweet taste) and the lowest in cultivars ‘Umberto’ and ‘Litoral’ (more acidic taste).

The data on the chemical composition of fruits are in accordance with the previous findings (Gurrieri et al., 2001; Ruiz and Egea, 2008).

Cultivars ‘Roksana’ and ‘Mari de Cenad’ stand out for attractive fruit appearance and got significantly higher scores than the control cultivar. The best scores for fruit quality got cultivars ‘Silistrenska kompotna’, ‘Kasna Drjanovska’ and ‘Mari de Cenad’. Cultivars ‘Litoral’ and ‘Umberto’ got significantly lower scores for fruit quality than the control cultivar.

Conclusion

Based on the six-year evaluation of ten introduced apricot cultivars in the Belgrade area, cultivars ‘Dacia’, ‘Gergana’, ‘Mari de Cenad’, ‘Neptun’ and ‘Roksana’ can be recommended for growing, predominantly for fresh fruit consumption. In addition, cultivars ‘Silistrenska kompotna’ and ‘Kasna Drjanovska’ can also be recommended, mostly for fruit processing.

Abstract

Alfalfa (*Medicago sativa* L.) is the most important forage plant in many regions of the world. The yield, quality and persistence of alfalfa depend on harvesting system and timely harvesting should ensure high yield and good quality of seed and forage crops and good persistence. The objective of this research was, in field conditions, in a model of dual utilization (seed, forage), to examine the effect of harvest term on the number of plants. The experiment was established in 2002 and the application of different harvesting systems started in next 5 year. The research included the first cut, as pre-cut to seed harvest, and it was harvested at different times – early harvesting, medium early harvesting, late and very late harvesting and harvesting system where two pre-cuts are harvested before seed harvest. The average number of plants decreased from 199 (second year) to 49 (in the sixth year). Growing conditions during some years and harvesting system had effect on the number of plants. In the first year of production, with denser density and extreme climatic conditions, reduction of the number of plants was greater than in the later years of exploitation and moderate conditions during the year. In the harvesting system with two pre-cuts, at the beginning there was a rapid decline in the number of plants.

Key words: *alfalfa, cutting term, plants*

Introduction

Economic importance of alfalfa is reflected in the production of high-quality forages, however, the seeds of alfalfa is valuable commodity in the domestic and international markets.Yield, quality and persistence of alfalfa depend on system of cutting (Sheaffer et al., 1988; Undersander et al., 2004). The system of cutting of alfalfa for forage production is used to harmonize the relationship between the yield of dry matter and content of nutrients in the plant to ensure maximum yield of nutrients per hectare. The system of harvesting for seed production should provide an optimal ratio of yield components of alfalfa seed. Flowering of seed crops should be in the preferable time, i.e. when the temperatures are high and the number and activity of the main types of insect pollinators the highest (Marble, 1989; Mueller, 2008).

By delaying the first cut in the system of seed production, when the second cut was used for seed production, the total energy production of NE_M and NE_L is decreased (Terzić et al., 2014). Contrary, delaying of the first cut can result in higher seed yield, when second cut was used for seed production (Karagić et al., 2007;Terzić, 2011).

Effect of harvest period on the persistence of the crop is pointed out by numerous authors (Karagić, 2004, Undersander et al., 2004, Terzić, 2011). Number of alfalfa plants is the highest in the year of establishing of crop and decreases with age. Thinning of alfalfa crop during the period of exploitation is a regular occurrence due to aging plants and effect of external factors, primarily low temperatures, heavy trampling caused by machinery, diseases and pests. In addition, the method of exploitation, i.e. the system of harvesting significantly influences the reduction of the number of plants. Too early harvesting exhausts plants, the

carbohydrate content in the root and the crown is lower than optimal, which reflects negatively on the yield and longevity of the crop (Sheaffer et al., 1988;Undersander et al., 2004).

Frequent cutting of undeveloped alfalfa (from the phase of vegetative growth to budding) or autumn cutting that prevents vegetative growth and development, as well as filling of root reserves, may lead to lower concentrations of non-structural carbohydrates in the root. This may be associated with the thinning and loss of yield. Earlier harvest will contribute to obtaining of high-quality feed, and later harvest will increase the reserves of the roots and persistence of the crop. The harvest in the fall is associated with persistence and yield (Undersander et al., 2004).

There has been lot of studies and activities worldwide focusing on the problem of finding an optimal solution in the seed production sector, however, there is no single uniform opinion. Most of the studies indicate that for each area must specific solutions must be determined.

The aim of this research is to examine the impact of different systems of cutting on number of plants in a combined mode of production (seed/forage).

Material and methods

Study was carried out on experimental field of the Institute for forage crops in Kruševac; Serbia.Size of the basic plot was 10.5 m^2. Treatments were different time of pre-cut of alfalfa seed crop: A_1- early cut (around May 5th), A_2- medium early cut (around May 15th), A_3- late cut (around May 25th), A_4- very late cut (around June 5th), A_5- cut (A5 I- around May 5th and II - around June 5th). Contrary to the harvest procedure in the A_1 to A_4 systems, where the second cut was used for seed production, in the A_5's harvest procedure the third cut was used for seed production. The final cut was done at the end of October. At the moment of cutting the plants were on average in the early system (A_1) in the stage of budding, in the medium early system (A_2), in the stage of the beginning of flowering, in the late (A_3), in the stage of full flowering and in very late system (A_4) in the stage of post-flowering. In a system with two pre-cuts (A_5), at the time of cutting, plants were in the budding stage and in final cut, plants were in various stages of intensive growth. Cutting of growth for forage was done manually at height of about 5 cm.The number of plants was determined by counting the number of plants per meter in all replications in the seed cut. The crop was established in 2002 and seed production started from the second year (2003). The number of plants was determined in the second, third (2004), fourth (2005), fifth (2006) and sixth year (2007).

Statistical processing of obtained data was done by variance analysis. Testing of the significance of differences was done by LSD test.

Results and Discussion

The number of plants (tab. 1) in the test period ranged from 205 (the second year of examination, treatment A_5) to 34 (the sixth year of treatment A_4). In the second year of life and the first year of exploitation of crop intended for seed production, the average number of plants was 199 plants m^{-2}, and there were no significant differences between treatments. In the present research, almost identical number of plants was obtained as in the results reported by Karagić (2004) 198.6 plants m^{-2} and Beković (2005) with sowing at 20 cm in the second year of study (197.3 plants m^{-2}). In the same research by Beković (2005) the variety K-28, the same inter-row distance, showed somewhat thinner structure (177.2 plants m^{-2}).

In the third year, it was registered that the number of alfalfa plants significantly decreases with age. The largest number of plants was recorded in the early harvest system (A_1) 153 plants per m^{-2}, and the lowest number of plants in the harvest system with two pre-cuts (A_5) 130 plants per m^{-2} or by 15.0% less compared to the harvest system A_1. For other systems of cutting the number of plants was uniform.

Tab.1 Impact of harvest system and the exploitation year on the number alfalfa plants m^{-2}

Year	A_1	A_2	A_3	A_4	A_5	Average
II	199	201	195	197	205	199
III	153	147	152	149	130*	146
IV	104	99	101	79*	84*	93
V	91	89	81	63**	66**	78
VI	60	58	55	34**	38**	49

* Significantly different P<0.05; ** significantly different P<0.01

In the third year, the average number of plants was 146 plants m^{-2} and it was similar to number of plants (141.9 plants m^{-2}) recorded in research by Beković (2005), and more than the number of plants (94 plants m^{-2}) reported by Karagić (2004).

The number of plants in the fourth year ranged from 79 to 104 and the average value of 93 plants m^{-2}. During the fifth year, the trend of reduction of the number of plants continued. The minimum number of plants was realized in the harvest systems A_4 and A_5 (63 and 66 plants/m^2, respectively), which was statistically significant difference compared to the other harvest periods. The number of plants decreased slower in the previous harvest systems and was the highest in the A_1 and A_2 systems.With the aging of crops, the number of crop plants decreased and the lowest was in the sixth year, average of 49 plants m^{-2}.

Considering the system of harvest, it can be concluded that the number of plants decreased from the first $A_1$to the last A_4harvest system. Particularly low was number of plants in the harvest systems A_4 and A_5 in relation to the number of plants obtained in the harvest systems A_1, A_2 and A_3.

Looking at the absolute decline in the number of plants we can see that in the third year the number of plants has declined by 53 plants m^{-2}, compared to the second year. A similar decline is recordedin the fifth relative to the fourth year, while in the fifth year the number of plants decreased by 15 plants m^{-2}, in the sixth it decreased by 29 plants per m^{-2}. It can be concluded that the year had a major impact on decline of the number of plants. In the first years of exploitation (for seed production), with denser crop structures, the decline in the number of plants was greater than in the later years of exploitation, which is confirmed by the results reported by many authors (Vučković, 1994;Beković, 2005).

The effect of the year on the number of plants per unit area can be explained as alfalfa tends to reduce the structure density with aging, but also growing conditions and harvest system during certain years had an impact on the number of plants.

In the third year in our research, the greatest decline in the number of plants was in the A_5 system (75 plants m^{-2}), which is in line with the results of Karagić (2004), in similar agro-ecological conditions in the harvest system with two pre-cuts, 20% less plants were recorded compared to the secondary system early harvest with one pre-cut. However, in the next year (fourth), the greatest decline occurred in A_4 system (70 plants m^{-2}) and A_3system(51 plants m^{-2}). Subsequently, in fifth year, the greatest decrease occurred in the A_5period of harvest (18 plants m^{-2}). In sixth year, a uniform reduction of the number of plants was recorded.

The greatest decline in the number of plants in the A_5 system of harvest in the third and fifth year was a result of more frequent cutting, i.e. cutting with two pre-cuts in the A_5 harvest system. In our research, the distance between the two harvests in the system A_5 was approximately 30 days, which is according to Undersander (2004), in terms of persistence of crops, short period.

Sheaffer et al. (1988) report that the storage and use of non-structural carbohydrates has a cyclical nature; from the decline in the early vegetative growth to a height of 20 to 30 cm,

after which the amount of carbohydrates increases with the development of plants to full bloom, but generally an adequate level is considered at the beginning of flowering.
O 'Rourke and Millar (1996),quoted by Krnjaja (2004) report that populations of *Fusarium spp*. in cases of frequent cutting, significantly increase in the rhizosphere compared to other types of fungi. The stresses in plants, such as the insufficient potassium fertilization, frequent cutting and disease, clearly affect the greater presence of *Fusarium spp*. on the alfalfaroot. Also, there is a causal link between the presence of *Fusarium spp*. and deterioration of the root crop.
The counting of the plants was carried out during the harvest of crops. In the second year, the same treatments were applied(frequent cutting in the two pre-cuts) as well as in subsequent years, but in that year there was no change in the number of plants. This indicates that the number of plants was also under the influence of autumn harvest. Seed harvest in the A_4 and A_5 system was in September, which is according to the opinion of Silkett et al. (1937)andRather and Harrison (1938) cit. Sheaffer et al. (1988), Undersander (2004), cutting in the,, critical period "in which alfalfahad not enough time to make up for reserves in the roots and thus enterthe winter period more prepared. Postponement of the first pre-cut harvest influenced also somewhat later seed crop harvest and subsequent regeneration which contributed to the reduction of yield in the autumn, confirming the lower level of development of crops with late cut. The lowest yield and crop development were recorded in the harvest system A_5. Later seed harvest contributed to the formation of lower amount of carbohydrates in the roots in the autumn, so plants, going from A_1 to A_5 system, entered winterwith lower reserves, which had adverse effect on the abundance of plants, especially prevalent in the A_5 system of harvest.
Considering the number of plants in the A_4 and A_5 systems it can be seen that in the second year the number of plants was even, and that in the third year of the A_5 system lower number of plants in relation to the A_4 (and other systems) was obtained. However, in the fourth year (2005) there was a significant decline in the number of plants in the system A_4, followed by the lowest number of plants in this system until the end of exploitation. It can also be noted that in the fourth year a significant decline in all variants occurred. Average decrease was 53 plants m^{-2} and almost identical decline which occurred in the previous year, while in the next year the average reduction of only 15 plants m^{-2} was recorded.
Undersander et al. (2004) report that excessive soil moisture in autumn interfered with acclimatization of plants and increased predisposition to winter damage**.** A major decline in the number of plants in the fourth year was likely due to the large amount of rainfall. From September 2004 to September 2005, there was 879 mm of rainfall.
Particularly pronounced was the precipitation in November 2004 and May and August 2005. During the experiment, in November 2004, even 141mm of rain was recorded, which probably contributed to plants with increased predisposition to winter damage to enter the winter period.
One of the most important pathogens that attack alfalfa and induce the shortening of life expectancy of alfalfa in Serbia is *Colletotrichum trifolii* (Vasićet. Al., 2005, Vasić2007).The major types of*Colletotrichum* attack legumes at a temperature of 18-20^{o}C and when the relative air humidity is above 90% (Lenn cit. Bailey and Jeger, 1992).The authors note that frequent grazing or cutting reduce spreading and development of inoculum and development of disease from the group of *Colletotrichum* genus.
On the other hand a greater degree of damage in winter increased the susceptibility to diseases in the subsequent year. In May 2005,precipitation amount was 104 mm, which probably favored the development of diseases of the *Colletotrichum* genus and led to diseases occurring in the late cut (A_4) when the temperature was higher, which is favourable to the development of these pathogens.

This, together with wet conditions in 2005, in addition to increased relative decline in the number of plants in relation to the previous year, resulted in lower reduction of the number of plants in variants of the earlier harvest (A_1, A_2, A_3), and in particular in the variant with two pre-cuts (A_5). Delaying first cutting in the extremely humid year 2005 probably led to the greater thinning of crops and as a result, the A_4 harvest system in 2005 realized the least number of plants.

Finally, it can be concluded that more frequent cutting and later harvesting seed in the fall, led to a greater decline in the number of plants in the A_5 harvest system. In addition, the above combination of factors, such as large amounts of rainfall during the year, especially in November and May and later first harvest have contributed to decline in the number of plants, especially noticeable in A_4 harvest systems.

Conclusions

Growing conditions during certain years and harvest system had effect on the number of plants. Number of plants declines with aging. The years of exploitation had a major impact on decline of the number of plants**.** In the first years of production, in densercrop structures and extreme climatic conditions, decline in the number of plants was greater than in the later years of exploitation and moderate conditions during the year. In a system with two harvest pre-cuts wherethe third cutwas intended for the seed production, at the beginning there was a rapid decline in the number of plants. Also, in years with high rainfall in November and May, and later first harvest,the decline in the number of plants was greater. The minimum number of plants was recorded in the production of seed,from the second harvest in the system of very late first harvest and in the system where the seed production was realized from the third growth.

LONG-TERM EFFECTS OF INCORPORATION OF CROP RESIDUES AND INCREASING DOSES OF NITROGEN ON THE MAIZE YIELD

Dragana LATKOVIĆ[1]*, Branko MARINKOVIĆ[1], Jovan CRNOBARAC[1], Janoš BERENJI[2], Vladimir SIKORA[2], Goran JAĆIMOVIĆ[1]

Abstract

Study of the effects of crop residue incorporation (CRI) combined with fertilization by increasing nitrogen (N) doses on grain yield of two maize hybrids was carried out on a long-term stationary experimental field of the Institute for Field and Vegetable Crops, established in 1971 at Rimski Šančevi, Novi Sad, Republic of Serbia. The trial involved the following variants: a) treatments with CRI plus use of increasing nitrogen doses: 0 (Ø; control variant), 60, 90, 120, 150 and 180 kg of pure nitrogen per ha, and b) treatments without CRI and using of next increasing nitrogen doses: 0, 90 and 150 kg N ha^{-1}. Grain yield obtained by the treatment with CRI on average for all variants of N-fertilization was 8.38 tha^{-1}, being for 1 tha^{-1} higher in relation to the average yield on treatments without CRI. On average, the highest yield for the both of the studied hybrids (9.09 tha^{-1}) achieved by fertilization of 180 kg N ha^{-1} with CRI, and was statistically significantly higher compared to all variants in treatments without incorporation of crop residues. Positive effects of long-term CRI to maize grain yields in comparable N-variants, depending on hybrid and doze of the applied nitrogen varied in the range of 180 to 1530 kg ha^{-1}.

Key words: *maize, crop residues, nitrogen, grain yield.*

Introduction

Crop residues present the mass of organic matter left on the field after harvest or picking of the main products. They can be used in many different ways: as animal feed, litter in livestock production, for ploughing (incorporation in the soil), for mulching, composting and preparation of artificial manure, as a material for energy production etc. If the farm does not have livestock and crop residues cannot be used as animal feed or litter, and be returned to the soil improved as manure, incorporation of crop residues has advantages in comparison to the other ways of use. They represent significant quantity of bio-mass that has extremely important role in cycling of agricultural ecosystem matters, especially under condition of insufficient use of organic fertilizers.

Fertilization with organic and mineral fertilizers has positive effect to humus content. Organic plant nutrition returns organic matter directly into the soil and by use of mineral fertilizers, increases plant aerial and root mass. It is known that incorporation of organic fertilizers and crop residues does not only improve nutritional land potential, but also water capacity, aerial and thermal soil properties as well as microbiological activity necessary for mobility of biogenic elements (*Čuvardić, 1993*).

In our fields, crop residues are often burned, causing partial or complete loss of biogenic elements. Burning of crop residues is undesirable practice prohibited by our legislation. In a long term, permanent removal of plant residues from fields or their burning is very harmful, which is reflected in nitrogen and humus loss, and destruction of living world in it. Crop residues are characterized by a relatively high content of biogenic elements essential for plant nutrition that are completely or partially lost by burning (*Latković et al., 2009*). For the purpose of organic matter increase in soil, it is necessary to increase incorporation of biomass

and crop residues by ploughing, or to apply organic fertilizers. Fate of crop residues (ploughed, burned or removed) has significant effect to the amount of nutrients that are need to be applied.

Incorporation of plant crop residues has positive effect to soil quality, primarily on organic matter content. By ploughing, plant residues are included in the process of organic matter cycling in soil, improves biological activity and structure of soil as well as water-aerial and thermal soil properties. Incorporation of hay or maize stalks into soil cannot increase the amount of humus suddenly nor rapidly – it is slow and a time consuming process, but it can improve soil structure, which is especially important for heavy soils. This enables better air and water regime, better moisture uptake and keeping, forming of the favourable structure and "biological maturity" of soil, which allows easier and better late soil cultivation, with low fuel consumption *(Malinović and Meši, 2008).*

In plant production mass of crop residues (hay, stems, leaves, and roots) can be rather large. For instance, in maize it is even up to 10 tha^{-1}, in wheat 4-6, in sunflower 4-5, in soybean about 4 tha^{-1}, and in sugar beet even 40-60 tha^{-1}. Ploughing, but not removal or burning of this mass, with combined use of organic and mineral fertilizers has effect on significant increase in nutrient content and availability, increase humus content in soil, and thus its general fertility. Application of mineral fertilizers only can partially and in short term amortize harmful effect of organic matter removal and burning of crop residues. It was established that last in last decades humus content in Vojvodina soil decreased for 0.2 to 0.81%, on average for 0.38% *(Bogdanović et al., 1993).* In trials carried out in our country and in the world, convenient effect of incorporation of crop residues to yield and its quality has been proved on increase of total nitrogen and carbon, improved soil fertility or reduction in nitrogen leaching *(Nicholson et al., 1997; Powlson et al., 1987),* and on grain yield increase *(Pracházková et al, 2002; Silgram et al., 2002; Latković et al., 2012).*

The aim of the research in this paper was to examine impact of effect of crop residues incorporation in combination with different nitrogen doses on grain yield of two maize hybrids. It was expected that the obtained results justify long-term ploughing of crop residues providing higher grain yield.

Materials and methods

Two years lasting study of the effect of crop residues incorporation (CRI) with different nitrogen fertilization doses on the yield of two maize hybrids was performed on international long-term stationary field trial (called ISDV - *Internationale Stickstoff Dauer Versuche*). The experiment began in 1971, within the series of trials of the International Commission for the study of soil fertility, at the experimental field of the Institute for Field and Vegetable crops in Rimski Šančevi, Novi Sad (Serbia). The soil on which the experiment was performed is the calcareous chernozem on loess, with slightly alkaline reaction, about 3% of humus in the upper layer, medium supplied with easily available phosphorus and well supplied with potassium. Maize is grown in three-crop rotation system (maize-soybean-wheat). Maize was planted at a row spacing of 75 cm, and the distance between plants in a row was 25 cm. The row length per plot was 7 m. Preceding crop for maize was wheat. Maize sowing was performed in optimal sowing time for conditions in Vojvodina - in mid-April in 2012 and 2013. The study presents the average results of these two years of the experiment. The trial was two factorial in randomized block design and carried out in 4 replications. The trial had nine variants, of which six were with ploughing of crop residues (CRI), and three without it. The experiment involved the following variants of nitrogen fertilization (Factor A):

a) Treatments with CRI and use of increasing nitrogen doses: 0 (Ø; control variant), 60, 90, 120, 150 and 180 kg of N ha^{-1} (each third year under maize 5 tha^{-1} of crop residues were

ploughed, with addition of 50 kg of N ha^{-1} from the mineral fertilizer (10 kg N per 1t of CR) in order to prevent nitrogen depression),
b) Treatments without CRI and with application of increasing nitrogen doses of: 0, 90 and 150 kg of pure N ha^{-1}.
As objects of investigation two maize hybrids were selected (Factor B): NS-540 and NS-6030. Application of the envisaged nitrogen doses in the trial was conducted in two occasions: ½ in autumn, before the basic tillage and ½ in spring (pre-sowing treatment of maize). In all variants, constantly the same amount of phosphorus and potassium were applied: 80 kg of P_2O_5 and K_2O ha^{-1} in autumn before the basic tillage.
The obtained results of maize grain yield in different trial treatments with and without CRI and with different nitrogen supply were statistically processed by the method of analysis of variance for two factorial *split-plot* design (statistical software GenStat v.9.1.) where statistically significant differences of treatments was tested by LSD test.

Results and discussion

Based upon variance analysis of maize grain yield in the trial (Table 1), significant impact on yield on the bases of F-test showed fertilization system (F_{pr}=0.013*) and interaction of fertilization and hybrids (F_{pr}=0.026*), while hybrids did not have more significant impact to grain yield (F_{pr}=0.184). Observation of the percentage share of individual sources of variation in the sum of total squares, indicates also that fertilization variants had the largest share in the total of yield variation (28%), followed by interaction A*B (15%), while the hybrid participated in yield variation with only 1%.

Table 1. Analysis of variance of maize grain yield

Sources of variation	Degrees of freedom	Sum of squares	Sum of squares (%)	Mean of squares	F-test	Probability of F-test (F_{pr})
Replications	3	19.137	10	6.379	3.32	/

Error	30	35.836	19	1.195	/	/
Total:	79	188.519	100	/	/	/

The achieved average grain yield for the trial in whole was 8.05 tha^{-1} (Table 2). However, grain yield obtained by the treatment with ploughing of crop residues (average for all variants of nitrogen fertilization) was 8.38 tha^{-1}, and it was for 1 tha^{-1} (i.e. for 13.55%) higher in comparison to the average for fertilization variants without ploughing of crop residues (7.38 tha^{-1}).
For the both of the studied hybrids, the highest average yield of 9.09 tha^{-1} was obtained by fertilization with 180 $kgha^{-1}$ of nitrogen with ploughing of crop residues. However, grain yield obtained in this variant was statistically significantly higher only in relation to variants in the treatment without ploughing of crop residues. The other differences between fertilization variants were not statistically significant.

Table 2. Grain yield (tha^{-1}) with different N doses in treatments with and without incorporation of crop residues

Fertilization variant (A)			**Hybrid (B):**		**Average (A):**
	No.	**Doses of N (kg ha^{-1})**	**NS-540**	**NS-6030**	
With incorporation of crop residues	1	**0**	8.24	7.51	**7.88**
	2	**60**	9.30	8.07	**8.69**
	3	**90**	8.60	7.46	**8.03**
	4	**120**	8.65	7.69	**8.17**
	5	**150**	7.85	9.06	**8.46**
	6	**180**	8.86	9.32	**9.09**
	Average:		**8.58**	**8.19**	**8.38**
Without incorporation of crop residues	7	**0**	7.23	7.33	**7.28**
	8	**90**	7.07	7.56	**7.32**
	9	**150**	6.96	8.12	**7.54**
	Average:		**7.09**	**7.67**	**7.38**
Average (B):			**8.08**	**8.01**	**8.05**
		A	B	B*A	A*B
LSD	5%	1.42	0.50	1.77	1.58
	1%	1.92	0.67	2.36	2.13

In the treatment without ploughing of crop residues, the highest grain yield of 7.54 tha^{-1} was achieved with the highest dose of the fertilizer - 150 kg N ha^{-1}, however, there were no statistically significant differences in comparison to the control and variant with 90 kg N ha^{-1}. Results of *Starčević et al. (1999)* indicate statistical and economic justification of maize fertilization by nitrogen in doses that do not exceed 120 kg ha^{-1}, which is partially in agreement with the obtained results in this work.

On average for all fertilization variants, hybrid NS 540 (8.08 tha^{-1}) did not achieve statistically significantly higher yield in comparison with hybrid NS 6030 (8.01 tha^{-1}), i.e. the yield was higher for only 70 kg ha^{-1}. On the treatment with ploughing of crop residues, this difference between hybrids was slightly higher for hybrid NS 540 (for 390 kgha^{-1}), but it was also statistically insignificant. However, in the treatment without ploughing of CR, hybrid NS 6030 (with grain yield of 7.67 tha^{-1}) achieved yields that was for 580 kgha^{-1} significantly higher in comparison to hybrid NS 540 (7.09 tha^{-1}).

Hybrid NS 540 had the highest yield of 9.30 tha^{-1} achieved by doses of 60 kg N ha^{-1} on treatment with crop residues ploughing. In this variant, the yield was significantly higher in comparison with all three doses of N on treatments without crop residues ploughing, but in relation to other doses of N on treatment with crop residues ploughing statistically significant differences were not found. Fertilization with 180 kg N ha^{-1} and with crop residues ploughing also resulted with statistically significantly higher yield compared to variants with 90 and 150 kg N ha^{-1} on treatment without crop residues ploughing.

Hybrid NS 6030 had the highest grain yield of 9.32 tha^{-1} achieved by fertilization with the highest N doses with crop residues ploughing. In this variant, grain yield was statistically significantly higher compared to the control and variant with 90 kg N ha^{-1} on treatment with crop residues ploughing, as well as in relation to the control on treatment without crop residues ploughing.

Positive effect of long-term crop residues ploughing on maize grain yield in comparable trial variants is presented in Table 3, and depending on studied hybrids and doses of the applied nitrogen, it was within limits of only 180 kg of grains for hybrid NS 6030 in variant without nitrogen fertilization, up to 1530 kg ha^{-1} for hybrid NS 540 fertilized with 90 kg N ha^{-1}.

Table 3. Effect of CRI to maize grain yield (tha^{-1})

Nitrogen rate	Crop residue (CR)	Hybrid (B)		Average
		NS-540	NS-6030	
0 kg N ha^{-1}	With CR incorporation	8.24	7.51	**7.88**
	Without CR incorporation	7.23	7.33	**7.28**
	Difference:	**1.01**	**0.18**	**0.60**
90 kg N ha^{-1}	With CR incorporation	8.60	7.46	**8.03**
	Without CR incorporation	7.07	7.56	**7.32**
	Difference:	**1.53**	**-0.10**	**0.72**
150 kg N ha^{-1}	With CR incorporation	7.85	9.06	**8.46**
	Without CR incorporation	6.96	8.12	**7.54**
	Difference:	**0.89**	**0.94**	**0.92**
Average for all 3 N doses:	With CR incorporation	**8.23**	**8.01**	**8.12**
	Without CR incorporation	**7.09**	**7.67**	**7.38**
	Difference:	**1.14**	**0.34**	**0.74**

On average for both hybrids, in control variant without nitrogen use, CRI increased grain yield for 600 kgha^{-1}; in variant with 90 kg N for 720 kgha^{-1}, while the most intensive fertilized variant with 150 kg N ha^{-1} and CRI provided the highest effect in grain yield increase - 920 kgha^{-1}.

On average for both hybrids and all three nitrogen doses, CRI increased yield for 740 kgha^{-1}; hybrid NS 540 had increase of 1140 kg, i.e. 340 kgha^{-1} for hybrid NS 6030. Table 3 shows that hybrid NS 540 in control and with use of 90 kg N ha^{-1} had significantly better reaction to CR ploughing, while the use of the highest N dose was reverse, i.e. hybrid NS 6030 gave a higher yield in comparison to NS 540.

In literature there many examples in which CRI provides identical results as well as manure application in soil properties improvement and yield height. Use of N fertilizers also significantly increases quantity of plant residues which incorporation in to the soil increases humus content and efficiency of carbon retention in the soil (*Halvorson et al., 1999*). In trials carried out in our country and in the world, beneficial effect of CR ploughing to yield and its quality has been proved (*Latković et al., 2011; 2012*).

Conclusion

Based upon results of the study on affect of growing nitrogen doses to maize grain yield in variants with or without CR ploughing, the following conclusions can be made:

Grain yield obtained in treatment with CR ploughing, on average for all nitrogen fertilization variants was 8.38 tha^{-1}, being for 1 tha^{-1} higher compared to the average in variants without CR ploughing.

On average, the highest yield for the both of the studied hybrids obtained with 180 kg N ha^{-1} with CR ploughing and was statistically significantly higher compared to variants in treatment without CR ploughing.

Positive effects of long-term CR incorporation to maize grain yields in comparable N-variants, depending on hybrid and doze of the applied nitrogen varied in the range of 180 to 1530 kg ha^{-1}.

On average for both hybrids, in control without nitrogen use, CR ploughing increased grain yield for 600 kg ha^{-1}, in variant with 90 kg N for 720 kg, while in variant with the most intensive fertilization, CR ploughing resulted in grain increase for 920 kg ha^{-1}.

Abstract

Research on efficiency of mineral nutrition of winter wheat in three production years were carried out in long-term field experiment at the Institute of Field and Vegetable Crops at Rimski Šančevi location, Novi Sad, Serbia. This paper presents the results about effects of mineral nutrition on grain yield of winter wheat in 20 different fertilization treatments with increasing rates of nitrogen, phosphorus and potassium, and agronomical use efficiency of the applied fertilizers. As expected, nitrogen had significantly highest impact on the wheat yield. The highest increase in the grain yield with one kilogram of the fertilizer used was with nitrogen (33.89 kg of grain/1 kg of N, on average for three years), followed by phosphorus (9.11 kg of grain/1 kg of P_2O_5), and potassium (3.01 kg grain/1 kg of K_2O). Agronomical N use efficiency differed depending upon weather conditions of the year, but in all analyzed years as well as on average, it had tendency to decrease if intensity of fertilization increased.

Keywords: *wheat, yield, fertilization, nitrogen, nutrient efficiency*

Introduction

It is well known that deficiency of mineral nutrients, as well as high fertilizer rates can cause reduction in wheat yield. Use of higher amounts of fertilizers than optimal provides not only economically inadequate results from the aspect of direct investments, but such rates can be also harmful for a large number of plant species and varieties (lodging and more intensive occurrence of diseases, etc.), and are a common cause of agroecosystems pollution.

Efficient nitrogen fertilization is one of the key elements for economical production of wheat, but also for protection of underground and above ground waters from pollution caused by leaching of nitrates due to excessive and inappropriate application of N *(Vuković et al., 2008)*. Efficiency of nitrogen application in winter wheat (WW) is valuable indicator of rational N-fertilization. The term "*Nitrogen Use Efficiency*" *(NUE)* has several definitions and calculation procedures, depending on the purpose of the study *(Dobermann, 2005).* In agricultural practice the most wide spread is use of *Agronomic N use Efficiency (AE_N),* based on the "method of difference" and it is determined as the ratio of the yield increase achieved by N-fertilization and used amounts of N *(Craswell and Godwin, 1984; Dobermann, 2005)*: $AE_N=\Delta GY/F_N$ *(kg grain / 1 kg N)*; where ΔGY = grain yield on the plot fertilized by nitrogen – grain yield on control plot (without N use); F_N – amount of applied N in fertilized treatment (plot). *Dobermann (2005)* states that typical values of AE_N in wheat are between 10–30 kg of grain per 1 kg of the applied N, and values >30 kg kg^{-1} are found in well organized growing systems or at low levels of nitrogen fertilization and on poor soils. *Raun and Gordon (1999)* stated that on the global level, worldwide NUE in cereal production is 33%.

Materials and methods

Research on WW mineral nutrition efficiency was conducted in a long-term stationary field trial, established in 1965 at the experimental fields of the Institute of Field and Vegetable Crops at Rimski Šančevi location, Novi Sad, Serbia. The trial is based on 4-year crop rotation

(four fields) including sugar beet, maize, sunflower and wheat. In this paper results from three years of experiment (2010/11-2012/13) are presented.

The trial was set up on a calcareous chernozem soil type, with slightly alkaline reaction (pH = 7.64), moderate content of humus (3.27%) and readily available phosphorus (15.98 mg/100 g of soil) and with high content of readily available potassium (25.64 mg/100 g of soil). The experiment was set up in 4 separate fields, where different crops were grown on different fields each year. The size of each field is 68 x 270 m and is divided into 4 replication with 20 experimental plots in every replication, meaning that every field is divided into 80 plots with randomized treatments (different NPK doses and ratios), where every plot is additionally divided into more subplots, depending on the number of varieties examined. Fertilization treatments were:

1. Control (unfertilized plot)
2. N_2
3. P_2
4. K_2
5. N_2P_2
6. N_2K_2
7. P_2K_2
8. $N_1P_1K_1$
9. $N_1P_2K_1$
10. $N_1P_2K_2$
11. $N_2P_1K_1$
12. $N_2P_2K_1$
13. $N_2P_2K_2$
14. $N_2P_3K_1$
15. $N_2P_3K_3$
16. $N_3P_1K_1$
17. $N_3P_2K_1$
18. $N_3P_2K_2$
19. $N_3P_3K_2$
20. $N_3P_3K_3$

where index number represents doses of pure active matter of each nutrient: $_1$=50, $_2$=100, $_3$=150 kg of N, P_2O_5 and K_2O per ha.

Each year standard WW cultivation practice for agro-ecological conditions in Vojvodina province was applied. The whole amount of P_2O_5 and K_2O and the half of the N dose were applied in autumn before tillage. Remaining amount of N fertilizers for WW was given in spring at topdressing and before seeding for other species in the trial. Wheat straw and harvest residues of other crops are ploughed under after harvest. In all examined years, sowing was done in optimal sowing time for conditions of Vojvodina (in October) with sowing density of 500 viable seeds per m^2, and spacing between rows of 12.5 cm. Application of pesticides was done sporadically, only if it was necessary. For investigation purpose, WW variety Zvezdana was chosen, as one of the most widespread in Vojvodina region.

Weather conditions (table 1) in 2010/11 and 2011/12 indicates that both years were moderately dry, mostly due to low precipitation amounts in March, i.e. at the beginning of spring vegetation, but also in June, during the period of grain filling and ripening. In comparison to Long-Term Average values (LTA for period 1964-2012), in 2010/11 growing season there was only 389 mm of rainfall, i.e. for 63 mm less than LTA (452 mm).

[1]LTA – Long-Term Averages (1964-2012)

In 2011/12 during WW growing season in relation to LTA, precipitations were for 87 mm lower. Average temperature conditions in these years were on the LTA level, with higher deviations in November and December, but probably without negative effects on WW. However, temperature conditions in April, period of intensive growth (stem elongation), were

slightly warmer (about 2 ºC), which in addition with dry Mart and June in 2012 could decreased WW yield in this year. 2012/13 production year was characterized by more favorable precipitation and temperature conditions during the spring part of growing season and earlier start of the vegetation period, accompanied with heavy rainfall in May and June, resulted in a significant increase in grain yield.

Results and discussion

Results in table 2 shows average WW yields and its variation to different amounts applied and ratios of NPK nutrients in 20 different fertilizing treatments in 3 analyzed years. Average WW yield in the trial was 5.68 t ha^{-1}, ranging from 2.86 to 6.94 t ha^{-1}. Average mean yield deviation per years and fertilizing treatments from the overall mean was ±1.41 t ha^{-1} i.e. average mean relative yield deviation (CV) was 25%.

The effects of fertilization on WW yield were significant in all years. Significantly lower yields in comparison to all other treatments were obtained on treatments without nutrient application (control treatment), followed by the treatments with only potassium applied (K_2 treatment), only phosphorus (P_2) and on treatment P_2K_2 (table 2).

Table 2: The effect of mineral nutrition on wheat grain yield (t ha^{-1})

*significant on the level α=0.05

Considering the effect of a *single nutrient application*, it can be concluded that N had the most significant influence on the WW yield. In average for all investigated years, by applying nitrogen only (N_2 treatment) yield increased for 2.88 t ha^{-1} (101%) in comparison to control. On treatment with only phosphorus applied (P_2), yield increased for 380 kg ha^{-1}, i.e. for 13%, while the potassium didn't have any significant effect on the yield. When these three elements were used in *dual combinations*, it can be observed that fertilization with N and P (N_2P_2) had

the significant advantage in relation to combined application of N and K (N_2K_2). However, both treatments were significantly better than the treatment P_2K_2.

The highest WW yield in the trial (6.94 t ha^{-1}) was obtained on the treatment $N_3P_3K_2$, but statistically equally high yields (α=0.05; i.e. over 6.36 t ha^{-1}) were obtained on other triple fertilizing variants with the highest or moderate N doses, regardless to amounts of P and especially K. By applying all three nutrients at moderate or high N amounts (all treatments with $\mathbf{N_2}P_xK_x$ and $\mathbf{N_3}P_xK_x$; except $N_2P_1K_1$), yield ranged from 6.59 to 6.94 t ha^{-1}, i.e. varied only 350 kg. Statistical analysis didn't show any significant differences between these treatments. Higher doses of nutrients in these cases were not economically justified.

In order to get more complete insight into the statistical significance of individual nutrients in WW mineral nutrition, simple coefficients of correlations between applied amounts of nutrients and WW yields were calculated (table 2). In all analyzed years, as well as in three years average, there was a high and statistically significant (α=0.05) correlative relationship between N application and yield (r=0.72-0.94). Significant moderate correlations (0.43-0.59) was noticed between P application and yield, while correlation between applied amounts of K and yield was found no significant ($r=0.16-0.39^{ns}$).

Nutrient efficiency in WW yield formation: Complete influence of certain nutrients on plants (nutrient efficiency) is not easy to determine because of their different effects with individual and combined application. According to *Sarić and Jocić (1993)*, with combined application of nutrients, interaction among these nutrients occurs. For this reason, single nutrient effect can't be easily and precisely determined. However, by using "difference method", i.e. by comparing yield obtained at the joint application of NPK and treatment where the one of the nutrient is omitted, approximate contribution of a missing element to yield formation could be determined. In this specific case, to determine the effect of each single nutrient to grain yield formation, method of difference between the yield achieved on treatment with balanced mineral nutrition ($N_2P_2K_2$) and dual combinations where one of the nutrient is omitted (N_2P_2, N_2K_2 and P_2K_2) was used. From the data presented in table 3, it can be noticed that the N had the highest influence on yield increase per 1 kg of nutrient applied (33.89 kg of grain/1 kg of N, on average for three years), followed with the P (9.11 kg grain/1 kg P_2O_5) and K (3.01 kg grain/1 kg K_2O). Low values obtained with K-application indicate good supply of this nutrient in soil.

Table 3: Grain yield increasing with 1 kg of nutrients applied

Years	Grain Yield (t ha^{-1})				Yield increasing with 1 kg a.m. of nutrients applied (kg grains / 1 kg nutrient)		
	$N_2P_2K_2$	**P_2K_2**	**N_2K_2**	**N_2P_2**	**N**	**P_2O_5**	**K_2O**

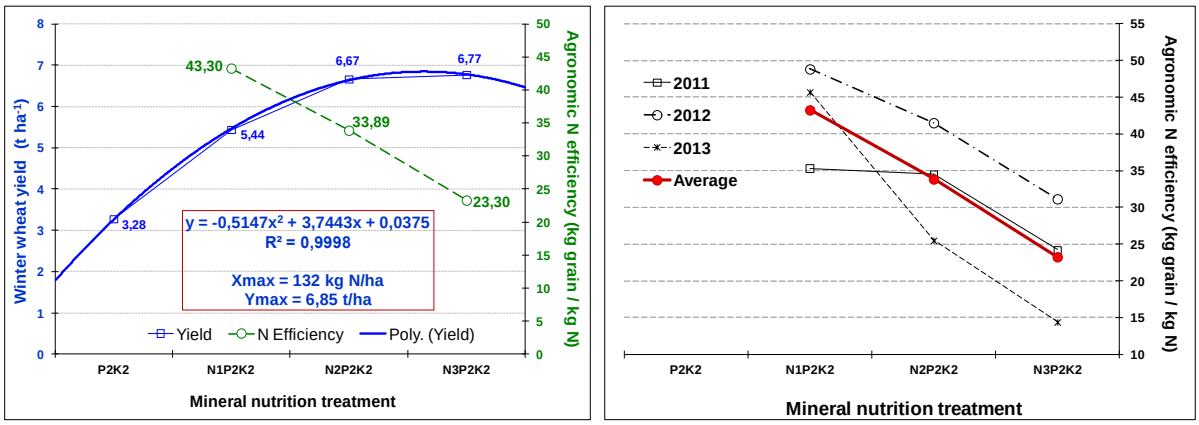
Influence of nitrogen fertilization doses on its efficiency. One of the main aims of this paper was to determine how different N fertilization levels influenced WW grain yield and nitrogen use efficiency (NUE). Determination of *„Agronomic N use Efficiency"*- AE_N (in this case effect of fertilization with increasing N doses on its efficiency) was done by the difference method, between yields on treatment $\mathbf{P_2K_2}$ (taken as control) and $\mathbf{N_1}P_2K_2$, $\mathbf{N_2}P_2K_2$ and $\mathbf{N_3}P_2K_2$. As can be seen from graph 1, average yield increase with 1 kg of N applied was the highest on treatment $\mathbf{N_1}P_2K_2$ (43.30 kg grain/1 kg N), then on treatment with moderate (33.89 kg/kg N) and the lowest on treatment with the highest N dose ($\mathbf{N_3}P_2K_2$; 23.30 kg grain/1 kg N).



Graph 1: The effects of increasing amounts of N on grain yield and yield increasing with 1 kg of nitrogen applied - agronomic N use efficiency, average results (left) and for all three years (right)

Agronomic N use efficiency differed among analysed years (graph 1, *right*). Highest AE_N values were in 2011/12 year and lower than average values in 2012/13. Differences could be partly explained by the climate conditions. In 2011/12 moisture reserve from February influenced intensive plant sorption of N applied at topdressing. Although March was dry, most N was already absorbed and more intensive absorption continued in wet April and May. In difference from this year, in extremely wet 2012/13 it is probably that the losses from N leaching were higher due to its removal to deeper soli layers.

In a specific year, as well as on average for all three years, AE_N had a decreasing tendency with increasement of N doses. The highest AE_N was on treatment with 50 kg N ha^{-1}, so this dose could be considered as the most rational in terms of lowest N losses and possible environmental pollution. However, from the aspect of joint influence on the yield of WW and nitrogen use efficiency, especially rational treatment was the one with 100 kg ha^{-1} of N applied (i.e. variant $N_2P_2K_2$).

With moderate amounts of P and K (treatments $N_xP_2K_2$; graph 1), the lowest N dose ($\mathbf{N_1}P_2K_2$) increased grain yield for 2.16 t in relation to treatment P_2K_2, which was taken as control. Next N dose increased yield for additional 1.23 t of grain, while the highest N dose (treatment $\mathbf{N_3}P_2K_2$) influenced non-significant yield increase of only 100 kg ha^{-1}. Average yield increase for every additional dose of 50 kg N ha^{-1} was 1.17 t of grain ha^{-1}. However, the first N dose influenced the most intensive yield increase compared to control, while the effect of following N doses was less expressed. Influence of increasing N doses on WW yield had the saturating effect, i.e. followed the shape of quadratic regression curve (R^2=0.99). Based on the equation of this regression, at moderate P and K doses (100 kg ha^{-1}), theoretically calculated maximum regression grain yield of 6.85 t ha^{-1} could be achieved by applying 132 kg N ha^{-1} (graph 1).

By analyzing the yield of WW during the 50 years trial period, *Kunzova and Hejcman (2009)* stated that in the fifth decade of the experiment, average yield increase per 1 kg of N applied was 18.7 kg of grain. Similarly to our results, *Vuković et al. (2008)* for conditions of Croatia found that NUE values decreasing with higher intensity of N fertilization. NUE values ranged from 9.21 kg kg^{-1} with 300 kg N ha^{-1} up to 24.13 kg kg^{-1} on treatment with 100 kg N ha^{-1}. Authors concluded that better N efficiency was at fertilization with 100 kg N ha^{-1}, which can be considered as rational amount in terms of grain yield and harmful influence on environment. Also, NUE was influenced by soli type and climatic conditions, mainly by precipitation and temperature regime during vegetation period *(Vuković et al., 2008)*. According to *Hatfield and Prueger (2004)*, NUE depended on soil moisture and N availability during vegetation. As well as in our research, *Pepó (2007)* concluded that the efficiency of fertilization was strongly modified by climatic conditions. *Ortiz-Monasterio et al. (2001), Ortiz-Monasterio (2002)* and *Raun and Gordon (1999)* stated that improvement in nutrition use efficiency by wheat can be achieved by two main strategies: application of more efficient

cultivation practices (amount and time of fertilizers application, nutrient source, etc.) and by breeding of varieties with better efficiency of nutrients applied.

Conclusion

In a 3-year investigation period, N had significantly the highest influence on the wheat grain yield. Fertilization with N only increase the yield compared to control up to 100%, while fertilization with K only wasn't statistically significant.

When nutrients were used in dual combinations, fertilization with N and P had the significant advantage in relation to combined application of N and K. However, both treatments were significantly better then the treatment PK.

The highest grain yield was obtained on treatment $N_3P_3K_2$, but statistically equally high yields were achieved on all other triple combinations with highest or moderate N doses.

The highest yield increase with 1 kg of nutrient applied was with N, then P, and lowest with K. Agronomic N use efficiency had the decreasing tendency with increasing N doses. In terms of joint influence on the yield of wheat and nitrogen use efficiency, especially rational treatment was the one with 100 kg of N ha^{-1} applied.

Abstract

Two-year survey was conducted according to the principles of organic and conventional dryland cropping technologies. Experiment was placed in Backa Topola, on calcareous chernozem with wheat as preceding crop. In ecological production basic soil fertilization was performed with 15 $t \cdot ha^{-1}$ cowshed manure, and in conventional production as pre-sowing treatment was applied 100 kg $N \cdot ha^{-1}$. In both years were similar weather conditions. Examination factors were production ways and application of microbial fertilizer. Microbial fertilizer was in liquid state and it contained various types of microorganisms. Microbiological fertilizer used in both varieties of production of sample plots in five variations: 1-control (with out specific microbiological fertilizer), 2-treat fields seven days before planting, 3-during phenological stage 1-3 leaves, 4-first flovering, 5- lots of flovering. Data were processed by two-factorial split-plot experiment variance analysis method, and differences between treatments were analyzed by LSD-test. Correlation analysis was conducted. The aim of this work was to determine protein content and oil of organic and conventional cropping technologies and correlational dependency between surveyed characteristics. Average content of protein is 39.93% in 2012 was above that figure. Analyis effected plant breeding didn't recognised regularity of examined traits. Effect of application of microbiological fertilizer on protein and oil was very significant. Average oil content was higher in the organic and by 2.32% in comparison to the conventional production. Ecological soybean production, as production system with respect of environmental principles and standards, as well as specific local agroecological conditions, has its priority.

Keywords: *conventional and organic production, protein and oil content, microbial fertilizers, soybean*

Introduction

Areas that are seeded with soya variety, partially because achieved yields and also economic conditions but it has become an important factor crop production (Dozet, 2009). Soya grain is used in the form of various to process for human consumption. Therefore it's essential for part of soya production without applying mineral fertilizers and pesticides. Soya has important economic importance, mainly due to chemical structure of grain which has the following components around 40 % proteins and 20% oil. It's used in food industry as well as in different branch industries. Soya represents "popular products" on the global market. Retailing soya is of great importance practically in processing soya as flour, soya oil etc. Therefore it is especially achieved significant cooperation between primary agricultural production of soybeans and industry. (Cvijanovic D. and Cvijanovic G., 1989). Primary microbiological fertilizers are very important factor in the manufacture of soybeans which significant impact on its growth, envelopment and productivity (Cvijanovic et al., 2013). Soybean because of high content of proteins has very high nitrogen requirements, but as leguminous plants biggest part of nitrogen provides by nitrification. Instability of soya beans

very often represents a problem in industry animal feed, because of level of proteins and oils in biggest measure depend of genotype and environmental (Westgate et al., 2000). In agriculture production one of rate targets and guidelines is integrated and organic production, this means finding alternative ways of fertilization in order to avoid the consequences of land degradation (Cvijanovic et al., 2010). The prices of organic products still are higher than average from 15% to 30% in compared with products obtained commercially producing (Dozet et al., 2013).

Target of this work was to determine the protein and oil content in organic and commercial way of cultivation and with it determine the optimal variant of application effective microorganisms in both technology cultivation which will enable getting high, stable yield good chemical composition of soybeans with rational use of nitrogen and fertilizers. I addition, paper aimed at determining correlation dependency between important surveyed feature.

Materials and methods

Field research to examine the impact of soybean growing technology and application of microbiological fertilizers on quality of soybeans and other important features was carried out on the basis of set of plot in localities Backa Topola (Serbia), on carbonate chernozem, after wheat as a previous crop during 2012 and 2013. Plot represented principle of organic and conventional growing, like as first research factor and application of microbiological fertilizers is the second research factor. Plot is set in four repeated with length lines from 5 m. Each repetition is shared on 10 large plots (5 plots for conventional and 5 plots on organic growing). For sowing were use seed soybean varieties Galina which one is early maturing varieties and belongs to the zero group of ripening and created in Institute of Field and Vegetable growing in Novi Sad. Previous crops for soybean in the previous three years were barley, corn, wheat. Previous crops not fertilized by mineral fertilizers, not used chemical protection for plants in the previous three years. On the surface of plot which is planned for organic production performed the basic fertilization by bovine manure in quantity of 15 tha^{-1}.On part of plot for conventional production for basic fertilization used 100 kg Nha^{-1}. By the manure and nitrogen also used microbiological fertilizer in liquid condition which contains mixture of different varieties microorganisms (bacteria of milk acid, photosynthetic bacteria, yeasts, actinomycetes, fungi). Sowing was performed by machines; six rowing machines in depth of 4 cm. Size of main plot is 15 m^2. Set of plants is 500.000 plants ha^{-1} . Protection crop from weeds was done by cultivating, hand digging and twitch weeds.

Microbiological fertilizer used in both ways of production per lot in five variants; 1-control (with out of used microbiological fertilizers), 2-tretment land seven days before of sowing, 3-in phonological stage 1.-3 leafs, 4-begining of flovering, 5-full of flovering. Reproduction stage, beginning and full of flovering is given in definition Fehr and Caviness (1977). Land treatment was carry out with quantity of 30 lha^{-1} microbiological fertilizer which was diluted with water in quantity of 500 lha^{-1}. It is put in land by rotary hole in depth of 10 cm. In variants with foliar applicant’s preparations was used quantity of 5 lha^{-1} microbiological fertilizer dissolved in 400 l of water.

It is applied with help of back sprayer. Harvest is done by hand, (plants taken from two central row instead of frontal plants and carefully are connected in bundles). Thrashing is done by Wintersteiger combines which is just used for soybean plots in Department of Field and Vegetable growing in Novi Sad. Threshed grain is measured, determined contains of moisture which is reduced to 13% and by this calculated yield per unit area. Contents of protein and oils in grain of soybean is stated by helping DA-700 FLEXI-MODE NIR/VIS spectrophotometer (Balesevic-Tubic et al., 2007) in Department of Field and Vegetable growing in Novi Sad. The air temperature and precipitation values are given from

Agricultural extension service, Backa Topola. Data are determinate by analysis variance according to the method two factor split –plot gate, differences between treatments tested by LSD-test. The correlation coefficients between tested properties of soybean were calculated. For statistical analysis of the results was used to program GENSTAT 9.1 (Trial Version) and Statistical 12.0.

Results and Discussion

Chemical properties of chernozem represent special value of this kind of soil (Tab. 1). $CaCO_3$ is present in this soil from its surface, but in AC and C horizon it is present in great amounts. Because of that, in humus accumulative horizon chernozem has neutral, and at greater depth weak alkaline reaction.

Table 1. Chemical properties of chernozem (Backa Topola, Serbia)

Horizons	Depth	pH		$CaCO_3$	Humus	N	mg/100g soil	
	(cm)	KCl	H_2O	(%)	(%)	(%)	P_2O_5	K_2O
A arable	0-35	7.01	8.05	1.95	2.63	0.173	11.2	20.5
A subarable	35-55	7.20	8.25	3.79	2.03	0.134	7.9	17.2

C	95-200	8.05	8.75	32.12	0.36	0.024	2.4	6.6

According to its requirements, soybean can be classified in plants which require higher temperatures and at high temperatures are well-developed, but also, soybean is resistant to short periods of low temperatures and frost. In flovering phase soybean is sensitive to low soil moisture, and o low relative humidity, especially if drought occurs at the same time with high temperatures (Sekulic and Kurjacki, 2008). In both year average month temperatures during vegetation were at the multy-year average (Fig. 1) and they were appropriate to soybean requirements during the grow and development phases. Precipitation significantly deviated from multy-year average for vegetation period from April to September. In 2012 precipitation sum was lower for 24.4 % (82.1 $l.m^{-2}$), and in 2013 it was higher for 43.5 % (146.4 $l.m^{-2}$) compared to multy-year average. However, precipitation distribution was better in 2012 because there were more precipitation in July compared to 2013 and multy-year average. Then soybean was in flovering phase and pod formation, when soybean needs the most the soil moisture. Too much water in stages from germination to flovering, as it was the case in 2013, plants form big aboverground mass and relatively shallow root system, which reduced plant’s resistence to drought. For soybean it is often more important distribution of precipitation than its sum during vegetation (Dozet, 2006, 2009, Djukic, 2009). Average relative humidity significantly deviated from multy-year average and in 2012 it was just 55 %, while in 2013 it was 63 %. Relative humidity wasn’t favorable for soybean in its reproductive phases.

An amount of average contents proteins is 39.93%, in conventional production was higher than in organic cropping system (Tab. 2). Influence of treatment by different technology in production of soybean was not showed regularity in measured values. They don’t have common statistical differences. Using microbiological fertilizers shows significant impact in contents of proteins in grains. In 2012 highest contents of proteins was registered on 4.

variants and it was very important in comparing with other variants, instead of 5. Variants. In 2013 on 5. Variants determined the lowest percentage of proteins in soybean grains in compare with control of rest of tested variants and by highest level of statistic relevancy. Measured average oil content which is 21.33%, but in 2012 was lower (21.11%) in compare in 2013.year (21.56%). On average for both years recorded highest percentage in soybean grains which was in organic productions (21.58%). For 2.32% higher than conventional productions (21.09%) (Tab. 2). In first researching year wasn't been significance differences in tested between applied growing technology.

However in 2013 significantly higher contents of oil recorded in organic productions and it is for 5.02% in compare with conventional productions. In research Djukic et al. (2015) using of microbiological fertilizer (effective microorganisms) fortified significant increased microbiological activity, fortified a higher total number of microorganisms and Azobacter in compare with control.

$p<0.05$* $p<0.01$**

Number of pods (PN) was in a very positivley correlation in number of grains (GN), and number of grains (GN) with plant height (PH) (Table 3). Yield (Y) was in a strong correlation between mass of grain (GW) and contains protein (P), but it was calculated a strong negative correlation between number of grains (GN) and weight of 1000 grains (W1000), such as and between grain yield (Y), hawever contains protein (P) and oil in grain (O) (-0.85 and -0.93). Similar results got Djukic (2009), Dozet i sar. (2014).

Conclusion

Application of growing technology not significant effect in contains of protein and oil in grain of soybean. These properties are conditioned by the genetically. Using of microbiological fertilizer has been significant impact depending on the time of using. But is not recorded appropriate regularity, and because of it plot required repeat on some or different region. Correlative dependence between important tested properties was been statistically important.

Ecological soybean production, as production system with respect of environmental principles and standards, as well as specific local agroecological conditions, has its priority.

Aknowledgement

Abstract

Crop sequences in crop rotation can be very important factor and can influence on different parameters. In this paper we compare two type of three-crop rotation with different crop sequence. We would like to find out on which way crop sequence influence on LAI, maize height and grain yield.

Experiment was set up 2009 on Maize Research Institute “ZemunPolje”. First crop sequence was wheat-soybean-maize (WSM) and second was soybean-wheat-maize (SWM). Difference between two crop rotations was only previous crop of maize and in first rotation it was soybean and in second it was wheat. We have sown hybrid ZP 606. In both crop rotation we had herbicide treatment: with herbicide application (B1) and without herbicide application (B2), it was weedy check. We measured LAI, maize height and grain yield.

In 2012, LAI and grain yield were higher in SWM then in WSM rotation in all treatments. Only, maize height was higher in WSM in weedy check in comparison with SWM rotation in same treatment, but it was not statistically significant.

Soybean-wheat-maize rotation is much better for achieving higher growing parameters and grain yield of maize. Always should sow wheat as previous crop for maize, because wheat as narrow crop, decreasing negative influence of weeds, insects and other pests.

Key words: *maize, crop rotation, LAI, grain yield.*

Introduction

The application of the crop sequence, and therefore the crop rotation, has positive effects on physical, chemical and biological properties of soil (Aziz et al., 2011). Moreover, soil is less compacted (Seremesic et al., 2008), and weed infestation can be reduced (Dolijanovic et al., 2011). Today, the crop sequence is one of important cropping practices, due to which optimum maize yields can be achieved without adverse effects on environments (Pop et al., 2009).

Various effects on crops can be achieved by the application of the certain growing system. Since more intensive cultivation of legumes, first of all of soybean, was initiated, a new type of crop sequence (maize-soya bean-wheat) has been applied. The presence of plants belonging to the family *Fabaceae*significantly contributes to the efficiency of the crop rotation, because the maize grain yield has been increasing, while the application of nitrogen fertilisers has been decreasing (up to 50%), which is a significant saving, and is important for soil conservation (Videnovic et al., 2007). Therefore, long-term crop rotations that include legumes are much more agronomical acceptable than the short-term crop rotations (Stranger and Lauer, 2008).

Three crop rotation, where are rotating maize, wheat and soybean have two type of crop sequences. In one soybean is previous crop for maize and in second wheat is previous crop. The role of previous crop is significant for maize (Idikutand Kara, 2011).These crops leave different amount of nutrients and weed seeds in soil, so that can influence on productivity of maize. If we have enough amounts of nutrients in soil and if they are well distribute and balance it will help to achieve higher leaf area and grain yield (Milosev et al., 2002). Higher

value of leaf area index (LAI) in early stage of development directly influence on grain yield increasing (Thornley, 2000).Increasing and improving of maize grain yield depend on increasing of harvest index and crop biomass (Sinclair, 1998). But, relation between leaf area and grain yield can vary depend of biotic and abiotic factors and can make problem to understand their interaction (Milosev et al., 2008).
Height of plants can be very important factor for prediction of grain yield. Relation between maize height and grain yield are in very strong positive correlation in stage when upper maize leaves are completely developed (Liu and Wiatrac, 2011).Cob height and plant height are in positive correlation with grain yield of maize (Golam et al., 2011).
So the aim of this paper was to investigate influence of different crop sequences on LAI index, height and grain yield of maize.

Material and methods

The experiment was set up at experimental field of Maize Research Institute ZemunPolje Belgrade (44° 52' 00" N 20°19' 00" E)in 2009. We investigated influence of three-crop rotation with different crop sequences. First crop sequence was soybean-wheat-maize rotation (SWM) and second was wheat-soybean-maize rotation (WSM). In first year (2009) and fourth year (2012) of experiment on both plots we sown maize hybrid ZP 606. In both crop rotation, we had herbicide treatment: with herbicide application (B1) and without herbicide application (B2), it was weedy check. We measured LAI, maize height and grain yield. In this paper we show results of maize from first year (2009) and after first rotation (2012) of maize, soybean and wheat in two different crop sequences.
Weather conditions were completely different in these two years (Table 1). In 2009, average monthly temperatures were lower in Jun, July and August with much more precipitation than in 2012, so on all measured parameters were lower in 2012 than in 2009. This 2012 year was very unfavorable for maize production.

Table 1.Average monthly temperatures and sums of precipitation in 2009 and 2012 in ZemunPolje.

Months	**Monthly temperatures**		**Sums of precipitations**	
	2009	**2012**	**2009**	**2012**
March	8.6	10.1	63.5	2.8

Jun	21.2	24.6	153.0	13.9
July	24.0	27.1	79.6	39.4
August	24.1	26.2	44.8	4.0
September	21.1	22.1	4.6	31.4
October	13.8	15.4	101.8	52.5
Average/Sum	**18.6**	**19.7**	**487.9**	**338.2**

Results and Discussion

If plant achieve LAI of 3.5-4.0 m^2/m^2 till tasseling stage, potentially yield mostly increasing (Jones, 2002). Higher leaf area of maize, make possible better using of sun light and so increase grain yield of maize (Ammanullah et al., 2009).
The plant height depends on the sowing density and rates of applied nitrogen fertilisers. According to results obtained by Hassan et al. (2000) the greater sowing density was the greater plant height, internode length and the ear height were. Between the plant height and

the grain yield of maize exist positive relationship (Spasojevic et al., 2013). Crop rotation has positive effect on increasing of LAI, height and grain yield of maize (Spasojevic, 2014).
Based on results from first year of experiment (2009), LAI, height and grain yield had, more or less, same values in WSM and SWM crop sequences (Table 2). But after first rotation of maize, soybean and wheat (2012), mostly we got higher values in SWM in B1 and B2 treatment with herbicide then in WSM rotation (Table 2). In SWM rotation, LAI was higher 0.92 m^2/m^2 (B1) and 0,33m^2/m^2 (B2) in comparison with WSM rotation. In B1, maize plants were higher in SWM, in average, for 21.7 cm, but in B2 plants were higher in WSM rotation for 3.3 cm. And finally, higher grain yield we achieved in SWM rotation, in average, for 1.09 t/ha (B1) and for 0.04 t/ha (B2) than in WSM, respectively.

Table 2. Influence of crop sequences on LAI, height and grain yield of maize

Quantity of herbicides	2009		2012	
	SWM	WSM	SWM	WSM
LAI (m^2/m^2)				
B1	3.76	3.78	3.90	2.98
B2	2.62	2.97	2.24	1.91
Height (cm)				
B1	253.5	246.5	197.5	175.8
B2	214.3	235.0	142.3	145.6
Grain yield (t/ha)				
B1	14.34	14.00	6.97	5.88
B2	12.32	13.98	4.15	4.11

	LAI	Height	Grain yield
$LSD_{0,05}$	0.42	7.1	0.56

All these differences between SWM and WSM, were statistically significant in B1 treatment, but in B2 we did not have statistically significant differences. That we have had better weather condition, maybe we have got bigger differences, especially in B2 treatment, and they have been statistically significant.
One of the most important reasons, why we got these results, can be previous crop, because all the other cropping practices are same. In SWM rotation wheat was previous crop for maize and in WSM rotation soybean was previous crop. The same results were got Bly et al. (2004) who were investigated influence of tillage method and previous crop on height and grain yield of maize. Mean corn plant heights following wheat were significantly taller when compared to soybeans as the previous crop and corn grain yield means were less following soybeans compared to wheat. These could be due to storage of more soil moisture after wheat compared to soybean, especially since the wheat was not harvested. Sims (2007) concluded that wheat is much better previous crop for sugar beet and he found out that when sugar beet is grown after a crop of soybean, root yields were still greater than when following corn but, less than following wheat. The findings of this research indicate that growing sugar beet after a wheat crop is consistently the better rotation of the three previous crops tested (wheat, soybean and maize). Wheat and other small grains species, achieved increasing in soil organic matter resulting in improved soil structure and increased water infiltration, disruption of pest cycles, and the addition of growth-promoting substances (Dogan and Bilgili, 2010).
Beside it, wheat can decrease weed infestation for following crop. Wheat as preceding crop, alongside with herbicides applied during the growing season as well as glyphosate-based herbicides applied to stubble fields after wheat harvest, greatly contribute to the reduction of weed infestation of maize as the following crop (Spasojevic et al., 2014). Wheat seedlings and

straw have allelopathic effects on the increase of weed plants (Wu et al., 1998). Small grains due to a higher growing density can suppress many weeds, particularly some perennial species, resistant to other control measures (Stefanović et al., 2011).

Conclusion

With application of soybean-wheat-maize crop sequence is possible to achieve higher maize plants, leaf area and grain yield than with application of wheat-soybean-maize crop sequence. Wheat is much better previous crop in comparison with soybean for maize production, because forming better soil conditions, leaving less weed seeds and reproductive organs and higher quantity of growth-promoting substances. We must take into consideration that in this experiment finished only one rotation and for precise results is necessary done few rotations, so we will continue with this experiment.

PHYSICAL ATTRIBUTES OF PLUM FRUIT AT PHYSIOLOGICAL AND HARVEST MATURITY

Ivan GLIŠIĆ*, Tomo MILOŠEVIĆ, Radmila ILIĆ

Faculty of Agronomy, Universtiy of Kragujevac, Čačak, Serbia
*Corresponding author: glishoo@yahoo.com

Abstract

During 2011 and 2012, differences in the physical properties of fruit at physiological maturity vs. harvest maturity were evaluated in nine plum cultivars (‘Boranka’, ‘Čačanska Rana’, ‘Čačanska Lepotica’, ‘Valerija’, ‘Timočanka’, ‘Čačanska Najbolja’, ‘Čačanska Rodna’, ‘Stanley’ and ‘Mildora’) grown in high density planting system under the environmental conditions of Čačak. In addition to recording the dates of the two maturity stages, the study involved measurement of fruit weight, three fruit linear dimensions (length, width, thickness) for fruit volume and shape index calculation, and soluble solids content (SSC). Results showed that harvest maturity in the tested cultivars occurred 6.28 days after physiological maturity. The number of days from physiological maturity to harvest maturity varied between 2.5 in ‘Čačanska Rana’ to 9 in ‘Čačanska Lepotica’ and 9.5 in ‘Čačanska Najbolja’. During this period, fruit length increased by 6.39%, width by 7.03% and thickness by 5.58% on average. When analysed across cultivars, the highest increase in fruit length, width and thickness was observed in ’Čačanska Najbolja’ (12.72%; 17.16% and 14.98%, respectively). Fruit shape index did not significantly change between the maturity stages. The average increase in fruit weight and volume was 18.24% and 16.81%, respectively, with the measured values ranging from 5.65% and 6.39% (‘Valerija’) to 41.08% and 29.69% (‘Čačanska Najbolja’). SSC in plum fruit was 12.26% higher at harvest maturity than at physiological maturity. The lowest increase in SSC was found in ‘Čačanska Rana’ (6.26%) and the highest in ‘Timočanka’ (22.89%).

Key words: *plum, physiological maturity, harvest maturity, fruit properties*.

Introduction

The plum (*Prunus domestica* L.) is the most common fruit crop in Serbia. Its fruits are used fresh, processed and dried (Milošević and Milošević, 2012). The fruit has a high water content, and also holds carbohydrates, fibre, pectin, organic acids, minerals, tannins, colouring matter, enzymes and vitamins. The predominant sugards include sucrose, glucose and fructose (Forni et al., 1992), and malic, tartaric and citric acids are the predominant organic acids. Physical and chemical attributes of plum fruits differ across cultivars, environmental conditions and growing methods (Nergiz and Yildiz, 1997; Usenik et al., 2008). Moreover, differences are also largely dependent on the degree of fruit maturity and harvest date (Nunes et al., 2009; Singh et al., 2009). Internal and external fruit quality parameters change during fruit ripening (Unuk et al., 2011). Understanding changes in the physical and chemical properties of the plum fruit during ripening i.e. from physiological maturity to harvest maturity, is of high importance in determining the optimum harvest time. Harvest time also causes substantial postharvest changes in fruit properties and affects fruit storage life (Taylor et al., 1995). Consumer acceptance of a plum cultivar is mostly related to its fruit weight and fruit physical and organoleptic attributes (Crisosto et al., 2007).

The objective of this study involving nine plum cultivars was to determine changes in major physical properties of the fruit at both physiological and harvest maturity.

Material and methods

The orchard trial with nine plum cultivars was established at the village of Gornja Gorevnica near Cacak (43°53'N latitude; 20°21'E longitude; 390 m a.s.l.), Western Serbia. Trees were planted in High Density Planting (HDP) at a spacing of 4 m × 2 m (1.250 trees ha^{-1}) and trained to the Spindle Bush system. Orchard management was consistent with standard practice for HDP, except irrigation. Summer pruning was used. In addition, climatic conditions in both years were similar.

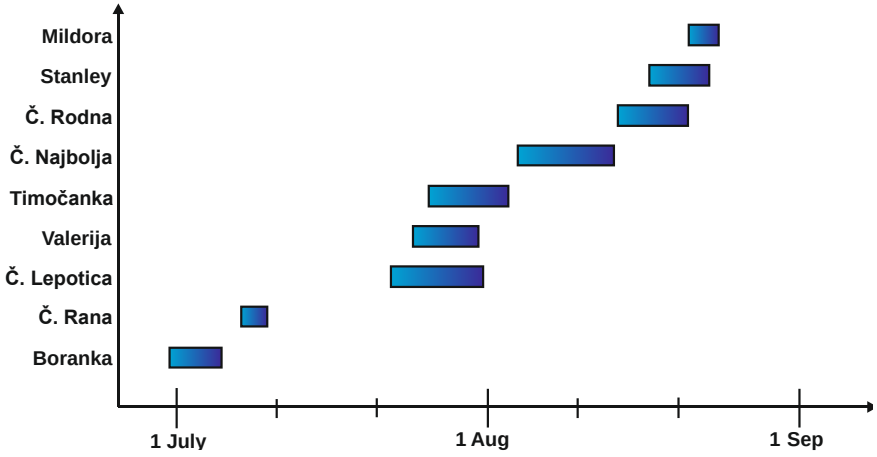
During 2011 and 2012, the research involved the following plum cultivars: 'Boranka', 'Čačanska Rana', 'Čačanska Lepotica', 'Valerija', 'Timočanka', 'Čačanska Najbolja', 'Čačanska Rodna', 'Stanley' and 'Mildora'. The Čačak area is well-known for plum cultivation. The tested cultivars (except 'Stanley') were created at the Fruit Research Institute, Čačak, and are the most common plum cultivars not only in the Čačak area but also in Serbia and other countries in the region.

In both years, dates of fruit physiological maturity and harvest maturity were recorded. Physiological maturity and harvest maturity were identified using the method specified by Crisosto 1994) and UPOV (2002). Fruit linear dimensions (length, width and thickness) were measured using an electronic digital caliper (WOMAX – Germany). Based on fruit length, width and thickness, the fruit shape index was calculated using the expression: Fruit Shape Index = $Length^2$ (Width × Thickness)$^{-1}$. Fruit volume was measured as follows: A graduated cylinder (PolyLab, 1000 ml) was filled with water to a certain level. The fruits were placed into the water one by one and their volume read as the equivalent of the difference in the water level in the cylinder before and after the fruit was submerged. Fruit weight was measured on a KERN FCB technical balance (Kern & Sohn GmbH, Belingen, Germany), weighing range 6100 g, accuracy ±0.2 g. The fruit juice produced by crushing and squeezing the fruit was analysed for soluble solids (^{o}Brix) using an MT 032 ATC manual refractometer (Turoni & C., Forlì, Italy). All measurements were made in 3 replicates with 10 fruits per replicate.

Statistical analysis and testing for the significance of differences were performed by the analysis of variance and the LSD test at $P \leq 0.05$, respectively, using the ANOVA statistical software (SPS Statistica, Software 5.0).

Results and discussion

The results on the difference between physiological and harvest maturity dates for plum cultivars are presented in Graph 1. The graph shows average values for 2011 and 2012.



Graph. 1. Physiological and harvest maturity dates for plum fruits

On average, harvest maturity of the fruit occurred 6.28 days after the physiological maturity date. Shorter than average intervals were observed in 'Boranka', 'Čačanska Rana',

‘Valerija’, ‘Stanley’ and ‘Mildora’, and longer periods in ‘Čačanska Lepotica’, ‘Timočanka’, ‘Čačanska Najbolja’ and ‘Čačanska Rodna’. The shortest period between physiological maturity and harvest maturity was registered in ‘Čačanska Rana’ and ‘Mildora’ (2.5 and 3 days). In contrast, the highest number of days from physiological maturity to harvest maturity was in ‘Čačanska Lepotica’ and ‘Čačanska Najbolja’ (9 and 9.5 days). Although fruit skin colour is not a realiable indicator of maturity (Walkowiak-Tomczak et al., 2008; Unuk et al., 2011), it is among the major indicators of physiological maturity. As confirmed by the present study, the fruits of ‘Čačanska Lepotica’ and ‘Čačanska Najbolja’ typically turn blue very early and enter the stage of physiological maturity relatively early (Milošević, 2002).

The length, width and thickness of plum fruit at both physiological and harvest maturity in the tested plum cultivars are given in Table 1.

The different lowercase letter(s) in columns indicate significant differences among means within each cultivar at $P \leq 0.05$ by LSD test. PM = physiological maturity; HM = harvest maturity; D = difference between harvest maturity and physiological maturity (%)

The analysis of variance showed a very significant effect of cultivar on differences in fruit length, width and thickness between physiological and harvest maturity stages. Fruit thickness was also significantly affected by year as a variability factor.

The greatest change in fruit length and width between physiological and harvest maturity stages was observed in ‘Čačanska Najbolja’, ‘Timočanka’ and ‘Čačanska Lepotica’, whereas ‘Čačanska Najbolja’, ‘Stanley’ and ‘Čačanska Lepotica’ exhibited the greatest change in fruit thickness. The highest increase in fruit length, width and thickness was found in ‘Čačanska Najbolja’ (12.72±0.5%, 17.16±1.1% and 14.98±1.1%, respectively). The smallest change in fruit length and thickness between physiological and harvest maturity stages was exhibited by ‘Boranka’ (2.83±0.1%, 0.88±0.1%, respectively), and the smallest change in fruit width by ‘Mildora’ (0.65±0.1%). Apart from these cultivars, ‘Čačanska Rodna’ also showed small changes in fruit linear dimensions between physiological and harvest maturity stages. The findings also suggest that the cultivars that produce small sized fruit (‘Čačanska Rodna’ and ‘Mildora’) and those that went through a short period between physiological maturity and harvest maturity (‘Mildora’ and ‘Boranka’) exhibited a smaller increase in fruit length, width and thickness during the period. In contrast, the cultivars that produce large sized fruit ‘Čačanska Najbolja’, ‘Timočanka’ and ‘Čačanska Lepotica’ showed the highest increase in fruit length, width and thickness. Although producing large sized fruit, ‘Čačanska Rana’ exhibited no significant increase in fruit dimensions due to the very short period between physiological and harvest maturity stages.

Plum cultivars generally attain maximum fruit dimensions at full i.e. harvest maturity, when they also exhibit their cultivar-specific characteristics (Ionica et al., 2013). This finding was confirmed by the present study.

Changes in the fruit shape index, fruit volume and fruit weight in plum cultivars between physiological and technological maturity stages are presented in Tab. 2.

A×B			**			ns			ns

The different lowercase letter(s) in columns indicate significant differences among means within each cultivar at $P \leq 0.05$ by LSD test. PM = physiological maturity; HM = harvest maturity; D = difference between harvest maturity and physiological maturity (%)

In terms of the fruit shape index, very significant interactions were observed between cultivar and year. Overall, no significant changes in the fruit shape index were found between physiological and harvest maturity stages.

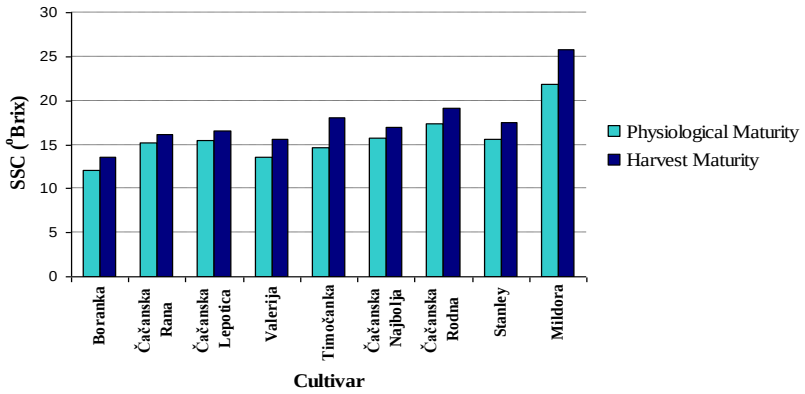
As for the change in fruit volume and weight, the analysis of variance revealed a highly significant effect of cultivar.

Fruit volume between physiological and harvest maturity stages increased in all plum cultivars. The highest increase was in ‘Čačanska Najbolja’ (29.69±2.0%), followed by ‘Čačanska Lepotica’ (26.81±1.3%) and ‘Timočanka’ (26.51±1.1%), and the lowest in ‘Valerija’ (6.39±0.7%), ‘Boranka’ (6.81±0.2%) and ‘Čačanska Rodna’ (6.89±0.2%).

A similar pattern was observed in fruit weight. The highest increase in fruit weight between physiological and harvest maturity stages was, as with fruit volume, in ‘Čačanska Najbolja’ (41.08±2.7%), followed by ‘Čačanska Lepotica’ (34.18±2.7%) and ‘Timočanka’ (24.50±1.1%), and the lowest in ‘Valerija’ and ‘Boranka’ (5.65±0.4% and 6.91±0.3%, respectively).

Changes in fruit weight occur even after harvest depending on storage conditions and length of storage (Khan et al., 2013). Nevertheless, fruit weight undergoes the most substantial change during the last several days to its full i.e. harvest maturity (Milošević, 2002), which was confirmed by the present results.

Changes in soluble solids content of plum fruit at physiological and harvest maturity are presented in Graph 2.



Graph. 2. Soluble solids content of plum fruit at physiological and harvest maturity

In all tested cultivars, the average increase in the fruit soluble solids content between physiological and harvest maturity was 12.26±1.1%. The highest increase was in ‘Timočanka’ and ‘Mildora’ (22.89±1.4% and 18.21±0.3%, respectively), and the smallest change in ‘Čačanska Rana’ and ‘Čačanska Lepotica’ (6.26±0.4% and 6.99±0.5%, respectively).
Fruit maturity can be defined as the stage of development giving minimum acceptable quality for the ultimate consumer (Crisosto, 1994). Soluble solids content is a very important parameter in identifying the optimal harvest ripeness of fruit (Usenik et al., 2014), and it shows signficant differences both across cultivars and in the same cultivar during fruit ripening. Certain cultivars can attain some cultivar-specific traits (colour) much before they reach an adequate soluble solids content (Unuk et al., 2011). This result was confirmed by the present findings.

Conclusion

The results presented in this study suggest the following:
The number of days from physiological maturity to harvest maturity varied between 2.5 in ‘Čačanska Rana’ to 9.5 in ‘Čačanska Najbolja’.
During the period, the highest increase in fruit linear dimensions (length, width and thickness) was observed in ‘Čačanska Najbolja’, and the lowest in ‘Boranka’ and ‘Mildora’. The fruit shape index did not significantly change at harvest maturity compared to physiological maturity. Fruit volume and fruit weight exhibited the highest increase at harvest maturity in relation to physiological maturity in ‘Čačanska Najbolja’, ‘Timočanka’ and ‘Čačanska Lepotica’, whereas the lowest increase was measured in ‘Valerija’ and ‘Boranka’. As for the change in the soluble solids content, the highest increase was found in ‘Timočanka’ and ‘Mildora’, and the lowest in ‘Čačanska Rana’ and ‘Čačanska Lepotica’.

Abstract

This paper presents the results of a three-year study of ripening time and major physical and chemical properties of fruits of six promising plum (*Prunus domestica* L.) hybrids created at the Fruit Research Institute, Čačak. One of these hybrids was released as a new cultivar and was named ‘Nada’. The cultivar ‘Čačanska Lepotica’ served as the standard. The genotypes under study ripened between 29 July (hybrid 38/62/70) and 2 September (hybrid 22/17/87). An elongated fruit shape, a yellowish-green flesh colour and a firm fruit prevailed, whereas violet blue and dark blue skin colours were equally present. Fruit weight ranged from 26.96±0.68 g (22/17/87) to 56.92±2.87 g (38/62/70), with higher values obtained in 38/62/70 and the new cv.‘Nada’, compared to the standard. The highest flesh/stone ratio was found in hybrid 38/62/70 (96.91±0.19%), which was the only significantly higher result compared to the control cultivar. The highest soluble solids content was measured in hybrid 22/17/87 (17.01±0.96%), and the lowest in hybrid 38/62/70 (11.39±0.44%). Compared to the standard, higher values of soluble solids were exhibited by ‘Nada’ and hybrids 32/21/87, 34/41/87 and 22/17/87. Total acid levels were highest in hybrid 32/21/87 (1.42±0.05%), and lowest in ‘Nada’ (0.35±0.02%). Compared to the standard, higher levels were found in fruits of hybrids 38/62/70, IV/63/81 and 32/21/87. The ratio of soluble solids to total acids was highest in ‘Nada’ (43.72±1.47) and lowest in hybrid 32/21/87 (10.25±0.58). Compared to the control cultivar, higher values of this parameter were observed in ‘Nada’, and hybrids 34/41/87 and 22/17/87. The results of this research suggest that ‘Nada’ can be singled out among the tested genotypes as having the best combination of positive traits.

Key words: plum, hybrid, cultivar, fruit properties

Introduction

Breeding of continental fruit species has been developed in continuity at the Fruit Research Institute in Čačak, since its establishment in 1946, to date (Ogašanović *et al*, 1996). The most prominent achievements and the best results belong to the domestic plum (*Prunus domestica* L.). During the period spanning over six decades, 15 plum cultivars have been created (Paunović *et al.,* 2011). The initial breeding objectives were governed by the imperative to create table cultivars and cultivars with combined properties (Ogašanović *et al.,* 2006). Further expansion of breeding objectives went in the direction of developing resistance to the Plum Pox virus (Ranković *et al*., 1994), enhancing the level of adaptability to the conditions of temperate climate, regular and high cropping, harmonic taste, good transportability of the fruits and their multi-purpose utilisation value (Milenković *et al*., 2006). The initial selection of promising hybrids from the population of hybrid seedlings was performed based on analysis of their most significant biological and pomological properties after the start bearing, for three consecutive years. Further selections were performed among promising hybrids, based on results of many-year comparative studies involving best standard cultivars, aiming to select the genotypes with the best combinations of positive properties.

The aim of this study pertains to analysis of the most important biological and pomological properties of six promising plum genotypes that were created within different breeding programmes, through comparative studies involving cultivar ‘Čačanska Lepotica’.

Material and methods

The experimental research was conducted at the plantation of plum of the Fruit Research Institute in Čačak, located at approximately 4 km to the north of Čačak, at the altitude of around 250 m above the sea level. The plantation was set up in spring 2002, using standard one-year-old seedlings grafted on a Myrobalan rootstock and planted at the 6 x 5 m distance (333 trees per ha^{-1}). The planting was performed using the random block system, with each genotype participating with 15 trees in three replications. The open vase crown was chosen as the training system, and the plantation was treated using standard cultivation measures. The research was conducted during three years (2009–2011). The testing material comprised six promising plum genotypes created at the Fruit Research Institute in Čačak: hybrid 38/62/70 (‘Hall’ × ‘California Blue’); hybrid IV/63/81 (‘Large Sugar Prune’ × ‘Scoldus’); hybrid 32/21/87 (‘Stanley’ × ‘Scoldus’); hybrid 29/29/87 (‘Stanley’ × ‘Scoldus’); hybrid 34/41/87 (‘Valjevka’ × ‘Čačanska Lepotica’) and hybrid 22/17/87 (‘Čačanska najbolja’ × ‘Zelta Boutilcovidna’). Hybrid 29/29/87 was approved as a cultivar in March 2012 and was named ‘Nada’ (Ogašanović *et al*., 2012).

The respective dates of full technological ripeness were monitored and recorded, in order to establish the fruit ripening time. The fruit weight (g) and stone weight (g) were determined by measuring 25 randomly selected fruits and their stones in three replications, using the technical scales (Adventurer Pro AV812M, Ohaus Corporation, Switzerland). The flesh percentage (%) was determined by calculation. Soluble solids content (%) was established using the manual refractometer (Carl Zeiss, Jena, Germany) at room temperature (20°C). Total acids content (%) manifested in malic acid was determined by neutralising the fruit juice using 0.1 N NaOH, with the addition of phenolphtaleine as the indicator of pH value up to 8.1. Based on the obtained data, the ratio between the soluble solids content and total acids was calculated. The fruit shape, skin colour, as well as the colour of the flesh and its firmness was described in accordance with the methodology recommended by UPOV-a (2002). The standard cultivar was ‘Čačanska Lepotica’.

Data analysis was performed using the SPSS statistical software package, Version 8.0 for Windows (SPSS. Inc., Chicago, IL). The variance analysis (ANOVA) was used for establishing the impact of genotype on the fruit weight and stone weight, the flesh percentage, soluble solids content and content of total acids, as well as the ratio between the total soluble solids content and total acids. In the cases when the *F* test was significant, testing of arithmetic means was performed using the test of Least Significant Differences (LSD test) for significance threshold of $P \leq 0.05$.

Results and discussion

The analysed plum genotypes ripened in the period from 29th July (hybrid 38/62/70) and 2nd September (hybrid 22/17/87). An earlier ripening time when compared to cv. Čačanska lepotica was established in hybrid 38/62/70 (Table 1). The average values of fruit and stone weight and the flesh percentage differed significantly depending on the examined plum genotype (Table 1). The average fruit mass of the analysed plum genotypes varied within the range from 25.10±0.89 g (hybrid 34/41/87) to 56.92±2.87 g (hybrid 38/62/70). A larger fruit compared to the standard was determined in hybrid 38/62/70 and the ‘Nada’ cultivar. The largest average stone weight was determined in hybrid 38/62/70 (1.76±0.03 g), which was in accordance with the largest fruit weight, whereas the smallest stone weight was recorded in the standard ‘Čačanska Lepotica’ cultivar (1.34±0.04 g). The only insignificant differences in relation to the standard were established in hybrid IV/63/81. The highest value of flesh percentage was

determined in hybrid 38/62/70 (96.91±0.19%), which was the only significantly higher result in comparison to the control cultivar. The fruit flesh ratio in the ‘Nada’ cultivar was at the level of the standard cultivar, whereas it was significantly lower in all the other genotypes.

Table 1. Harvest time, fruit and stone weight and flesh percentage of plum hybrids.

Genotyp	Harvest time	Fruit weight (g)	Stone weight (g)	Flesh percentage (%)
Hybrid 38/62/70	29 Jul	56.92±2.87 a	1.76±0.03 a	96.91±0.19 a
Hybrid IV/63/81	08 Aug	31.98±0.65 e	1.36±0.05 e	95.75±0.07 c
Hybrid 32/21/87	15 Aug	35.11±1.71 d	1.62±0.01 c	95.38±0.23 d

Hybrid 22/17/87	02 Sep	26.96±0.68 f	1.46±0.02 d	94.58±0.18 e
Čačanska lepotica	31 Jul	42.24±0.69 c	1.34±0.04 e	96.75±0.06 b

The different lower-case letters assigned to columns show significant differences for $P \leq 0.05$ after applying *LSD* test.

Ripening time and the duration of the fruit development are a specific property of each genotype (García-Mariño *et al*., 2008). Considering the fact that genotypes with either earlier or later fruit-ripening time are generally given preference (Neumüller, 2010; Пауновић *et al*., 2011) it is probably worth noting the potential of the early-ripening hybrid 38/62/70, as well as the lat-ripening ‘Nada’ cultivar and hybrids 34/41/87 and 22/17/87. According to the classification of plum cultivars in relation to the fruit weight as stated by Mišić (1996), hybrids IV/63/81, 32/21/87, 34/41/87 and 22/17/87 represent genotypes with medium-large fruits, whereas hybrid 38/62/70 and cv. ‘Nada’ belong to genotypes with large fruits. The large fruit of hybrid 38/62/70 is a confirmation that cv. ‘California Blue’ appeared as a donor of this property (Mišić, 2002). Hybrid 34/41/87 was characterised by the smallest fruit mass, which contradicted the results previously published by Jakubowski and Lewandowska (2004), where it was reported that cultivar ‘Čačanska Lepotica’ produces progeny with large fruits. The positive impact made by ‘Stanley’ as the mother plant on the fruits weight in the hybrid progeny, as reported by Mišić (2002) and Jakubowski & Lewandowska (2004) is observed in ‘Nada’ cultivar, but not in hybrid 32/21/87. Contrary to results of Blazek and Vávra (2007), and in agreement with the findings of Milošević and Milošević (2011), the positive impact of cultivar ‘Čačanska Najbolja’ on the fruit weight in the hybrid progeny was not confirmed in our studies. The results of our research related to the stone weight have confirmed the previous reports that the mass of stone is considered as a stable cultivar-specific property (Огашановић *et al*., 1996; Depypere *et al*., 2007). The previous research in this field have established a high degree of positive correlation between the stone mass and the mass of fruit (Okut and Akca, 1995), which was partly confirmed by our research. The flesh percentage is considered as an important property of plum (Miletić and Petrović, 1996; Nenadović-Mratinić *et al*., 2007). The same authors have reported the cultivar variability of this property, which is in accordance with the results obtained in our research.

The results of the study related to the fruit shape, skin colour, colour of the flesh and fruit firmness are shown in Table 2. Oval fruit shape was typical for hybrids 38/62/70 and 32/21/87, whereas all the other studied genotypes had an elongated fruit shape, including ‘Čačanska Lepotica’ as the standard cultivar. In addition to the standard cultivar, dark blue colour of the fruit skin was established in hybrids 32/21/87, 34/41/87 and the ‘Nada’ cultivar, whereas hybrids 32/21/87, IV/63/81 and 22/17/87 had a violet- blue colour of the skin. The yellow colour of the flesh was found in hybrid 32/21/87 and the ‘Nada’ cultivar, whereas the remaining genotypes under consideration had a yellowish-green colour of the flesh, which was also present in the standard cultivar as well. Hybrid 32/21/87 had the lowest firmness of

the fruit, as opposed to hybrids IV/63/81 and 22/17/87 which had medium fruit firmness; at the same time, hybrids 38/62/70, IV/63/81 and 34/41/87, together with cultivar ‘Nada’ and standard ‘Čačanska Lepotica’ recorded the highest degree of this parameter.

Table 2. Fruit shape, skin colour, flesh colour and fruit firmness of plum hybrids.

Genotype	Fruit shape	Skin colour	Flesh colour	Fruit firmness
Hybrid 38/62/70	circular	violet blue	yellowish green	firm
Hybrid IV/63/81	elliptical	violet blue	yellowish green	medium
Hybrid 32/21/87	circular	dark blue	yellow	soft
‘Nada’	elliptical	dark blue	yellow	firm
Hybrid 34/41/87	elliptical	dark blue	yellowish green	firm
Hybrid 22/17/87	elliptical	violet blue	yellowish green	medium
‘Čačanska Lepotica’	elliptical	dark blue	yellowish green	firm

In the assessment of the fruit attractiveness, the primary importance is assigned to the fruit size, followed by its colour and shape. In certain Central European countries, preference is given to cultivars with an elongated fruit and blue colour of the skin, with intense bloom (Neumüller, 2010). The same author reports that firmness of the fruit and flesh colour represent highly important properties of table plum cultivars, where advantage is given to genotypes with firm fruits and orange of yellow flesh colour. In this regard, ‘Nada’ stands out owing to its elongated fruits with dark-blue skin and firm yellow flesh.

The soluble solids content and the content of total acids in the fruit, as well as the ratio between them were cultivar-specific for each of the examined plum genotype (Table 3).

Table 3. Soluble solids content, total acids content and soluble solids content and total acids ratio of plum hybrids.

Genotyp	Soluble solids content (%)	Total acids content (%)	Soluble solids content/ Total acids content
Hybrid 38/62/70	11.39±0.44 g	1.03±0.04 b	11.11±0.16 ef
Hybrid IV/63/81	12.62±0.65 f	1.06±0.02 b	11.98±0.80 e
Hybrid 32/21/87	14.27±0.52 d	1.42±0.05 a	10.25±0.58 f
‘Nada’	14.73±0.28 c	0.35±0.02 e	43.72±1.47 a
Hybrid 34/41/87	16.49±3.21 b	0.77±0.05 d	21.37±3.94 b
Hybrid 22/17/87	17.01±0.96 a	0.97±0.04 c	17.77±1.02 c
‘Čačanska Lepotica’	13.97±0.70 e	0.97±0.03 c	14.63±0.99 d

The different lower-case letters assigned to columns show significant differences for $P \leq 0.05$ after applying *LSD* test.

The highest average value of the soluble solids content was established in the fruits of hybrid 22/17/87 (17.01±0.96%), as the latest-ripening one, whereas the lowest value of this parameter was found in the fruits of hybrid 38/62/70 (11.39±0.44%) as the earliest-ripening one. Compared to ‘Čačanska Lepotica’ the highest content of soluble solids in the fruit was recorded in ‘Nada’ cultivar and hybrids 32/21/87, 34/41/87 and 22/17/87. The highest content of total acids in the fruit was found in hybrid 32/21/87 (1.42±0.05%), whereas the lowest value of this parameter was recorded in ‘Nada’ cultivar (0.35±0.02%). Compared to the standard, higher values of the total acids content were typical of the fruits of hybrids 38/62/70, IV/63/81 and 32/21/87. The highest ratio between the soluble solids content and the total acids content was established in ‘Nada’ cultivar (43.72±1.47), whereas the lowest value of this ratio was found in hybrid 32/21/87 (10.25±0.58). Compared to the control cultivar, the highest values of this parameter were typical of cultivar ‘Nada’ and hybrids 34/41/87 and 22/17/87 (Table 3).

The results obtained based on the analysis of the soluble solids contents in the fruits of the cultivars examined in this study confirm the existence of a positive correlation between the soluble solids content and the ripening time of the fruit (Neumüller, 2010). Considering the fact that the soluble solids content of ≥12,0% is generally taken as the limiting value for better acceptability of a plum cultivar by consumers (Crisosto *et al*., 2004), it can be concluded that these criteria are not met only by the earliest hybrid 38/62/70. Given the assumptions that later-ripening cultivars ought to have a soluble solids content in excess of 17% (Neumüller, 2010), hybrid 22/17/87 has made a distinction in this regard. With the exception of the values obtained for cultivar 'Nada', the total acids contents obtained in this paper were within the ranges reported in the studies conducted by Miletić and Petrović (1996). On the other side, Družič *et al*. (2007) have reported total acids content in certain German plum cultivars which corresponded to values obtained for cultivar 'Nada' in our research. It is a well-known fact that the ratio between the soluble solids content and total acids, rather than the very content of dry soluble solids, represents a reliable indicator of a cultivar's suitability for acceptance by consumers (Crisosto *et al*., 2004). It is also known that European plum cultivars are generally regarded as cultivars with a good fruit quality, provided that the ratio between the soluble solids content and the total acids falls within the range between 12 and 24 (Robertson *et al*., 1992). In this regard, hybrids 34/41/87 and 22/17/87 can be viewed as promising. Owing to its low content of total acids in the fruit, cultivar 'Nada' recorded considerably higher values of this parameter compared to the upper border value reported by the cited author. Similar information is reported by Družič *et al*. (2007) for 'Elena' cultivar.

Conclusion

The late ripening time and the large size of the fruit, its firmness, elongated shape, dark blue colour of the skin, the yellow flesh and good chemical composition – these are all properties that support the assertion that the new cultivar 'Nada' represents a genotype with the best combination of positive characteristics. Considering its early ripening time, as well as the large size and firmness of its fruits, hybrid 38/62/70 can also be interesting, and so can be hybrid 22/17/87, from the point of view of its late ripening time and the good chemical composition of the fruit. Apart from their obvious potential in production, the examined cultivars can be used in future plum breeding programmes.

Abstract

In the total food production in Serbia, potato (*Solanum tuberosum* L.) occupies an important place. The great economic importance of potato arises from the fact that this crop is grown on 78.000 ha, with an average yield of 11.3 t ha^{-1}. The average yield in Serbia is significantly lower compared to average potato yield in Europe of 37.0-55.0 t ha^{-1}. Commercial production of potato is carried out in the 50.000-60.000 ha with an average yield of about 15-25 t ha^{-1}, but it still does not nearly meet the standards of modern agricultural production. Every 3-4 years, the major problem in potato production in our country is extreme drought that limits crop yield and quality of tubers. A two-year study (2011 and 2012) was conducted to investigate the effects of subsurface drip irrigation on productive characteristics of different potato cultivars: Desiree, Marabel, Laura, Agria, Bellarosa, Carrera and Jelly. Field trials were carried out on a slightly calcareous chernozem soil at Zemun Polje and experimental design was two factorial split plot with four replications. The occurrence of stress during the growing season, as a result of high soil temperature, lack of soil moisture, compaction and poor aeration resulted in significant reduction in potato productivity. Subsurface drip irrigation significantly increased mass of tubers and total tuber yield in both 2011 and 2012, while the number of tubers per plant was mainly determined by genotype/cultivar.

Key words: *drip irrigation, potato yield, drought*

Introduction

Potato yield is influenced by numerous factors during growing season, such as selected cultivar, planting time, agricultural practice and weather conditions. Soil water shortage is a common adverse factor for the growth of plants in the field. Potato is the crop grown in the moderately moist climate and drought has negative impact on all yield components. One of the reasons for potato sensitivity on soil water deficit is shallow root system whose base mass is concentrated in upper soil layer approximately at 0.3 m. Some authors consider drought to be the main yield-limiting factor in the global potato production (Van der Zaag & Burton 1978). Long period of intensive drought stress could retard the growth of plants, causing the changes of the morphological structure and the distribution pattern of biomass, or even death (Christina and Gisela, 2013; Dias et al., 2007).

Sensitivity of the potato crop to water stress varies with the developmental stage of the crop. During first stages of vegetative growth, potato requires minimally 70% field water capacity (FWC), while requirements at the flowering and tuber-bulking stages are 70-80% FWC. Water deficit during tuber initiation and onset of tuber growth significantly decreases yield and increases portion of deformed tubers, while at tuber bulking stage significantly reduces tuber quality and yield (King & Stark, 2011; Poštić et al., 2013). Abiotic stress conditions, such as high soil temperatures, low soil moisture, soil compactness and low

aeration, cause secondary growth of tubers and thus lower market value of potato (Beukema and Van der Zaag, 1979; Momirović et al., 2000).

In the last several years, serious problem in potato production in Serbia is occurrence of extremely dry periods that limit crop production (Broćić et al., 2009; Poštić et al., 2012). Irrigation is an important agrotechnical practice for reduction of drought effects, which has a key role in attaining high and stable yields. In arid regions, potato yield linearly accedes with addition of water amount that, altogether with precipitations, compensate amount lost by evaporation (Ferreira and Goncalves, 2007; Bošnjak et al., 1996). During hot and dry summers, potato can lose over 50 mm H_2O per week by evaporation and irrigation represents prerequisite for secured production (Bošnjak, 1994). Subsurface drip irrigation ensures optimal water supply in hilled potato rows, where tubers are form, during whole vegetative period. The major objective of this study was to investigate the effects of subsurface drip irrigation on productive characteristics of seven potato cultivars: Desiree, Marabel, Laura, Agria, Bellarosa, Carrera and Jelly.

Materials and methods

Virus-free tubers of seven commercial potato cultivars, Desiree, Marabel, Laura, Agria, Bellarosa, Carrera and Jelly, were obtained from Solanum Komerc (Guča, Serbia). Tubers were planted in the experimental field in Zemun Polje, Serbia (44°88′ N, 20°35′ E, 82 m altitude) by early April in years 2011 and 2012. Two-factorial split plot design with four replications was used and plots of 21 m^2 with 5 rows spaced 80 cm apart were seeded. Shortly before planting, tubes for subsurface drip irrigation were positioned and buried in the middle of hilled rows at 0.15 m depth. Soil was irrigated to continuously maintain 75-80% FWC. Control plots received no special treatment and they were watered only by natural rainfall. The soil type was slightly calcareous chernozem with high clay content (>32%). Calcium carbonate content was 3.89-4.54% in the humus-accumulative horizon, which determines soil as slightly calcareous. Soil solution was neutral to slightly alkaline (pH: in water – 7.60-7.75, in nKCI 6.75-6.90), which was adequate for potato growing. According to humus content, soil was medium fertile, with high amount of P_2O_5 (28.55-31.00 mg per 100 g of soil) and K_2O (29.10-34.80 mg per 100 g of soil). Investigated slightly calcareous chernozem belongs to soils with a medium productivity potential, requiring irrigation, besides fertilization, for successful crop production during the dry years.

Standard tillage treatment for potato crop was used. Pre-sowing soil treatment included fertilization with Multi-Comp base and BitterMag, as well as organic fertilizer Stallatiko. Plants were foliar fertilized with Haifa Bonus (N:P:K = 13:2:44, 6 kg ha-1), Haifa Chemicals, Israel. Weeds and pests were controlled post-emergence with commercial formulations of Tarot 25 WG (rimsulfuron 12.5 g ha-1), Du Pont International, Switzerland, Force 0.5 G (tefluthrin 75 g ha^{-1}), Syngenta, Switzerland, Actara 25 WG (thiamethoxam 15 g ha^{-1}), Syngenta, Switzerland.

Data considering basic climate parameters (daily maximum and minimum air temperature, precipitation quantity and distribution) were collected in the period April-September. At the end of vegetation period, 8 samples, each comprising tubers of plants developed from common seed, were collected per each investigated cultivar. Tuber number and mass, as well as yield per plot were analyzed. Total yield per ha was estimated theoretically according to plant density in the field.

Table 1. The average monthly air temperatures and precipitation from April to September.

Months	Temperature (°C)			Precipitation (mm)		
	2011	2012	1981-2010	2011	2012	1981-2010
April	14.5	14.6	12.4	14.1	66.9	56.8
May	17.7	18.0	17.2	66.8	127.9	58.0
June	22.1	24.6	20.1	41.4	16.0	101.2
July	24.2	26.9	21.8	95.0	39.0	63.0
August	24.6	26.0	21.4	14.0	4.5	58.3
September	22.9	22.0	17.7	47.7	30.7	55.3
Average/Sum	**21.0**	**22.0**	**18.4**	**279**	**285**	**392.6**

Weather conditions during potato vegetation period were unfavorable, especially in year 2012 which was extremely hot and dry. During summers 2011 and 2012, average monthly air temperatures were significantly higher than multiple-year average (1981-2010), which adversely affected potato growth and development. Precipitations in summers 2011 and 2012 were below limits of multiple-year average with an uneven distribution during vegetative period in both years.

Statistical analysis was performed using STATISTICA 10 (StatSoft, Inc. 1984-2011, USA). The data concerning tuber number, tuber mass or yield were subjected to two-factor analysis of variance (ANOVA) with Irrigation and Cultivar as factors. If significant interaction between factors was determined, the means were separated by Fisher's-LSD multiple range test at the significance level $\alpha = 0.05$ for each Cultivar and Irrigation combination. Otherwise, LSD multiple range test (significance level $\alpha = 0.05$) was conducted for one significant factor at a time, Cultivar or Irrigation, but on each level of the other factor.

Results and discussion

Data regarding productive characteristics of seven investigated potato cultivars are presented in Tables 2, 3 and 4. In general, investigated parameters/productive characteristics mainly had higher values in 2011 compared with 2012. The probable reasons for observed differences are lower average air temperatures and less uneven distribution of precipitations during potato vegetation period in year 2011 (Table 1.).

The number of tubers per plant was mainly determined by genotype/cultivar, while irrigation increased number of formed tubers only in cvs. Agria and Carrera in extremely hot 2012. Conversely, mass of tubers was mainly affected by irrigation. In year 2012, drip-irrigated potato cultivars, with exception of cv. Desiree, produced from 1.4- to 2.2–fold heavier tubers compared to variant without irrigation. Total yield was also affected by irrigation in years 2011 and 2012. Interestingly, yield of only two cultivars, Agria and Carrera, significantly increased with irrigation in moderately hot 2011 and irrigated Carrera had the highest yield (68.3 t ha^{-1}) in this particular year. In extremely hot and dry year 2012, the lowest yield was determined for cv. Agria (11.4 t ha^{-1}) without irrigation. Irrigation was an especially significant factor in this year, which caused from 1.4- to 2.7-fold increase in yield of seven investigated cultivars. Drip-irrigated Laura had the highest yield (45.2 t ha^{-1}) in 2012, while irrigated Carrera and Agria showed the highest increase in productivity (2.5- and 2.7-fold increase) compared to non-irrigated control.

Conclusions

Results of our study, conducted in moderately hot 2011 and extremely hot and dry 2012 on seven potato cultivars, indicate that the number of tubers per plant was mainly determined by genotype/cultivar, while irrigation affected mass of tubers and total tuber yield. Two of the cultivars, Agria and Carrera, responded exceptionally well on subsurface irrigation in both investigated years. Drip-irrigated cv. Carrera had the highest yield (68.3 t ha^{-1}) in moderately hot 2011, while irrigated cv. Laura had the best yield (45.2 t ha^{-1}) in extremely hot and dry year 2012. Marabel was the most productive cultivar without irrigation with yield of 28.7 t ha^{-1} in year 2012.

Abstract

Being under great pressure to improve energy safety in terms of environmental protection and to decrease dependence on imports, many countries shift their production to alternative bio-fuels, such as ethanol and bio-diesel obtained from plant products.

The subject-matter of the study is two-year research (2012-2013) on variability of morphological properties of Miscanthus depending on nitrogen rates used for fertilization. The study analysed the following morphological properties: plant height, number of leaves and leaf width. The results show that increased nitrogen rates significantly affect the investigated morphological properties. In fertilization variants, plants were significantly higher than in the control variant in both years of research, which affected the number of formed leaves and leaf width. The effect of the applied nitrogen rates depended on weather conditions (distribution of precipitation). In a favourable precipitation regime the optimal biomass growth was obtained when 80 kg ha^{-1} nitrogen was applied.

Having analysed the correlations, the authors found strong statistical dependence among the investigated parameters. A non-significant positive correlation was found between plant height and precipitation and between number and width of leaves and precipitation. A non-significant negative correlation was found between plant height and temperature of air, as well as between number and width of leaves and temperature of air.

Key words: *agro-ecological conditions, nitrogen, biomass, Miscanthus, morphological properties*

Introduction

Miscanthus is a perennial, highly productive C_4-grass, originating from eastern Asia. It belongs to so-called “bioenergy crops”, whose stem is dried and used as a fuel, thus being an alternative to existing energy sources. According to the results of Lewandowski et al. (2010), the energy value of Micanthus biomass is at the level of firewood (17.7 MJ kg^{-1}). Considering these data, the most of developed countries have set a goal to increase crop production suitable for energy production from renewable energy resources. A strong incentive has been given to this research after the adoption of the *Kyoto Protocol* (1997) on climate change and reducing greenhouse gas emissions and the greenhouse effect (Glamočlija et al., *2007*).

Vegetative growth begins when shoots emerge from underground stems-rhizomes in early April. Annual above-ground stems grow from the intercalary meristems. The stems are nodded, straight and unbranched. They reach their maximum height in late August. At the end of vegetative growth, tassels with sterile flowers emerge, and assimilates start to move down to the underground stems-rhizomes. Plants use these nutrients to form new stems next year. Over years, rhizomes branch, increasing their mass. In commercial production, there are used as planting material for new Miscanthus plantations (Dželetović et al., 2009).

Miscanthus growing requires a very simple technology, what can be conducted by using standard machinery. Only for harvest it is necessary to use some specific machinery – combines that work on the principle of silo–combines, compressing harvested plants in bundles or bales, depending on the future use of this biomass. According to numerous authors, the best time to harvest Micanthus is when there is a minimum amount of water in stems. The stems harvested in this period will have the highest energy value, as pointed out by Dželetović (2002), Lewandowski et al. (2010) and other researchers. Previous studies have shown that the Miscanthus stem has the minimum amount of water during the winter period (January, February). However, snowfall can damage some of the above-ground biomass, which affects yields (Dželetović et al., 2012). In areas without heavy snowfall *Lewandowski et al*. (2010) recommend having a so–called "late harvest" at the end of winter when stems have the minimum amount of water. Yields, however, may be up to 30% lower than usual.

Previous studies on Miscanthus crop practice in the first year of planting have shown that the limiting factor to successful Miscanthus production is weediness, especially if it is planted on weedy and deserted fields (Dražić et al., 2010; Ikanović et al., 2010). Perennial grasses predominate on such soil, making it difficult to use herbicides against narrow-leaved weeds. The same authors emphasize that using total herbicides is not efficient enough since most grassy weeds appear later, at the time of shoots emerging.

The main objective of this paper is to introduce energy crops in our agricultural production, in order to determine the adaptability of these plant species to agro-ecological and soil conditions in our production area, characterized by continental climate with cold winters, a small amount of snowfall and very hot and dry summers. Miscanthus environmental requirements are quite specific, since it is a perennial plant with rhizomes that over winter in a shallow soil layer. On the other hand, Miscanthus is tolerant to short–term drought, but it also very sensitive to the lack of precipitation in the year of planting (Dražić et al., 2014).

Material and methods

The research was conducted in 2012 and 2013, on brown forest soil in Sremska Mitrovica, Serbia. A multi-year trial was set up in a randomized block design with three replications. The subject-matter of the research was Miscanthus. Miscanthus rhizomes, purchased from a commercial supplier from Austria, were manually planted in the pre-prepared soil. Planting was carried out using 10-15 cm long rhizomes with 2-5 nodes, at the density of 20,000 rhizomes per ha^{-1}. Planting was conducted in the first decade of April, to the depth of 10 cm.

The research comprised two variants with applied nitrogen (N_1=50 kg ha^{-1} and N_2=80 kg ha^{-1}). A variant without nitrogen was taken as a control variant (N_0). Nitrogen was applied into soil during planting preparations in the first year, and again when shoots emerged in the second year.

Soil and meteorological conditions

The field trial was set up on brown forest soil (*Eutric Cambisol*, according to the FAO soil classification system). This type of soil has low levels of humus (1.38%) and total nitrogen (0.114%). It is poor in easy available phosphorus (5 mg per 100 g soil) and potassium (11.8 mg in 100g soil). Due to an extremely acid reaction (pH 6.1 in H_2O), it has a high content of available Fe, Cu, Mn and Zn, as well as Pb derived from the rock it was formed on (Pb-Zn belt on the bottom of Mt Avala and Mt Kosmaj (Glamočlija et al., 2012, 2015).

Meteorological conditions (temperatures and precipitation) in a particular area can be quite variable, so it is necessary to monitor them during the growing season, and to know their effect on physiological processes and critical stages of plant development, in order to achieve the maximum productivity of crops (Popović, 2010; Ikanović et al., 2015a, 2015b).

Meteorological data were retrieved from the weather station in Sremska Mitrovica. The average monthly air temperature in the 2012 growing season was 11.79 ^{o}C, which is 0.29^{o}C

higher than in 2013 (11.50 ^{o}C). Total amount of precipitation in 2013 was 809 mm, being 34 mm higher than in 2012 (775 mm) (Graph 1). The thermal regime in the growing season is very important for the optimal development of Miscanthus. In the year of planting, overwintering depends on the planting depth. Shallow planted Miscanthus with poorly developed rhizomes is particularly sensitive and such rhizomes often suffer from frost and large amounts of precipitation in winter (Dželetović et al., 2000).

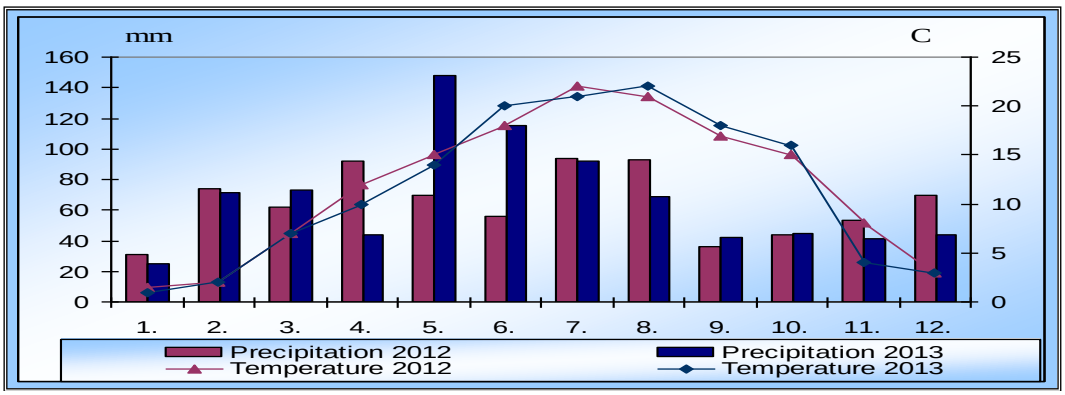

Fig. 1. Precipitation (mm) and temperatures (ºC), Sremska Mitrovica, Serbia, 2012-2013

Meteorological conditions, especially the water regime in the year of planting, were not favorable due to the shortage of precipitation in April and May, which resulted in slow emergence of plants. Year 2013 was more favorable for Miscanthus. Miscanthus has quite specific environmental requirements, since it is a perennial plant with perennating roots and rhizomes that overwinter in a shallow soil layer. On the other hand, Miscanthus is tolerant to short-term drought but it also very sensitive to the lack of precipitation in the year of planting.

Results and discussion

Miscanthus morphological properties

Miscanthus is an ideal energy crop, considering its high multi-year production of dry biomass, efficient utilization of nitrogen and water, good resistance to drought and the possibility of growing on degraded soil (Ikanović i sar., 2015a).

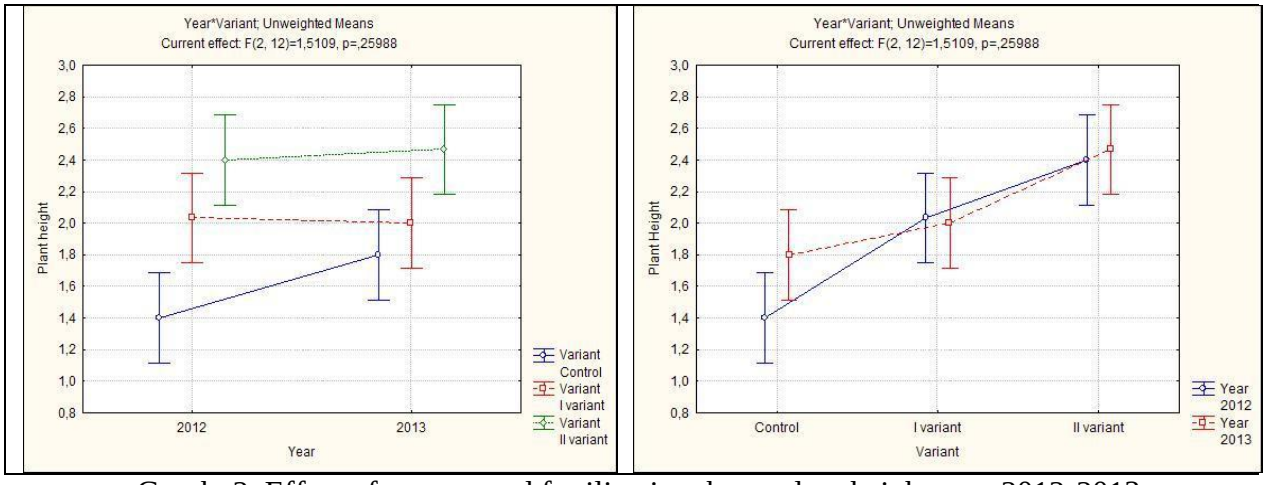
Plant height

This parameter was significantly affected by the applied nitrogen rates (Table 1). The average plant height was 2.02 m. The lowest values were recorded for the control variant, and highest in the variant with 80 kg ha^{-1} nitrogen. The variants with nitrogen and the interaction between the factors, as well as variant x year interaction had great effect on plant height ($p<0.5$). On average, the plants in 2012 were lower than in 2013, but this difference was not significant (Graph 2.a, 2.b). Standard deviation for plant height averaged 0.416 (Table 1).

Table 1. Miscanthus morphological properties, 2012-2013

Parameter	Control	Variant 1	Variant 2	Average	Std. Dev.	Std. Err
Plant height, m						
2012	1.40	2.03	2.40	1.94	0.45	0.15
2013	1.80	2.00	2.47	2.09	0.39	0.13
Average	1.60	2.02	2.43	2.02	0.41	0.09
Number of leaves						
2012	9.00	11.67	16.33	12.33	3.50	1.16
2013	8.67	13.66	16.00	12.78	3.45	1.15
Average	8.83	12.66	16.16	12.55	3.38	0.79
Leaf width, cm						
2012	1.06	1.47	1.83	1.45	0.36	0.12
2013	1.17	1.80	1.93	1.63	1.40	0.13
Average	1.12	1.63	1.88	1.54	0.38	0.09

Parameter	LSD Test	Year	Variant	Y X V
Plant height	0.5	0.233	0.286	0.404
	0.1	0.328	0.402	1.751
Number of leaves	0.5	1.538	1.883	2.663
	0.1	2.165	2.651	3.749
Leaf width	0.5	0.200	0.245	0.347
	0.1	0.282	0.346	0.488



Graph. 2. Effect of year, a, and fertilization, b, on plant height, cm, 2012-2013

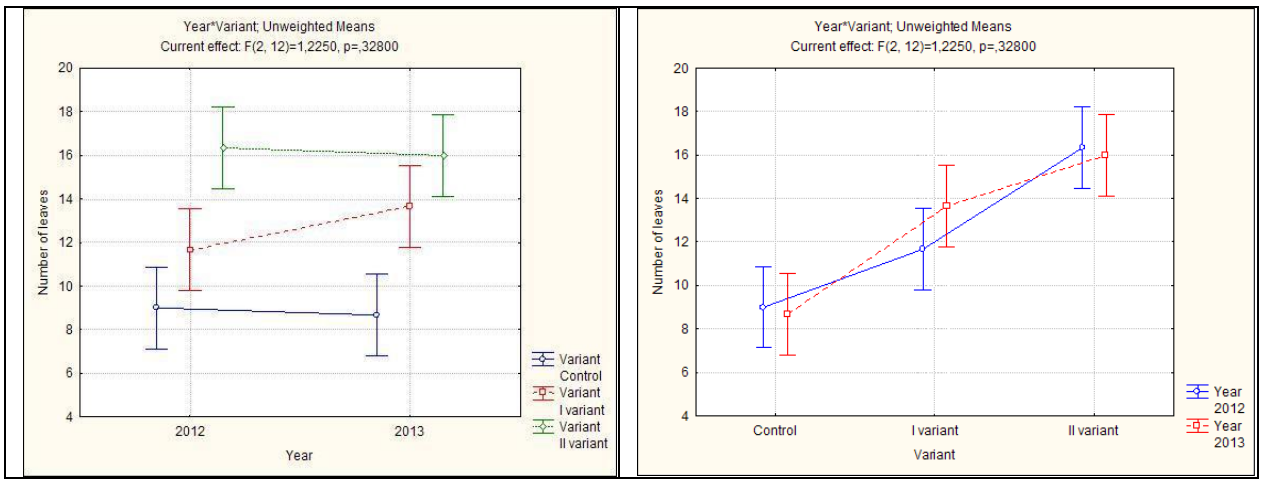
Meteorological conditions during the growing season affected plant height. In their research, Ikanović et al. (2015a) reported that the weather conditions had a significant effect on morphological and productive properties of Miscanthus. Dražić et al. (2014) point out that Miscanthus has not been put yet in commercial production, although the experimental results show that it can be successfully grown in Serbian agro–ecological and soil conditions.

Number of leaves

The average number of leaves per stem was 12.55. When observed by years, the plants in 2012 had less leaves on average than in 2013, but this difference was not significant (Graph 3.a). Standard deviation for plant height averaged 3.38 (Table 1).

With an increase in the amount of nitrogen the number of leaves also increased, statistically being significantly higher in the variant with the maximum nitrogen rate than in the control

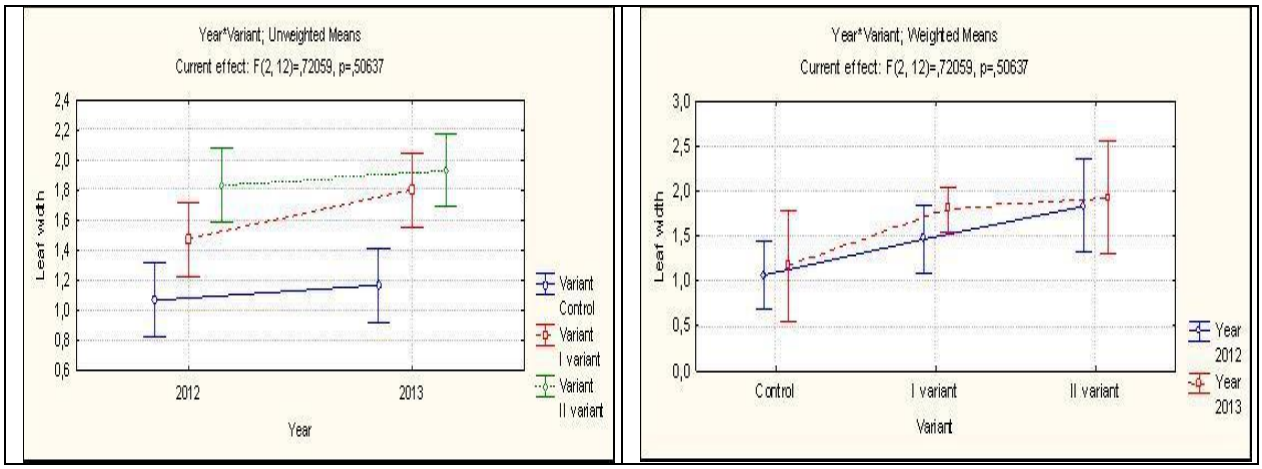
variant. On average, plants had a significantly higher number of leaves in variant 1 with 50 kg ha^{-1} (N_1) and in variant 2 with 80 kg ha^{-1} (N_2) than in the control variant (N_0) (Table 1 and Graph 3.b).Variant and the interaction of factors, as well as variant and years of research exhibited statistically significant effect on the number of leaves ($p<0.5$).



Graph 3. Effect of yield, a, and fertilization, b, on the number of leaves, 2012-2013

Leaf width

The average leaf width was 1.45 cm, Table 1, Graph 4a, 4b.



Graph 4. Effect of yield, a, and fertilization, b, on leaf width, 2012-2013

On average, lower values of this property were recorded in 2012 than in 2013, but the difference is not significant (Graph 4.a). Like in the previous parameters, variant and interaction, and variant and year of research exhibited statistically significant effect on the number of leaves ($p<0.5$). On average, plants had significantly higher values of this property in the variants with nitrogen than in the control variant (Table 1, Graph 4.b). Standard deviation for plant height averaged 0.38 (Tab. 1).

Interdependence of the investigated properties

The research studied correlations (interdependence) between the investigated properties. A significant and strong positive correlation was found between plant height and the number of leaves, whilst a significant positive correlation was recorded between plant height and leaf width (Table 2). The coefficient of correlation indicates that the number of leaves per stem and plant height are positively and statistically very strongly correlated.

Table 2. Coefficients of correlations between the investigated properties

Parameters	Plant height	Number of leaves	Leaf width	Temperature	Precipitation
Plant height	1.00	0.76**	0.64*	-0.18^{ns}	0.20^{ns}
Number of leaves	0.76**	1.00	0.84**	-0.07^{ns}	0.10^{ns}
Leaf width	0.64*	0.84**	1.00	-0.24^{ns}	0.20^{ns}
^{ns} –non significant; * significant at p < 0.5 and ** significant at p < 0.1					

The authors recorded a highly significant positive correlation between the number of leaves and leaf width, as well as a non-significant positive correlation between plant height and precipitation and the number of leaves, leaf width and precipitation (Table 2).

Plant height and temperature were non-significantly and negatively correlated, as well as the number of leaves, leaf width and temperature (Table 2). The results of previous research on the effect of increased nitrogen rates on C_4 grasses confirm these plants are greatly depended on nitrogen, which was shown as a statistically significant increase of leaf mass in total above-ground biomass (Ikanović et al., 2010; Glamoclija et al., 2007). When water regime is favorable, shoots emergence is better in the first year and Miscanthus has larger leaf mass and a greater number of leaves, as confirmed by the results of Ercoli et al. (1999).

Živanović et al. (2014) and Dražić et al. (2014) point out a manifold significance of energy crops, which is reflected in a more rational utilization of soil less favorable for production and soil under recultivation. The same authors also point out another advantage – growing energy crops in order to obtain more biomass and energy than from post-harvest residues. Moreover, a significant improvement of the ecosystem was noticed, since these crops have intensive annual growth of biomass and use large amounts of carbon dioxide and other gases from the atmosphere.

Conclusions

The following conclusions were made from the research:

During the two-year research, the average plant height ranged from 1.94 m to 2.09 m. The average values of plant height were higher in 2013 than in 2012. The nitrogen variants had significantly higher plants than the control variant. The average number of leaves was 12.55 and varied from 12.33 to 12.78 (in 2012 and in 2013). Significantly higher number of leaves was recorded in the variants with nitrogen than in the control variant. The average leaf width was 1.54 cm. This parameter had higher average values in 2013 than in 2012. In the variants with nitrogen, plants were significantly higher than in the control variant.

Having analyzed the correlations, the authors recorded a statistically strong positive relationship between the investigated Miscanthus properties.

A non-significant positive correlation was found between plant height and precipitation, as well as between the number of leaves, leaf width and precipitation, whilst a non-significant negative correlation was found between plant height and temperature, the number of leaves, leaf width and temperature.

Abstract

To ensure safe food production, cultivar-specific traits of winter small grains were analysed in terms of mineral nutrition in order to determine differences between small grain (barley, oat and triticale) genotypes in the level of certain heavy metals (Ni). This study examined the effect of mineral (NPK), organic (manure) and lime (Njival Ca) fertilisers on the uptake of chrome and its content in kernel and the aboveground portions of winter small grains. The investigation was conducted under field conditions in a soil having acid reaction (pH_{KCl} = 4.20) it is included of two winter barley cultivars, one winter oat cultivar and one winter triticale cultivar. Apart from the control, four various fertilisation variants were also included in the trial: NPK; N +$CaCO_3$; NPK + $CaCO_3$; NPK + $CaCO_3$, + organic (manure). The kernel of mature small grain plants and their vegetative biomass were found to contain quite different levels of Cr, depending on genotype properties and fertilisation systems. The amount of chromium in the above-ground portions was higher than the kernel, and that relationship is as follows: Control -3.70; NPK - 4.72; N + $CaCO_3$ - 1.79; NPK $CaCO_3$ + - 2.5; NPK + $CaCO_3$ + organic manure -4.8. On the $CaCO_3$ + NPK + manure of his mobility is lowest, because the application of manure reduces the mobility of chromium (DTPA-extraction) and thus reduces its toxic effects in plants.

Introduction

Heavy metals in soils originate primarily from geochemical sources i.e. from the lithosphere, and their concentration in soils is dependent on their content in the parent rock (Ubavić et al., 1995). The behaviour of heavy metals in soils is governed by a range of factors that affect their mobility and accumulation by plants, the most important being soil reaction, organic matter content and colloidal clay content (Pelivanoska, 2011). In addition to these factors, the mobility and harmful effects of heavy metals can also be induced by moisture, calcium carbonate content, hydrated iron and aluminium oxides, cation exchange capacity, redox potential, groundwater level etc. (Pelivanoska, 2011).

Recent research has also identified the increasing presence of heavy metals in agricultural soils (Markoski et al., 2011) which are further endangered by the increasing or inappropriate use of chemicals, as well as by wastewaters, sewage, sludges and mineral fertilisers. Polluted soils are an important factor contributing to total chromium concentrations in plant tissues. Plants growing on soils highly contaminated with chromium contain higher levels of chromium compared to similar plants on soils with a low content of this element (Cary and Kubota, 1990).

Similar to arsenic, chromium is a redox active soil contaminant but one that has dramatic alterations in toxicity and mobility with changes in oxidation state. Trivalent Cr is rather benign to most plants and animals and binds strongly to soil solids (Fendorf, 1995). In contrast, hexavalent Cr is toxic to living cells, being a Class A human carcinogen (Kargacin et al., 1993); because of its anionic nature and inability to form strong chemical complexes with

most soil materials, chromate is also highly mobile within the surface environment (Fendorf, 1995; Ball and Nordstrom, 1998).
Most toxic elements typically react with organic compounds to produce stable complexes with ligands containing oxygen, sulphur or nitrogen as electron donors. The toxic effect is based on their irreversible binding to metabolically active groups in amino acids, polypeptides and proteins (Mihaljev et al., 2008). It is understood that toxic elements primarily affect the cell membrane, whereas their secondary effect in most cases includes damage to the enzyme systems residing in the cell interior (Milošević and Vitorović, 1992). Through plants, heavy metals enter the food chain and have cumulative properties in the human body i.e. they accumulate in certain organs or tissues, where they exhibit their deleterious effect.
Small grains (oat, barley and triticale) are annual plants considered the leading and major field forage crops for quality feed production, and are also used fresh and preserved as hay, silage and flour.
The objective of this study was to evaluate the content of Cr in the aboveground vegetative biomass and kernel of small grains to obtain information on the safety of these feedstuffs. Cultivar specificity of winter small grains with respect to mineral nutrition was analysed to determine differences among genotypes in the content of certain heavy metals (Cr).

Materials and methods

The investigations were conducted over a three–years period (1999/00–2001/02) at an experimental field of the Small Grains Research Centre in Kragujevac, on the very acid soil (pH in KCl 4.20). The trial was set up according to a randomized block design in three replications. The trial plot was 14 m^2 (7 m x 2 m). The trial involved an examination two barley cultivars (Jagodinac and Grand), one oat cultivar (Vranac) and one triticale cultivar (Knjaz). The following fertilization treatments were used in the trial: 1. the control (without fertilization); 2. NPK; 3. N + CaCO3; 4. NPK + CaCO3; 5. NPK + manure + CaCO3. The mineral fertilizer was used at the rate of 500 kg/ha NPK (15:15:15), nitrogen at the rate of 75 kg N ha^{-1} (as KAN), and lime (CaCO3) at the rate of 2.0 t ha^{-1}. "Njival Ca", the product of the Serbian Glass Factory–Paracin, was used as a lime fertilizer with 98.5% CaCO3. The applied farmyard manure was a mixture of poultry and cow manures, and it was well–matured (maturing for several years). Kernel samples were collected at the full maturity stage and the aerial plant parts were sampled at the heading/tasselling stage. Cr and Cd concentrations were determined by the AAS method following dry sample burning.

Results and discussion

Chromium is an essential element for animals, given its vital role in normal carbohydrate and lipid metabolism. In humans, there is an increased need for chromium in people with impaired glucose tolerance. The essential role of Cr in plant metabolic processes is not known, but in some plant species low concentrations of certain non-essential heavy metals (Cr) can stimulate plant growth and development (Ernst, 1996). In agricultural soils, Cr originates not only from the parent material, but also from sludge, composted waste and fungicides, which are increasingly used. Similar to arsenic, chromium is a redox active soil contaminant but one that has dramatic alterations in toxicity and mobility with changes in oxidation state. Trivalent Cr is rather benign to most plants and animals and binds strongly to soil solids (Fendorf, 1995). In contrast, hexavalent Cr is toxic to living cells, being a Class A human carcinogen (Kargacin et al., 1993); because of its anionic nature and inability to form strong chemical complexes with most soil materials, chromate is also highly mobile within the surface environment (Fendorf, 1995; Ball and Nordstrom, 1998). Chromium forms very strong bonds in soils rich in clay and organic matter, and therefore has very low mobility and is adsorbed in the 5-10 cm deep topsoil. Cr amounts in the soil range from 5 to 100 mg/kg (Ubavic and

Bogdanovic, 1995), but they can often occur at much higher concentrations, up to 3400 mg/kg (Markoski et al., 2001), particularly in soils formed on serpentine rocks. The concentrations of available Cr in soils are very low, hence its very low content in plants of 0.2 to 0.4 mg/kg (Pelivanoska et al., 2001).

The content of Cr in the tested samples of small grains (Tab. 1) indicates that Cr concentration in the aboveground vegetative biomass and kernel of small grains varied considerably depending on genotype and fertilisation treatment. The highest average Cr concentration in the vegetative biomass was recorded after NPK fertiliser treatment. Somewhat lower concentrations were found in the control and N+$CaCO_3$ treatment. NPK fertilisers, $CaCO_3$ and manure significantly reduced the absorption of this element in both the aboveground portions and the kernel of the tested cultivars. At a high redox potential and in the presence of organic matter, Cr(VI) is reduced to Cr(III). Cr(VI) is a soluble anion toxic to plants (Bartlett, 1991), and at an adequate pH and redox potential it is released into the soil solution in substantial amounts to be more intensely uptaken by plants. At a pH> 6, the dominant forms of Cr(VI) include: $HCrO_4^-$; $Cr_2O_7^{2-}$ and CrO_4^2. In contrast, Cr(III) ion has a lower solubility, and is available to plants only at biological pH values, if complexed to organic complexes of low molecular weight. Of the tested genotypes, the highest average Cr contents were found in the vegetative biomass of both barley cultivars (1.4 mg/kg in ‘Jagodinac’, range 0.5-2.2 mg/kg, and 1.1 mg/kg in ‘Grand’, range 1.0-1.3 mg/kg). In the other two genotypes of small grains (oat and triticale), the average contents and ranges of Cr were the same (0.5 mg/kg and 0.4-0.6 mg/kg, respectively), which is in agreement with the results obtained by other authors (Pelivanoska et al., 2011).

As reported in the literature, the average critical and toxic concentrations of Cr in crops are 1.0 mg/kg and 2.0 mg/kg dry matter, respectively (Pelivanoska et al., 2011), with the maximum tolerable level in feed of 3000 μg/g for chromium oxide and 1000 μg/g for chromium chloride (Vapa, 1997). The results and limit values for critical and toxic contents indicate that Cr content in the vegetative biomass of barley cv. ‘Jagodinac’ in the control and NPK fertiliser treatment was above toxic concentrations, due to which the vegetative biomass could not be used for safe food production. Toxic effects of Cr on plant growth and development include alterations in the germination process as well as in the growth of roots, stems and leaves, which may affect total dry matter production and yield. Cr also causes deleterious effects on plant physiological processes such as photosynthesis, water relations and mineral nutrition (Shanker et al., 2005). Toxic amounts of Cr lead to plant stress due to the impeded absorption of almost all nutrients in the aboveground portions and K, P, Fe and Mg in the root (Kabata Pendias, 2011). Chatterjee and Chatterjee (2000) reported that an excess of Cr in plants caused poor protein formation resulting from the disruption of the N metabolism. Increased level of Cr^{6+} in nutrient solution decreased CO_2 assimilation and other

parameters associated with the photosystem of Lolium perenne leaves (Vernay et al., 2007). Conversely, the content of Cr in the other vegetative biomass samples was below critical levels, except in barley genotype ‘Grand’ where Cr levels were above critical and below toxic values. Previous literature data show that very low Cr levels of 1 to 2 mg/kg inhibits the growth of sensitive plant species (Kloke et al., 1984) and**can reduce dry biomass yield of plants by 10% (Jakšić et al., 2013).

* i ** *and* ** *= Significance for* F_{tab} *0,05 i 0,01*

The results of the present research show high differences in Cr accumulation between the aboveground portions and the kernel of small grains. Chromium is known to have poor availability for plant uptake, and its concentrations in plants are very low, ranging from 0.2 to 0.4 mg/kg (Pelivanoska et al., 2011). Chromium is slightly available to plants and not easily translocated within plants, thus it is concentrated mainly in roots, apparently because of the propensity of Cr^{3+} to bind to cell walls (Zayed et al., 1998). The amount of chromium in the aboveground portions of plants was higher than in the kernel, as follows: control - 3.70; NPK – 4.72; N+$CaCO_3$ – 1.79; NPK+$CaCO_3$ – 2.5; NPK+$CaCO_3$ +farmyard manure - 4.8. The highest effect on Cr mobility was produced by NPK fertilisers and manure. Under NPK+$CaCO_3$+manure treatment, its mobility was the lowest, since these fertilisers reduce chromium mobility (DTPA-extraction) (Singh et al., 2007). High application rates of organic, lime and phosphorus fertilisers are important in terms of environmental and health impacts as they mitigate the phytotoxic effects of Cr.

Conclusion

The Cr contents of the tested small grain samples suggest the following:

-Cr concentrations in the aboveground portions of the vegetative biomass and kernel of small grains varied considerably depending on genotype and fertilisation treatment.

-The results and limit values for critical and toxic contents indicate that Cr content in the vegetative biomass of barley cv. ‘Jagodinac’ in the control and NPK fertiliser treatment was above toxic concentrations, due to which the vegetative biomass could not be used for safe food production. In other samples, Cr content was below critical and toxic concentrations. Accordingly, the tested samples satisfied quality requirements with respect to Cr content.

-In terms of environmental and health impacts, the use of fertilisers, organic ones in particular, resulted in the reduction of Cr(VI) to Cr(III) and, hence, led to its decreased

solubility and toxicity, thus reducing its negative effect on plants and animal and human health.

-In all tested small grain genotypes, under all fertilisation treatments, Cr contents in the kernel were considerably lower than in the vegetative biomass, due to poor mobility and translocation, and were below critical and toxic levels. Therefore, the tested genotypes satisfied quality criteria with respect to Cr content.

THE ROLE OF BIOFERTILIZATION IN IMPROVING APPLE PRODUCTION

Marijana PEŠAKOVIĆ*, Jelena TOMIĆ, Rade MILETIĆ, Milan LUKIĆ, Žaklina KARAKLAJIĆ-STAJIĆ

Abstract

Intensive agricultural production and increased synthetic nitrogen inputs affect environment through pollution with nitrogen metabolites. Over the past years, fruit growing practice has been focused on new concept which relies primarily on the application of microbial inoculants i.e. biofertilizers for gaining high yields and quality of fruits. In line with the concept, we conducted comparative study of the impact made by bio- (PGPR 1 and PGPR 2) and chemical fertilizers (Multi-Comp Base 14-13-20+2MgO+ME) on the yield-related characteristics of three apple cultivars (‘Gloster’, ‘Morens Jonagored’, ‘Hapke Delicious’). In addition, the paper presents the results related to the soil biological properties in the rhysosphere of the above-mentioned cultivars. The microbiological properties of soil were monitored by determining the total microbial count, numbers of soil fungi, actinomycetes, oligonitrophilic bacteria and azotobacter. The yield-related characteristics of the tested plants were evaluated for generative potential parameters i.e flowering intensity, fruit set intensity, final fruit set intensity and yield (kg tree^{-1}; t ha^{-1}).

The analysis of the results points to the fact that the introduction of biofertilization in apple production can meet the basic principles of sustainable agriculture, i.e. sustain stability and quality of yield, while at the same time preserving the ecological balance.

Key words: *biofertilization, apple, soil biological properties, generative potential*

Introduction

In recent years, intensive development of agricultural production has been directed towards optimisation of agro-technical measures in accordance with the modern trends of sustainable growth. Concerning these observations, Styła and Sawicka (2009) point out that improper implementation of agro-technical measures may cause disturbances in the functioning of the entire agro-system, with a negative impact on the development of soil microorganisms and fertility of farming land.

Nitrogen element (N_2) is the major component in the earth's atmosphere (approximately 80%). It is an essential element for most biochemical compounds in plants (proteins, nucleic acids, phytohormones, vitamins, etc.) which actively participate in biological processes responsible for growth and production. However, N_2 cannot be incorporated directly in plants' biological systems. In order to achieve this, it needs a reduction reaction – either chemically by adding hydrogen element to it or by recycling N_2 from the unavailable atmospheric form to available forms in the biosphere using the intermediary (Nitrogen fixing bacteria). In relation with this and to the purpose of securing a more efficient supply of fruits with necessary biogenic elements, apart from highly soluble chemical fertilisers, there is a recent trend of using microbial inoculants – biofertilizers. Abd El-Gleel Mosa et al. (2015) report that the biofertlization of fruits as a method of fertilization is considered a healthy alternative and/or supplement to mineral fertilizers. .

The active biological roles of N element on metabolism activities in fruit trees, with special emphasis on yield production, fruit quality and improving performance of roots, make N-fertilizers some of the most widely used fertilizers in the world (Mengel and Kirkby, 1987;

Westwood, 1993; Raese and Drake, 1997). In order to achieve and maintain the optimum balance between the growth and productivity in fruits, it is necessary to apply adequate combinations of pomo-technical measures and nutrition methods. Stiles and Reid (1991) state that a manifestation of deficiency symptoms or some of the toxicity symptoms related to excessive application of fertilizers, the plants are far from their optimum nutrition regime, either from the physiological or the economic and environmental point of view. In order to establish and maintain the optimum fertilisation regime of fruits, it is therefore necessary to monitor various parameters of growth in the plantations, from the early spring until the fruit-bearing season, while sustaining regular checks of the soil's productive capacity (Miller, 2002).

The generative potential of the apple is determined by numerous biotic and abiotic factors. According to Keserović et al. (2012), the main factors with an impact on bud formation are nutrition, foliage development, presence of fruits and seeds in fruits, as well as the growth of lateral shoots. On the other side, there are numerous references in the literature related to studies of the apple productivity, which point to the significant impact made by the genotype on this particular quality.

The aim of this paper is to examine the impact made by the fertilizer and apple genotype on microbiological activity of the soil and the most significant parameters of generative potential.

Material and method

The study included cultivars 'Gloster 69', 'Morens Jonagored', 'Hapke Delicious' and was conducted in the period 2011–2012, at the apple production plantation of the Fruit Research Institute in Čačak (west-central Serbia). The plantation was set up in 2006, using standard one-year-old plantings grafted on the M9 rootstock, planted at the 4 x 1 m planting distance (2.500 trees per ha^{-1}). The plantation was treated with standard pomo-technical and agro-technical measures, in accordance with the requirements of the apple as the fruit.

In the course of the study, two types of fertilizer were used – the chemical fertilizer (Multi-Comp Base 14-13-20 + 2MgO + ME) and two bio-fertilizers (PGPR 1 and PGPR 2).

The Multi-Comp Base 14-13-20 + 2MgO + ME is a highly soluble chemical fertilizer from the 'Haifa Chemicals Ltd' production programme. PGPR 1 represents a pure culture of *Gram*-negative nitrogen-fixing bacteria *Klebsiella planticola* TSHA-91. The bacteria titer in the inoculum was in the range 20-40 x 10^6 cm^{-3}. PGPR 2 is a microbiological fertilizer which contains bacteria of the *Azotobacter, Derxia, Pseudomonas* and *Bacillus* genera, as well as natural vitamins, enzymes and growth stimulators.

The fertilizers were applied using the drip irrigation system (in a concentration of 0.3% with 30 mm water (30 l /m^2)), applying the Venturi pipe, in three periods during the vegetation period (between the end of June until beginning of August). The irrigation periods were determined taking into consideration the condition of soil moisture, which was recorded using a tensiometer, as well as precipitation data.

Soil samples for microbiological analysis were taken at the end of the vegetation season. The microbiological analysis were performed in the Microbiology Laboratory of the Fruit Research Institute in Čačak, comprising determination of total numbers of microorganisms and numbers of fungi, using the method of dilution at corresponding solid culture media (Pochon and Tardieux, 1962). The total numbers of microorganisms were established on the media, for the total number of microorganisms. To determine the total numbers, 0.5 *mL* 10^{-6} of soil dilution was used. The number of soil fungi was determined using Chapec agar, whereas the number of actinomyces was determined on the synthetic Krasilnikov agar (1949); the number of oligonitrophilics and azotobacter was determined using the Fiodorov media. These groups of microorganisms were planted with 0.5 *mL* 10^{-5} of diluted soil suspension, except for azotobacter, where the planting was performed using the method of

fertile droplets with 0.2 *mL* suspension 10^{-2}. The incubation was performed over 7 days for the total numbers of microorganisms and actinomyces, over 5 days for fungi, 4–5 days for oligonitrophilics and 2 days for azotobacter, at the temperature of 28°C. The numbers off microorganisms have been calculated as per 1.0 *g* of absolutely dry soil.

Determining the intensity of flowering, as well as of the initial and final fruit set was accomplished using a 1-5 point scale. Yield per tree and unit of area was determined during the phase of physiological maturity by measuring the fruit mass and is expressed in kg tree^{-1}, i.e. t ha^{-1}.

The data was subjected to analysis of variance (ANOVA) using MSTAT-C statistical computer package (Michigan State University, East Lansing, MI, USA). The Least Significance Difference (LSD) was used to compare treatment means and treatments declared different at $p = 0.05$ level of significance.

Results and discussion

Table 1 shows the results obtained in the study of the impact made by the applied fertilizer and genotype on the total numbers of microorganisms, fungi, actinomyces, azotobacter and oligonitrophilics in the soil of the experimental apple orchard.

Table 1. Impact made by the fertilizer and genotype on the overall number of microorganisms, number of fungi, actinomyces, azotobacter and oligonitrophilics in the soil of the experimental apple plantation

The results of the variance analysis revealed a significant impact on the total number of microorganisms, number of actinomyces and oligonitrophilics, whereas the genotype had an important impact on the number of all of the analysed groups of microorganisms, with the exception of oligonitrophilics. A significant impact made by the interaction effect of the fertilizer/genotype was recorded only in the number of fungi in the soil.

Barabasz & Vořišek (2002) believe that rational chemical fertilization has a favourable effect on plant yielding. It must be stressed, however, that incorrect agro-technical treatments and irrational application of fertilization may cause disturbances in the functioning of the whole agrosystem and contribute to the development in soil environments of different noxious compounds (nitrozoamines, mycotoxins) acting unfavourably upon soil microorganisms, as well as upon cultivated plants and fertility of arable soils. Myśków and Kobus (1986), Wołoszyk and Nowak (1993), Myśków et al. (1996) found that repeated chemical

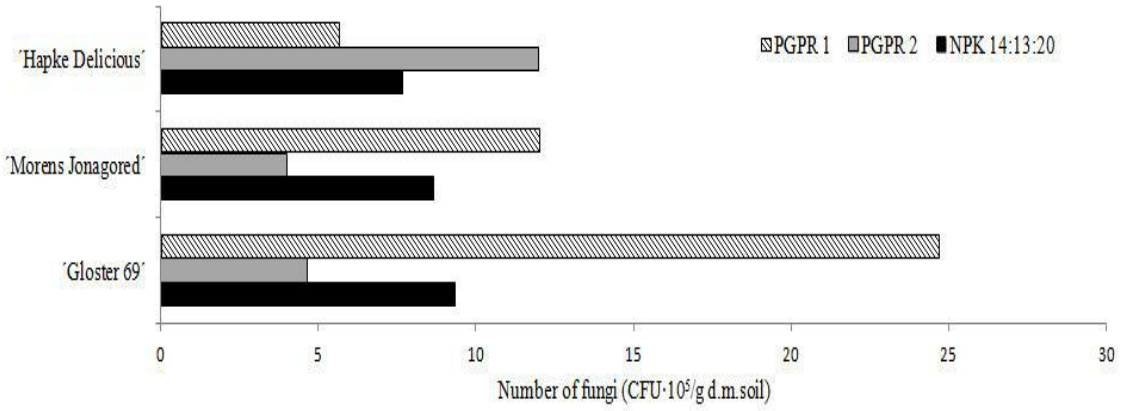
fertilization, particularly with high doses of nitrogen, can cause strong acidification of soils and increase the development of fungi which is in accordance with our results. Myśków et al. (1996) have found that the development of microfloral communities in the soil depends also on the type of the applied nitrogen fertilizer. These authors confirmed in their studies the presence of the greatest number of fungi in the soil fertilized with ammonium sulphate.

The values for the total number of microorganisms were in the range between 14.20 and 44.00. The largest total number of microorganisms was determined in the PGPR 1 treatment (44.00), which was considerably higher compared the chemical fertilizer treatment (22.29) and treatment with PGPR 2 (15.29). As for variances among the cultivars, significant differences in the total number of microorganisms in the rhizosphere were determined only between cv. ‘Hapke Delicious’ (41.11) and cv. ‘Gloster 69’ (14.20).

The number of fungi in the rhizosphere of the examined apple cultivars ranged between 5.44 and 12.89. Significant differences in the number of fungi in the soil existed between the ’Hapke Delicious’ and ‘Morens Jonagored’ cultivars, which can be explained by the differences in the exudates production. Comparing the interaction effects of the applied fertilisers and the genotypes involved, a significantly larger number of fungi was recorded in the PGPR 1 treatment in cv. ‘Gloster 69’ (Graph 1).

A significantly higher number of actinomyces in the apple rhizosphere was recorded in the PGPR 1 treatment (38.56), whereas the best results from the aspect of genotype effect were demonstrated by cv. ‘Hapke Delicious’ (46.22). The number of azotobacter in cv. ‘Gloster 69’ (10.00) was significantly higher, compared to cvs. ‘Morens Jonagored’ and ‘Hapke Delicious’ (6.67 and 6.22, respectively).

The most favourable impact on the number of oligonitrophilics in the apple rhizosphere as made by the chemical fertilizer and PGPR 2 (19.56 and 18.22, respectively), whereas the lowest number of oligonitrophilics was recorded in the treatment with PGPR 1 (8.78).



Graph 1. Impact made by interaction effect fertilizer/genotype on the number of fungi in the soil of the experimental apple plantation

Based on the results obtained in studying the parameters of the apple generative potential (Table 2), it can be inferred that the fertilizer, genotype and their interaction effect made no significant impact either on the intensity of flowering or the initial and final fruit set.

Table 2. Impact made by the fertilizer and genotype on the generative potential parameters in apple

Factor		Flowering intensity (1–5)	Fruit set intensity (1–5)	Final fruit set intensity (1–5)	Yield (kg tree^{-1})	Yield (t ha^{-1})
Fertilizer (A)	NPK 14:13:20	3.56±0,33 a	2.57±0.32 a	2.10±0.29 a	7.99±1.64 a	20.04±4.09 a
	PGPR 2	2.97±0.28 a	2.13±0.24 a	1.97±0.17 a	8.15±1.35 a	20.38±3.37 a
	PGPR 1	3.63±0.26 a	2.40±0.33 a	2.33±0.18 a	8.32±1.10 a	20.79±2.76 a
Cultivar (B)	‘Gloster 69’	3.20±0.26 a	2.57±0.17 a	2.20±0.09 a	11.66±1.37 a	29.21±3.39 a
	‘Morens Jonagored’	3.13±0.37 a	2.40±0.36 a	2.17±0,30 a	6.82±1.04 b	17.04±2.60 a
	‘Hapke Delicious’	3.83±0.22 a	2.13±0.33 a	2.03±0.23 a	5.98±0.65 c	14.96±1.63 b
ANOVA						
A		ns	ns	ns	ns	ns
B		ns	ns	ns	*	*
A × B		ns	ns	ns	ns	ns

The variance analysis revealed that significant differences in the measured yield per tree and yield per ha existed only between the examined cultivars. A significantly higher yield per tree was determined in cv. ‘Gloster 69’ (11.66 kg tree^{-1}), compared to the two other cultivars under consideration. In addition to this, the highest yield per ha was determined in cv. ‘Gloster 69’ (29.21 t ha^{-1}), which was not considerably different compared to the yield of cv. ‘Morens Jonagored’. The lowest yield per unit of area was recorded in cv. ‘Hapke Delicious’ (14.96 t ha^{-1}). Similar conclusions were made by Aslantaş et al. (2007) in their study of the rootstock (M9, MM106), of the cultivars under consideration (‘Granny Smith’ and ‘Stark Spur Golden’) and the impact made by PGPR (OSU-142, OSU-7, BA-8 i M-3) on apple growth and yield. Favourable effects of sensible application of fertilizers on the volume of yield have been further confirmed by the results obtained by Barabasz and Vořišek (2002).

Conclusion

Based on the results obtained in the research, it is possible to reach the following conclusions:
The most favourable impact on biological activity of the soil in the apple plantation was achieved in the treatment deploying PGPR1;
The most favourable effect of the genotype on the biological activity of the soil was determined in cv. ‘Hapke Delicious’;
The most favourable interaction effect was determined in the PGPR 1/‘Gloster 69’ combination.
The largest yield per tree and unit of area was obtained in cv. ‘Gloster 69’.

The analysis of the results points to the fact that the introduction of biofertilization in apple production can meet the basic principles of sustainable agriculture, i.e. sustain stability and quality of yield, while at the same time preserving the ecological balance.

Abstract

Physiological and morphological traits of seed and their variability in dependence on the growing location were studied in 2014. The analyses were carried out on hybrid seed of three commercial hybrid combinations produced in three locations. The following seed traits were observed under laboratory conditions: germination energy, total germination and 1000-seed weight. The highest, i.e. lowest values of germination and germination energy were recorded in the hybrid H3, i.e. H1, respectively. The greatest 1000-seed weight was detected in the hybrid H3. With regard to the growing location, the highest values of germination and germination energy were recorded in the location B (97.166%), while the location A was most suitable for the expression of 1000-seed weight. The greatest 1000-seed weight amounted to 394.67 g. The hybrid combination × location interaction significantly affected all three traits. The highest energy and germination were recorded in the hybrid H1 in the location B. The hybrid combination H2 and the location C had the highest effect on 1000-seed weight. This trait mostly varied in the hybrid combination H3 in the location C. Average values of germination energy, total germination and 1000-seed weight very significantly depended on the hybrid combination and the growing location.

Key words: *hybrid, location, seed trait*

Introduction

Hybrid maize seed is produced under diverse agro-ecological and agro-technological conditions and therefore traits of such seed depend on many factors: genotypic combinations of parental inbreds, coincidence of flowering times of parental inbreds, duration of pollination in seed crops, duration of seed filling, duration of maturation of formed and filled seed, moisture content in physiologically mature seed at harvest, seed maturation, seed infection by disease-causing agents, presence of pests. It was determined that numerous factors affect the process of maize seed germination both, individually and interactionally, while obtained results refer to seed as an entity (*Antonić et al., 2003, Dačić et al., 1997, Sabovljević et al., 1997.*). Agro-ecological conditions depend not only on meteorological and edaphic conditions in a region but also on applied cropping practices in the production of seed crops. Furthermore, all traits of hybrid maize seed depend on a genotypic combination and interactions of this combination with agro-ecological conditions during the growing season of seed crops. *Lee et al. (2002)* presented important differences in cold tolerance related to a genotype. These differences manifested in different rates of the root development but also in development rates of the above-ground shoots. Based on the stated, traits of produced hybrid maize seed depend on procedures absolutely controlled by humans, on ecological conditions influenced, to a certain extent, by humans, on traits of parental inbreds and on interactions among all stated factors.

The aim of the present study was to observe effects of growing locations on physiological and morphological traits of maize seed: germination energy, total germination and 1000-seed

weight, as well as, their variatons in relation to the production region in the year of investigation.

Material and Methods

The study was carried out with three commercial single-cross combinations of maize of different FAO maturity group (FAO 300, FAO 400 and FAO 600) derived at the Maize Research Institute, Zemun Polje.

Hybrid seed of the F1 generation for each hybrid combination was produced in three locations, during 2014: SC341(H1) - Sanad (A), Žarkovac (B) and Feketić (C), SC427 (H2) - Sanad (A), Žarkovac (B) and Sivac (C), SC666 (H3) - Sanad (A), Žarkovac (B) and Feketić (C). In the production of seed crops, all standard and prescribed cropping practices and procedures were applied in due time and in the right way in each of locations. Harvest of seed ears was done by maize pickers. Husking was performed immediately prior to artificial drying. After drying, ears were shelled and the natural seed material was cleaned. Submitted samples of 25-30 kg were drawn out of natural seed material for each hybrid combination and each production location. Non-destructive methods were applied to study hybrid maize seed. Seeds were observed and evaluated as entities. Total germination, germination energy and 1000-seed weight were determined under laboratory conditions according to the Regulation on Seed Testing Quality of Agricultural Crops 47/87 and ISTA Rules (currently valid edition). The standard method for total germination and germination energy was applied (t_1=20/30^{o}C and (16:8) light : dark photoperiod). The first, i.e. final count were done on the forth, i.e. seventh day, respectively.

Each of obtained parameters was statistically processed by descriptive statistics for parameters at the annual level. Differences among analysed maize hybrids as well as their interactions were evaluated by the analysis of variance. Gained experimental data were processed by the appropriate mathematical and statistical methods using the statistic package STATISTICA 10.0 for Windows.

Results and Discussions

Table 1 illustrates data of means of qualitative and quantitative seed traits. In all three hybrids and in each of three locations standards prescribed by the Regulation on Seed Testing Quality of Agricultural Crops were met, except for H1 in the location A (germination energy was bellow 90%). Results obtained in the fields and the laboratory confirmed better germination and germination energy at higher temperatures (*Sabovljević et al.,* 1997; *Rosić*, 1959; *Popović*, 1982; *Pinnel*, 1949). According to Živanović et al. (2012), Marić et al. (2013) daily temperatures in the stage of germination and emergence should be 8-10^{o}C for germination and 10-12^{o}C for emergence in order to have successful maize production. The expression of germination energy and total germination in this study was uniform, with variations less than 2.1%, while the third observed trait was characterised by a significantly greater variation in relation to both factors. The analysis of the first factor (hybrid combination) shows that the hybrid H3 had the highest mean for germination energy and germination of 96.9%, while 1000-seed weight amounted to 432.6 g in the hybrid H2. Furthermore, the analysis of different groups of hybrids points out to the effect of a hybrid combination on germination and germination energy (*Tabaković et al., 2015*). The best conditions for germination energy and total seed germination were registered in the location B with the mean of these traits amounting to 97.2%. The highest mean value of 1000-seed weight (394.6 g) was estimated in the location A. *Shien* and *Mc Donald* (1982) determined the influence of seed size, shape and treatment on seed quality of two inbred lines.

A, B, C - location, H1, H2, H3 - hybrid combination, ge - germination energy, g - total germination, sw - 1000-seed weight, $\overline{X}$-mean, $S\overline{x}$-standard error

The effect of hybrid combinations and locations on studied physiological and morphological traits was determined by the two-factorial analysis of variance (Table 2). The statistically significant difference among observed groups of hybrids and locations was estimated at the $p<0.05$. Moreover, the influence of interactions of factors on the expression of seed traits was also determined ($F=23.25$, $p<0.05$, $F=19.12$, $p<0.05$). An effect size measure was done by partial eta-squared. The eta-squared values ($\eta=0.535$, $\eta=0..486$) point to great effects of hybrid combinations and locations on trait variances. The highest partial effect was estimated for the hybrid combination on 1000-seed weight ($\eta=0.542$).

Table 2. Two-factorial analysis of variance and partial eta-squared

Factor	Seed trait	d.f.	Mean squares	F-test	Partial eta-squared
hybrids	germination	2	49.411	9.882*	0.196
	energy	2	81.378	9.309*	0.187
	1000-seed weight	2	78756.908	47.852*	0.542
location	germination	2	192.144	38.429*	0.487
	energy	2	258.411	29.560*	0.422
	1000-seed weight	2	9718.047	5.905*	0.127
hybrids * location	germination	4	116.294	23.259*	0.535
	energy	4	167.161	19.122*	0.486
	1000-seed weight	4	3630.965	2.206	0.098

Additional comparisons using the $LSD_{0,05}$ test (Table 3) indicated that means for all three traits differed significantly over hybrids, except in germination energy between the second and the third hybrid. The significant differences in germination energy were also detected between the locations A and B and A and C. On the other hand, significant differences in 1000-seed weight were recorded only between locations A and C.

g-total germination, ge- germination energy, sw- 1000-seed weight

Conclusion

Studies on physiological and morphological seed traits showed that these traits are commercially important. An appropriate number and arrangement of plants in mercantile crops of maize hybrids are primarily provided by sowing seeds of good physiological, physical and mechanical traits. Our studies pointed out that variations in seed traits depended not only on genetically predetermined limits, but also on different production conditions. Effects of hybrid combinations and locations were great on all traits. According to obtained results, germination energy and total germination were more dependent on production conditions, i.e. locations (η=0,487 and η=0,422, respectively), while 1000-seed weight depended more on genetic performances of a hybrid combination (η=0,542). The significance of a hybrid combination and a location was confirmed by the analysis of variance, while the significance of obtained differences was confirmed by the LSD test.

Abstract

Besides it is a significant cereal for bread making, rye is characterized by favorable nutritive properties. Furthermore, it also can be used as feed, then for production of alcohol, starch and vinegar, cellulose, lignin, while rye germ is used in pharmaceutical industry. This study has been aimed to investigate the effect of soil cultivation depth on some morphological and productive traits of winter rye in hilly and mountain areas of north Kosovo. The trial was carried out during 2009/10 and 2010/11 in mountain area of north Kosovo, at 630 m of altitude. It was set in random complete block design with three replications. Cultivar of winter rye Raša was used for the trial. Three depths of soil cultivation were investigated (disc harrowing to 10-15 cm of depth, plowing to depth of 20 cm and plowing to depth of 30 cm). Dependence on tillage depth of the following parameters was observed: plant height, spike length, number of grains per spike, absolute mass of grain, hectoliter mass of grain and grain yield at 14% of moisture. The data were collected for both years and statistically processed by analysis of variance. Results of the study showed that soil cultivation depth had significant effect on the all investigated parameters. Significant differences were observed in plant height, spike length and number of grains per spike between the variant where tillage was done only by disc harrowing and the variant with plowing to 20 cm of depth. Absolute and hectoliter mass of grain were the highest in tillage to 30 cm of depth, with significant differences only in regard to disc harrowing, while between disc harrowing and plowing to depth of 20 cm there was not any statistically significant difference. Grain yield was the highest in tillage to 30 cm of depth (2450 kg ha^{-1}) and was significantly higher in regard to tillage only by disc harrowing (1840 kg ha^{-1}). There was no statistically significant difference in grain yield between plowing to 20 and 30 cm of depth. In order to get rye grain yield of a satisfactory level, one should not do soil cultivation at depth lower than 20 cm.

Key words: *rye, number of grains per spike, absolute mass, hectoliter mass, grain yield*

Introduction

Rye (*Secale cereale L.*) is an annual plant from the family *Poaceae*. It is important as bread making cereal crop, especially in northern parts of Russia and northern Europe (Poland, Germany, Sweden, etc). Bread made of rye is tasteful, nutritious, and can keep freshness for a long time. It contains lower amount of starch than wheat, so bread made of rye is recommended in diet for diabetics. It is also an excellent forage crop, regardless as green forage, or as bran, flour and grain. Straw is good for house roofs, and for making straw hats or mattings. Rye also can be used for production of alcohol, starch and vinegar, cellulose, lignin, while rye germ is used in pharmaceutical industry. Rye is very rich by vitamins A, B and E, and has a great importance, so as human and animal food, as in industry (Oelke, 1990).

Among the other cereal crops, the total area sown by rye in the world is at the sixth place, just behind wheat, maize, rice, barley and oats (Todorović and Komljenović, 2009).

In our country rye is more rarely grown than the other small grain crops, but recently there is a greater interest for its growing. According to Jevtić (1992), the average rye grain yield in

countries of former Yugoslavia is quite low, which means that rye production did not earn enough attention, so in choosing genotypes as concerning agrotechnique.
The data reported by Biberdžić et al. (2011) point that rye has good competitive properties and the lowest degree of weed infestation comparing with the other small grain crops.
This study has been aimed to investigate the effect of soil cultivation depth on some morphological and productive traits of winter rye in hilly and mountain areas of north Kosovo.

Material and methods

The trial was carried out during 2009/10 and 2010/11 in mountain area of north Kosovo, at 630 m of altitude. It was set in random complete block design with three replications. Cultivar of winter rye Raša was used for the trial. Previous crops were fertilized by 20 t ha^{-1} of manure each, while mineral fertilizers and chemical preparations for plant protection were not applied. Sowing was carried out during the last decade of October, and previous crops were potato and maize. Three depths of soil cultivation were investigated (disc harrowing to 10-15 cm of depth, plowing to depth of 20 cm and plowing to depth of 30 cm). Dependence on tillage depth of the following parameters was observed: plant height, spike length, number of grains per spike, absolute mass of grain, hectoliter mass of grain and grain yield at 14% of moisture. The data were collected for both years and statistically processed by analysis of variance, while statistical significance was estimated by LSD test.

Soil conditions

Table 1.Chemical properties of the soil

Depth (cm)	pH		Humus	N	P_2O_5	K_2O
	H_2O	KCl	%	%	mg/100 g	mg/100 g
0-20	6.23	4.80	4.66	0.233	11.33	27.84

The data presented in table 1 point to the soil as an acid one. It is well-supplied by humus and nitrogen. Good humus supply is caused by application of manure in the previous years. Phosphorus content is low, at the line between poor and moderate supplied soils, while this soil is well-supplied by potassium. Although this soil has been acid, Nožinić et al. (2009) reported that rye genotypes have been tolerant to extremely acid soil environment, giving satisfactory grain yield in extremely droughty years.

Results and discussions

Rye grain yield, as well as one of the other grain crops, depends on many factors, primarily on cultivar, agroclimatic conditions of the area observed, agrotechnique, etc. One of important production factors is agrotechnique, especially tillage and soil preparation. Often, for many reasons (previous crop, shortage of time and machinery), we are not able to do basic soil cultivation on time. Therefore, not so rare, basic soil cultivation is avoided or minimized, which can cause a low and unstable grain yield. Table 2 gives the influence of tillage depth on some morphological traits of winter rye.

Table 2. Morphological traits of the rye, depending of tillage depth

Tillage depth (variants)	Morphological traits of the rye	
	Plant height (cm)	Spike length (cm)
Disc harrowing to depth of 10-15 cm	131.2	10.5
Plowing to depth of 20 cm	138.0	11.8

Plowing to depth of 30 cm	141.4	12.4
Average	136.8	11.5
LSD 0.05	4.45	1.25
LSD 0.01	6.74	1.89

Soil cultivation depth had significant effect so on plant height, as on spike length and number of grains per spike. The average rye plant height for the all cultivation depth values was 136.8 cm. The highest one was observed in soil cultivation variant III, amounting 141.4 cm, and the lowest one in the tillage variant I, where it was 131.2 cm. Rye plants from cultivation variants II and III had high-significantly greater plant height in regard to the plants of tillage variant I, while between variants II and III there was not any significant difference.

Plant height is an important trait, because plants with lower stem are more resistant to lodging. Milovanović et al. (2005) stated that this cultivar is 140 cm high in average, and shows a good resistance to lodging.

The average spike length amounted 11.5 cm. The lowest spike length (10.5 cm) had plants from tillage variant I, and it was significantly lower in regard to the plants from variant II, and high-significantly lower in regard to the plants from tillage variant III. There was not any significant difference in spike length between plants from tillage variants II and III.

Table 3 gives number of grains per spike, absolute and hectoliter mass of rye grain, that are important physical grain properties, as well as rye grain yield, desired by the all rye producers. Tillage depth showed significant effect on all the mentioned parameters.

Number of grains per spike is a very important and, besides number of plants per square unit and absolute mass of grain, one of the three crucial factors for total grain yield amount. The highest number of grains per spike (52.5) had plants from soil cultivation variant III, and the lowest one (46.3) plants from tillage variant I. There was not any significant difference between tillage variants II and III.

Absolute mass of grain is one of the three crucial factors influencing total amount of rye grain yield. It ranged from 39.3 g in tillage variant I to 41.8 g in tillage variant III. Absolute mass of grain achieved in soil cultivation variant III was high-significantly greater in regard to the cultivation variant I. There was not any significant difference in absolute mass of grain between tillage variants I and II, as well as between variants II and III. Hectoliter mass, as a parameter of grain largeness and fulfillment, showed similar tendency as absolute mass of grain.

Table 3. Important productive traits of the rye, depending of tillage depth

Tillage depth (variants)	Productive traits of the rye			
	No of grains per spike	1000 grain mass (g)	Hectoliter mass (kg)	Grain yield (kg ha^{-1})
Disc harrowing to depth of 10-15 cm	46.3	39.3	72.6	1840
Plowing to depth of 20 cm	50.8	41.2	74.6	2330
Plowing to depth of 30 cm	52.5	41,8	75.9	2450
Average	49.8	40.7	74.3	2330
LSD 0.05	4.32	2.05	3.00	380.10
LSD 0.01	6.55	3.11	4.55	575.90

Grain yield is the trait desired by the all rye producers. Soil cultivation depth had highly significant effect on rye grain yield. So that, the highest rye grain yield (2450 kg ha-^{1}) was achieved at the cultivation variant III, and the lowest one (1840 kg ha^{-1}) at the cultivation variant I, so the difference in grain yield between tillage variants I and III was 610 kg ha^{-1}. Difference in grain yield between tillage variants I and II was statistically significant, while the difference between tillage variants I and III was statistically highly-significant. There was not any significant difference between tillage variants II and III. The reported results point to importance of soil cultivation depth in formation of rye grain yield. It is often case that rye, as the other small grain crops, is sown without basic soil cultivation, i.e. called in slang, "under the disc harrow". It is usually done when farmers are in shortage of time (late harvest of previous crop), which is often case in our conditions. Result of such procedure is much lower grain yield, which was proven by our study. Our study shows that soil cultivatition ought to be done, at least, down to 20 cm, in order to achieve satisfactory results. Previous reports state that basic soil cultivation should be done at least 15 days before sowing, at the depth of 30 cm. Reasons for lower rye grain yield observed in our investigation could be found in a later sowing term and the absence of mineral fertilizers. We must point that before previous crops 20 t ha-^{1} of manure was applied, and chemical preparations for plant protection were not applied, so this production could be considered as the organic one.

Having in mind the cultivar Raša, Milovanović et al . (2005) recommend it to be sown during the end of September and the beginning of October.

Biberdžić et al. (2011) reported that, by application of mineral fertilizers with increased dose of phosphorus, they reach rye grain yield of 2913 kg ha^{-1}. Rye grain yield observed in our study was slightly lower than the average rye grain yield in Serbia during 2009, which was 2500 kg ha^{-1} (Statistical Yearbook of Serbia, 2010). Oljača et al. (2011) stated that the best rye grain yield can be reached by combined application of organic biostimulators and soil improving agents.

Conclusions

On the basis of the study we can conclude the following:

Tillage depth showed a significant effect on the all studied parameters;

Plant height, spike length and number of grains per spike at variants II and III of soil cultivation had significantly higher values in regard to those from variant I of soil cultivation;

Absolute and hectoliter mass observed in tillage variant III was significantly higher than in tillage variant I, while between tillage variants I and II, as well as between variants II and III, there was not any statistically significant difference;

Difference in grain yield between soil cultivation variants I and II was statistically significant, while difference between variants I and III was highly significant.

Difference between soil cultivation variants II and III was not statistically significant;

The highest values of the all studied parameters were observed at the variant III of soil cultivation;

Difference between soil cultivation variants I and III amounted 610 kg ha^{-1};

The observed grain yield in tillage variant II can be regarded as satisfactory one, having in mind that no mineral fertilizers and chemical preparations were used;

In order to keep rye grain yield at a desired level, one ought to do soil cultivation at the depth between 20 and 30 cm, together with sowing during optimal terms.

POMOLOGICAL PROPERTIES AND YIELD OF INTRODUCED APPLE CULTIVARS IN THE REGION OF WESTERN SERBIA

Milan LUKIĆ*, Slađana MARIĆ

Fruit Research Institute, Kralja Petra I/9, 32000 Čačak, Republic of Serbia
*Corresponding author: milanmlukic@yahoo.com

Abstract

The paper presents the results of a three-year study into pomological properties and yield of two intense-colouring sports of ‘Gala’ and ‘Elstar’ (‘Gala Must’ and ‘Red Elstar’, respectively) and two scab resistant (‘Rajka’ and ‘Topaz’) apple cultivars which were grown under agro-environmental conditions of Čačak, Western Serbia. Regarding harvest maturity, Gala Must’ and ‘Red Elstar’ belong to the group of autumn cultivars (18th August and 2nd September, respectively), while ‘Rajka’ and ‘Topaz’ are winter cultivars (18th and 21st September, respectively). Average fruit weight ranged from 143.33 g (‘Rajka’) to 157.56 g (‘Gala Must’), height from 54.21 mm (‘Topaz’) to 61.33 mm (‘Gala Must’) and width from 67.77 mm (‘Rajka’) to 71.80 mm (‘Red Elstar’). The best fruit quality among the assessed cultivars, measured by the chemical composition, was found in the ‘Topaz’ (soluble solids content – 14.86%; total sugars and acids content – 12.50% and 0.54%, respectively). ‘Gala Must’, ‘Topaz’ and ‘Rajka’ showed high cropping potential, although ‘Gala Must’ had the highest yield (24.63 kg tree^{-1} and 61.58 t ha^{-1}). Based on overall results, the assessed cultivars may contribute to the advancement of the Serbian apple assortment, while ‘Gala Must’ and ‘Topaz’ can be recommended for commercial production.

Keywords: *Malus* × *domestica*, cultivar, sport, pomological properties, yield

Introduction

Apple (*Malus* × *domestica* Borkh.) is economically the most important species of genus *Malus* Miller in the Republic of Serbia, with the total cultivated area reaching around 43,250 ha and the average production of 259,671 tons (for the period 2009–2013; Faostat, 2015). Lukić (2006) and Milatović *et al*. (2009) reported that ‘Idared’ is still the most popular cultivar, representing around 50% in the apple assortment structure of our country. Over the last few years more intensive orchards with introduced cultivars have been established and new technologies have been applied (Nikolić *et al*., 2012).

The modern apple production demands that a cultivar have consistent yields and quality fruit, be suitable for manipulation, storage and shipping. In addition to this, from the aspect of rational use of pesticides and environmental protection, growing cultivars resistant to pests and causal agents of the most serious diseases is one of the recent trends in apple production. Brown *et al*. (1999) pointed out that in determining the commercial potential of any new apple cultivars, three questions should be asked: what quality can you obtain with this cultivar; does that quality set it apart; is that qualityconsistent. Estimates of cultivar trends for 34 major producing countries (excluding China) were published by O′Rourke (2001), who reported that the volume of production of ‘Red Delicious’, ‘Golden Delicious’ and ‘Granny Smith’ will be stable in the next few years and production of ‘Gala’, ‘Braeburn’ and ‘Pink Lady®’ will record significant gains in volume.

‘Gala’ and ‘Elstar’ belong to the group of 12 apple cultivars that are currently the most important in the world trade (Hampson and Kemp, 2003). Both cultivars are prone to producing red colour sports, whose red colour – despite the fact that it does not affect the eating quality – influences consumer decisions to buy apples and thus indirectly determines

the profits of growers (Iglesias and Alegre, 2006). Recently, there has been a growing popularity of winter cultivars of Czech origin, such as ‘Rubinola’, ‘Rajka’, ‘Goldstar’ and ‘Topaz’ (Sosna, 2014). In addition to their other features, these cultivars can be compared even with ‘Jonagold’ in terms of taste, appearance and storage properties of fruits.
Paper aims at studing the pomological (morphometric and chemical) properties and yield of two intense-colouring sports of ‘Gala’ and ‘Elstar’ (‘Gala Must’ and ‘Red Elstar’, respectively) and two scab resistant (‘Rajka’ and ‘Topaz’) cultivars in the region of Čačak (Western Serbia). Based on these results, it will be established whether agro-ecological conditions of Western Serbia are suitable for their growing, while making it possible from the practical point of view to recommend the best cultivars for commercial growing.

Materials and methods

Plant material

The study was conducted over the three-year period at the apple trial at the Preljinsko brdo facility (43°53' N; 20°21' E; 350 m above the sea) of the Fruit Research Institute, Čačak, Republic of Serbia. The trial was set up using the ‘knip’ seedlings, grafted on the M9 rootstock, at the 4 × 1 m planting distance. Slender spindle was the applied training system.
Two of the intense-colouring mutants of ‘Gala’ (‘Gala Must’) and ‘Elstar’ (‘Red Elstar’) cultivars were examined: ‘Regal Prince’ (‘Gala Must’®) is the dark-red mutant of ‘Gala’ (‘Kidd’s Orange Red’ × ‘Golden Delicious’), featuring firm, sweet and juicy fruits, discovered by Pepinieres Davodeau, Angers, France (Rutkovski *et al*., 2005); and ‘Red Elstar’ is a mutant of ‘Elstar’ (‘Ingrid Marie’ × ‘Golden Delicious’), discovered in Holland (Zeeland) in 1981, differing from the standard cultivar in its intense red colour, covering almost the entire surface of the fruit, while at the same time having the same cropping potential as ‘Elstar’ (Goddrie, 1994).
Two scab resistant cultivars developed at Institute of Experimental Botany, Experiment Station Střížovice, Czech Republic were also assessed: ‘Rajka’ (‘Champion’ × UEB 1200/1) is an early-winter, dessert cultivar with outstanding colour, good, rather sweet flavour and medium storage life (Lukić and Marić, 2012); and ‘Topaz’ (‘Rubín’ × ‘Vanda’) is a late, long-keeping apple cultivar with an excellent eating quality (Lukić and Marić, 2012).

Methods

Within the three-year period, the pomological (morphometric and chemical) properties and yield of the aforementioned apple cultivars were analysed.
Morphometric characteristics of the fruits were determined using the standard methods on a sample consisting of 75 fruits, by monitoring the following parameters: fruit weight, height and width, fruit shape index, length of stalk and number of seeds per fruit.
The following parameters were assessed in order to determine the fruit chemical composition: content of soluble solids (using the ‘Carl Zeiss’ binocular refractometer); content of total and invert sugars (according to the Luff-Schoorl method); sucrose content (calculated as the difference between the total and invert sugars, multiplied by coefficient of 0.95); content of total acids, expressed in malic acid (titration of 0.1 N NaOH with the presence of phenolphthalein as indicator); pH value of the fruit juice (CyberScan 510 pH meter).
The yield of the examined cultivars (kg tree^{-1} and t ha^{-1}) was determined by measuring the yield of individual trees of each cultivar, together with calculating the yield per unit of area.

Statistical analysis of data

The statistical significance of the quantitative values was determined using the Fisher model of variance analysis (ANOVA) of two-way factorial experiment, applying the F test for $P \leq 0,05$ and $P \leq 0,01$. In the cases when the F test revealed significance, differences of arithmetical means and their interaction effect were further tested using the test of least significant differences (LSD test)

for significance threshold of $P \leq 0,05$ and $P \leq 0,01$. SPSS statistical software package (SPSS. Inc., Chicago, IL) was used for the data analysis.

Results and discussion

Pomological properties of the introduced apple cultivars

The examined apple cultivars demonstrated a regular order of fruit ripening times over the three years of study, while it was also observed that during the second and the third years off study, the fruit maturity occurred later in the ripening season (Table 1). On the average, the earliest harvest maturity was recorded in the fruits of 'Gala Must' (18th August). This cultivar belongs to the autumn cultivars, together with 'Red Elstar' (2nd September). The latest ripening time was recorded in 'Topaz' (21st September) which, together with 'Rajka' (18th September), belongs to winter apple cultivars. Fruits of 'Gala Must' reached harvest maturity in the period between 14th and 23rd August, which is in agreement with the data reported by Milatović *et al*. (2009) for this cultivar in the central Šumadija region. The average ripening time for 'Topaz' grown in the Čačak agro-ecological conditions is earlier compared to the ripening time for the conditions in Slovenia, where according to Beber (2009) this cultivar reaches harvest maturity nine days later compared to 'Golden Delicious'. Godec (2004) also reported a somewhat later ripening time for 'Rajka' and 'Topaz' in the same region.

Table 1. Ripening time of the introduced apple cultivars

Cultivar	Ripening time			
	I	II	III	Mean
'Gala Must'	14th August	18th August	23rd August	18th August
'Rajka'	13rd September	19th September	23rd September	18th September
'Red Elstar'	29th August	3rd September	5th September	2nd September
'Topaz'	17th September	22nd September	25th September	21st September

The variance analysis of the fruit morphometric properties in the assessed cultivars reveals a significant impact made by the genotype on the parameters of fruit size, length of the stalk and number of seeds in the fruit. The year of trial also made a significant impact on all of the examined parameters, except the fruit shape index. The interaction effect cultvar/year made a significant impact on the fruit shape index, stalk length and number of seeds per fruit. The 'Gala Must' recorded the statistical largest fruit weight (157.56 g), whereas the lowest one was found in 'Rajka' (143.33 g) (Table 2). Based on the average fruit weight, all of the assessed cultivars can be classified in the category of cultivars with medium-sized fruits. The average fruit weight of 'Gala Must' is higher than the values reported by Milatović *et al*. (2009) for this cultivar (144 g). However, Rutkowski *et al*. (2005) pointed out that within the three years of study, the fruit weight of 'Gala Must' ranged between 144 g and 218 g. Blažek and Hlušičková (2007) report slightly higher values than the ones obtained for the fruit weight in our study, for 'Gala Must' (162.8 g), 'Elstar' (158.3 g), 'Rajka' (184 g) and 'Topaz' (164.6 g). According to Sosna (2014), based on the eleven-year long study, it was determined that the average fruit weight of 'Rajka' and 'Topaz' were 149 g and 135 g, respectively. The highest average fruit height was recorded in 'Gala Must' (61.33 mm), while the lowest one was found in 'Topaz' (54.21 mm). The 'Red Elstar' was characterised by the highest average fruit width (71.80 mm), whereas the smallest width was recorded in 'Rajka' (67.77 mm). Consequently, the value of the fruit shape index indicates the elongated (conical) shape of 'Gala Must' (0.88), i.e. the elongated-flattened shape of 'Rajka' and 'Red Elstar' (0.84 and 0.82, respectively), and the flattened shape of 'Topaz' (0.77). The 'Gala Must' recorded statistically largest length of the fruit stalk (30.77 mm), which is important from the aspect of the strength of bond between the fruit and the bearing branch, especially in the conditions

marked by the absence of chemical thinning of flowers/fruits. The largest number of seeds was found in the fruit of ‘Red Elstar’ (10.16). According to Uemura *et al*. (2001), this parameter has an impact on the final fruit set, as well as on the morphometric characteristics of the fruit.

Table 2. Fruit morphometric properties and yield of the introduced apple cultivars

Parameter		Fruit weight (g)	Fruit height (mm)	Fruit width (mm)	Fruit shape index	Stalk length (mm)	Number of seeds	Yield kg tree^{-1}	Yield t ha^{-1}
Cultivar (A)									
‘Gala Must’		157.56	61.33	69.94	0.88	30.77	7.26	24.63	61.58
‘Rajka’		143.33	57.07	67.77	0.84	24.69	8.10	20.94	52.35
‘Red Elstar’		149.42	58.62	71.80	0.82	25.44	9.16	12.42	31.05
‘Topaz’		145.36	54.21	70.46	0.77	28.78	10.16	21.52	53.79

The variance analysis revealed that the parameters of fruit chemical composition are determined by both the genotype and the year of trial. The interaction effect cultivar/year made a significant impact on the contents of sucrose and total acids. Cultivar ‘Topaz’ recorded the highest soluble solids content (14.86%), as well a total and invert sugars and sucrose (12.50%, 8.36% and 3.87%, resp.) (Table 3). The average content of soluble solids in ‘Topaz’ fruits was slightly higher compared to the values reported by Beber (2009) and Blažek and Hlušičková (2007), which fall within the range of 12−13.5%, i.e 13.1%. According to Soska and Tomala (2006), the content of soluble solids in ‘Gala’, ‘Elstar’, ‘Rajka’ and ‘Topaz’ is equable (13.5%, 14%, 13.8 % and 13.8%, resp.), whereas Blažek and Hlušičková (2007) reported this parameter at 13.6% for ‘Gala Must’ and 14.2% for ‘Elstar’. The highest content of total acids was found in ‘Topaz’ (0.54%), accompanied by the lowest pH value of the fruit juice (3.49%). Based on the content of total acids in the fruit, the ‘Gala Must’ (0.28%) can be classified within the group of sweet-fruit cultivars, whereas ‘Rajka’ (0.38%) belongs to the moderately sweet-frut cultivars, compared to ‘Red Elstar’ (0.52%) and ‘Topaz’ (0.54%), which belong to the group of cultivars with mildly acidic fruits.

Table 3. Fruit chemical properties of the introduced apple cultivars

Parameter		Soluble solids (%)	Sugar content (%)			Total acids (%)	Fruit juice pH value
			Total	Inverted	Sucrose		
Cultivar (A)							
‘Gala Must’		13.54	10.96	8.05	2.75	0.28	4.06
‘Rajka’		13.46	10.68	8.26	2.30	0.38	3.91
‘Red Elstar’		14.29	11.84	7.76	3.84	0.52	3.73
‘Topaz’		14.86	12.50	8.36	3.87	0.54	3.49
Year (B)

Yield of introduced apple cultivars

The yield of apple cultivars depends on the biological characteristics of the cultivar and rootstock, the age of the fruit tree, its health condition, proper choice of the polleniser cultivar, growing system, natural conditions and applied agro-technical measures. The variance analysis revealed that the yield per tree and unit of area were determined by the genotype and year of study (Table 2). The highest yield per tree and unit of area was recorded in ‘Gala Must’ (24.63 kg tree^{-1} and 61.58 t ha^{-1}), whereas the lowest one was obtained in ‘Red Elstar’ (12.42 kg tree^{-1} and 31.05 t ha^{-1}). Apart from ‘Gala Must’, a high cropping potential was found in ‘Topaz’ (21.52 kg tree^{-1} and 53.79 t ha^{-1}) and ‘Rajka’ (20.94 kg tree^{-1} and 52.35 t ha^{-1}). The yield of ‘Gala Must’, obtained in this study, is considerably higher than the values reported by Milatović *et al*. (2009), who also pointed to the higher productivity of the ‘Royal Gala’ sport, compared to the ‘Gala Must’ sport. At the same time, Rutkowski *et al*. (2005) stated a significantly higher productivity of the ‘Gala Must’, compared to the standard ‘Gala’ cultivar. The results of yield for ‘Topaz’ are in agreement with the data reported by Blažek and Hlušičková (2007), who pointed a very high productivity of this cultivar in the region of the Czech Republic. The same authors reported a higher productivity of ‘Topaz’, compared to ‘Elstar’, ‘Rajka’ and ‘Gala Must’. In our study, ‘Rajka’ showed a slightly lower yield compared to ‘Topaz’, which is in agreement with the results reported by Sosna (2014),

according to which ‘Topaz’ (130.6 kg tree^{-1}) recorded a higher cumulative yield sustained over a period of eleven years, compared to ‘Rajka’ (118.4 kg tree^{-1}).

Conclusion

Based on the study of the pomological properties and yield of the four introduced apple cultivars, it is possible to make the following conclusions:

The ‘Gala Must’ and ‘Red Elstar’ belong to the group of autumn apple cultivars, whereas the ‘Rajka’ and ‘Topaz’ belong to the winter apple cultivars;

Based on the morphometric features of the fruit, all of the cultivars can be classified within the group of medium-sized and elongated fruits (‘Gala Must’), i.e. the elongated-flattened (‘Rajka’ and ‘Red Elstar’) and flattened (‘Topaz’) fruits, whereas the largest average weight and height of fruit were determined in ‘Gala Must’;

The chemical composition parameters point to a very good quality of ‘Topaz’ fruits;

A high cropping potential was demonstrated by ‘Gala Must’, ‘Topaz’ and ‘Rajka’. The largest yield per tree and unit of area was obtained in ‘Gala Must’.

The examined intense-colouring sports of ‘Gala’ and ‘Elstar’, as well as scab resistant cultivars, were shown good results in the Čačak agro-ecological conditions, inferring that they can make a significant contribution to the advancement of the apple assortment structure in the Republic of Serbia. Based on the overall results, growers can be recommended to consider using ‘Gala Must’ as a dominant cultivar in the worldwide apple production, featuring outstanding quality and cropping potential, as well as ‘Topaz’, owing to its commercial significance as a scab resistant cultivar with outstanding productivity and fruit quality, suitable for integrated and organic farming.

Abstract

Breeding and selection of maize hybrids have been performed in the Maize Research Institute, Zemun Polje for the past 70 years. This study encompassed tests of 11 commercial ZP maize hybrids that were carried out in total of 50 locations in Vojvodina (25) and central Serbia (25) during 2014. The objective of the study was to estimate grain yield stability. The method after *Eberhart and Rusell* (1966) was applied in the estimation of yield stability. The average yield in Serbia varied from 9.469 t ha^{-1} (ZP 341) to 11.656 t ha^{-1} (ZP 606). Moreover, the hybrid ZP 606 was a record yielder in both Vojvodina (11.274 t ha^{-1}) and central Serbia (12.037 t ha^{-1}). On the other hand, the hybrid ZP 434 (b_i=0.987) was the most stable in all 50 locations, while the hybrids ZP 548 (b_i=0.980) and 427 (b_i=0.987) were the most stable in central Serbia and Vojvodina, respectively.

Key words: *maize, grain yield, yield stability*

Introduction

Maize, one of the most important field crops not only in Serbia but in the world, was domesticated some 7700 years ago in Central America. It represents a plant species that is evolutionary most developed in the entire plant kingdom (Glamočlija 2004). Maize is one of the leading species in the global agricultural production ranking high in the world economy. It ranks first according to total production quantity and grain yield per area unit and second according to harvested areas in the world (FAOstat, 2013). Approximately 1.2 million hectares are sown with maize in the Republic of Serbia. There are two large production regions in our country: central Serbia and Vojvodina. The main difference between these two regions is somewhat drier climate with a lower precipitation sum that is characteristic for central Serbia. Breeding and selection of maize hybrids have been performed in the Maize Research Institute, Zemun Polje for the past 70 years, with the aim to develop high and stable yielding hybrids that are adaptable to various environmental conditions of growth. Stability is the ability of a genotype to have always the uniform yield regardless of environmental effects (Becker, 1981). Adaptability (Finly and Wilkinson, 1963) is the ability of a variety to provide stable and high yield under different environmental conditions. One way to check hybrids is to test them in a greater number of locations. While testing the stability of hybrids, it is possible to happen that the highest yielding hybrids show below-average stability (Babic, 2006). The high stability of genotypes is one of the most desirable features as one of the main preconditions for the expansion of the same hybrids for cultivation in large areas (Singh and Choudhary, 1977). The greater number of locations under various environmental conditions is the greater probability of obtaining more reliable data related to grain yield stability is.

The aim of the present study was to observe productivity of commercial ZP maize hybrids and to establish grain yield stability in both, entire Serbia and its two main production regions, Vojvodina and central Serbia.

Materials and methods

A total of 11 commercial ZP maize hybrids of different FAO maturity groups (300-600) were studied in production trials set up in 50 locations in Vojvodina and central Serbia in 2014. Half of the locations were placed in Vojvodina, and the other half in central Serbia.

The elementary plot size amounted to 0.1 ha. Sowing and harvest were performed mechanically. The sowing density per hectare differed over FAO maturity groups and it ranged from 70,000 plants ha^{-1} (FAO 300-400) to 60,000 plants ha^{-1} (FAO 500-600). The grain yield ha^{-1} was calculated in t at 14% moisture.

The average yields were calculated cumulatively for all 50 locations and separately for Vojvodina and central Serbia, which are two distinct environments for maize cultivation. Stability parameters were estimated after method of Eberhart and Russell (1966) for both, 50 locations cumulatively, and Vojvodina and central Serbia separately.

Eberhart and Russell method is represented by the following equation:

$Y_{ij} = m + b_i I_j + d_{ij}$

Y_{ij} - the average yield of the i^{th} genotype in the j^{th} location

m - the average yield of the i^{th} genotype in all locations

b_i - standardised regression coefficient of the environment and genotype, genotype relationship to the environment

I_j - index of the environment as the average of all genotypes in the j^{th} location, reduced from the total average

d_{ij} - deviation from regression of the i^{th} genotype in the j^{th} site

The standardised regression coefficient (b_i) shows the response of genotypes to environment. When b_i=1, then the average adaptability and stability of the tested genotypes is considered uniform under the influence of favourable and poor environment conditions; when $b_i > 1$, genotype is considered stable and good only under favourable environment conditions, and when the $b_i < 1$, genotype is considered to perform better than the average in less favourable growing conditions and environments. All calculations were done in the Excel programme.

Results and discussion

According to obtained grain yields of maize, the year of 2014 was favourable. Due to above-average precipitation obtained yields were above the long-term average. Hybrids ZP 606 and ZP 560 over-yielded all remaining hybrids in all 50 locations (11.656 and 11.128 t ha^{-1}, respectively). On the other hand, the lowest average yield (9.496 t ha^{-1}) was recorded in the hybrid ZP 341. Based on values of the regression coefficient (b_i) it may be concluded that stability of all hybrids was satisfactory. The hybrid ZP 434 (b_i=0.987) was the most stable (b_i=0.987) of all hybrids in all 50 locations cumulatively. It is interesting to emphasise that the most yielding hybrid ZP 606 was at the same time the least stable (b_i=1.158) (Table 1).

Table 1. Grain yield of commercial ZP hybrids in production trials in all 50 locations in 2014

Hybrid	Grain Yield (t ha-1)	Rank according to grain yield	b_i	Rank according to b_i
ZP 341	9.469	11	0.890	8
ZP 366	9.841	9	0.848	10
ZP 388	10.140	8	0.913	6
ZP 427	10.249	6	0.912	7
ZP 434	9.603	10	0.987	1

ZP 548	10.214	7	1.082	5
ZP 555	10.570	5	1.124	9
ZP 560	11.128	2	1.058	4
ZP 600	10.988	3	1.013	2
ZP 606	11.656	1	1.158	11
ZP 666	10.957	4	1.015	3
Average	10.438	/	1	/

In the region of Vojvodina the highest average yields of 11.274 t ha^{-1} and 10.910 t ha^{-1} were recorded in the hybrids ZP 606 and ZP 560, respectively, while the lowest average yield (8.956 t ha^{-1}) was detected in the hybrid ZP 341. The values of the regression coefficient point out that the most stable hybrid in this growing region was ZP 427 (b_i=0.987), while the most yielding hybrid ZP 606 ranked second (b_i=1.047). It is interesting to state that the most stable hybrid ZP 434 in total, was the least stable (b_i=1.323) in the region of Vojvodina (Table 2).

Table 2. Grain yield and stability parameters of ZP hybrids in locations in the region of Vojvodina

Hybrid	Grain Yield (t ha^{-1})	Rank according to grain yield	b_i	Rank according to b_i
ZP 341	8.956	11	0.744	8
ZP 366	9.369	9	0.823	7
ZP 388	9.792	7	0.930	3
ZP 427	9.837	6	0.987	1
ZP 434	9.178	10	1.323	11
ZP 548	9.645	8	1.268	10
ZP 555	10.542	5	1.124	6
ZP 560	10.910	2	1.112	5
ZP 600	10.666	4	0.905	4
ZP 606	11.274	1	1.047	2
ZP 666	10.681	3	0.735	9
Average	10.077	/	1	/

The most yielding hybrids in central Serbia were ZP 606 (12.037 t ha^{-1}) and ZP 560 (11.345 t ha^{-1}), while the lowest yield was recorded in the hybrid ZP 341 (9.982 t ha^{-1}). The most stable hybrids in central Serbia were ZP 548 (b_i=0.980) and ZP 600 (b_i=1.058), while the least stable hybrid was ZP 555 (b_i=1.212). It should be also noted that the most yielding hybrid ZP 606 in all locations was very unstable in central Serbia, and therefore ranked next to the last (b_i=1.203), (Table 3)

Table 3. Grain yield and stability parameters of ZP hybrids in locations in central Serbia

Hybrid	Grain yield (t ha^{-1})	Rank according to grain yield	b_i	Rank according to b_i
ZP 341	9.982	11	0.892	5
ZP 366	10.312	9	0.817	9
ZP 388	10.488	8	0.904	4
ZP 427	10.661	6	0.868	7
ZP 434	10.029	10	0.861	8
ZP 548	10.783	5	0.980	1
ZP 555	10.598	7	1.212	11
ZP 560	11.345	2	1.079	3
ZP 600	11.311	3	1.058	2
ZP 606	12.037	1	1.203	10
ZP 666	11.234	4	1.126	6
Average	10.798	/	1	/

Conclusion

ZP hybrids in 2014 showed very good results in terms of both, grain yield and yield stability. The most yielding hybrid in total was ZP 606 (11.656 t ha^{-1}). This hybrid also over-yielded the remaining hybrids in Vojvodina and central Serbia (11.274 and 12.037 t ha^{-1}, respectively). The hybrid ZP 341 was the least yielding hybrid overall and in Vojvodina and central Serbia. Since the region of Vojvodina is to a certain extent more favourable for maize cultivation due to agro-ecological conditions, it was somewhat surprising that the average yield of all hybrids in central Serbia was higher by 721 t ha^{-1} than in Vojvodina. The precipitation sum was great in 2014 and therefore hybrids of later maturity groups were averagely more yielding than earlier maturing hybrids. Generally, ZP hybrids were very stable and their regression coefficient on the territory of entire Serbia varied from 0.85 to 1.16. The hybrid ZP 606 was most yielding in all locations, but at the same time, was the least stable (b_i=1.158), which is in accordance with results obtained by BABIĆ (2006). The hybrid ZP 434 was cumulatively the most stable (b_i=0.987). On the other hand, the hybrids ZP 427 (b_i=0.987) and ZP 548 (b_i=0.980) were the most stable in Vojvodina and central Serbia, respectively. Late maturing hybrids showed better results in 2014, which was characterised by a lot of precipitation. This result leads to a conclusion that later maturing hybrids will be more yielding and stable in more humid climate, while medium early maturity hybrids (FAO 300-400) will have better results in dry (arid) years, because their pheno-phases of flowering, ear formation and grain filling occur earlier in the year when soil moisture is still sufficient.

Abstract

The polyphenolic compoundsnaturally present in medicinal and aromatic herbs have significant importance due to their bioactive and antioxidative properties, but sensorial, too. Herbs extracts obtained in this study have very pleasant odor, taste, and many bioactive compounds, therefore represent perfect base for soft drinks.

In this study, the aqueous extractions of 12 medicinal and aromatic plants were performed. The aim was to compare the content of polyphenolic compounds and antioxidant potential of obtained extracts. In order to optimize the extraction process, the influence of water temperature (room temperature, 60°C and 100°C) and extraction time (6h, 12h and 24h) were tested. The obtained extracts were characterized in their total polyphenolic content by Folin-Ciocalteu method whiles the antioxidant potentials were estimated by Ferric Reducing Ability of Plasma (FRAP) and 1,l-diphenyl-2-picryl hydrazyl (DPPH) method.

The results show statistically insignificant influence of extraction time. However, there were significant differences between samples obtained with different applied temperature. Also, the results indicate that the water extract of the medicinal and aromatic plants mixture is the great source of polyphenolic compounds with high antioxidant capacity.

These extracts of medicinal and aromatic herbs mixture could be applied in food industry, especially in the beverage industry for the development of natural products with high content of bioactive compounds.

Keywords: *herbs, water extraction, polyphenolic compounds, antioxidative properties, soft drinks*

Introduction

In recent years, research on phytochemicals, herbal food supplements and medicinal products has been intensified (Chen et al., 2007). Medicinal and aromatic plants contain a broad range of bioactive compounds such as alkaloids, glycosides, saponins, resins, oleoresins, sesquiterpene lactones, oils (essential and fixed), flavors, fragrances and pigments. Also, rare compounds like furanocoumarins, hydroxycoumarins, napthoquinones, acylphloroglucinols and sterols are also distributed among these plants (Saroya, 2011). Many herbs are an excellent source of phenolic compounds which determine their considerable role in the prevention of various degenerative diseases (Capecka et al., 2005). Phenolic compounds, especially flavonoids and stilbenes, exhibit a number of bioactive effects, such as antioxidant, anti-inflammatory, antimicrobial, antiallergic, antithrombotic, anticancerogenic, antimutagenic, antiaging and vasodilatory activities.Except for a physiological role, phenolicshave a significant affect to sensorial properties of herb products, such as appearance, taste, mouth-feel, fragrance, astringency and bitternes. Phenolic compounds are generally considered as one of the main antioxidant sources in herbs, and antioxidant capacity is highly correlated with the total phenolic content(Jaganath et al., 2010).

Medicinal and aromatic plants in different forms (powders, extracts, etc.) are widely used in the food, pharmaceutical and cosmetics industries (Wang and Weller, 2006). Extracts are prepared by separating the soluble matter from plant tissues by application of a suitable solvent like alcohol, water or some organic solvent. In the case of extracts application in the food and beverage industry, the most suitable solvents are water and ethanol, because organic solvents could be source of harmful residues.The parameters which have the greatest influence on physicochemical and sensory properties of herb extracts are type of solvent, temperature of solvent, extraction time and techniques of extraction (Ong, 2004).

Herbal extracts are often used in soft drink production and first herbal drink is probably older than 5000 years (Whitehead, 2005). The aim of this study was to investigate the influence of water temperature and extraction time on the total phenolic content and antioxidant activity of aqueous extract of 12 medicinal and aromatic herbs. This extract is formulated as a base for soft drinks production. The combination and number of plants for the production of extract was chosen based on the sensory analysis of several different herbal extracts. Water was used as a solvent because it is only acceptable solvent for soft drink production.

Materials and methods

Extraction of herbs

The aqueous extraction of following 12 medicinal and aromatic plants was performed: peppermint (*Menthapiperita*), chamomile (*Matriciachamomilla*), wild thyme or creeping thyme(*Thymus serpyllum*), mountain germander (*Teucriummontanum*), winter savory (*Saturejamontana*),common yarrow(*Achilleamillefolium*), common sage (*Salvia officinalis*), mellisa (*Melissa officinalis*), centaurea (*Erythraeacentaurium*Pers.), wall germander (*Teucriumchamaedrys*), stinging nettle (*Urticadioica*) and wormwood (*Artemisia absinthium*). The extraction of plants was carried out in glass bottles which were placed on shaker in dark place at room temperature. Air-dried plants or its parts were cut into small pieces and placed into bottles. After that, the water was poured over the plants. The plant materials-water ratio was 1:8.Temperature of water was 20, 60 and 100°C, while extraction time was 6, 12 and 24 hours. After extraction, the water-plant mixture was pressed by laboratory hydraulic press and obtained extracts were filtered through 70 g/m^3 filter paper. Volume of final extracts was 7.4 liter; so, yield of production was 7.4 L of liquid extract per kg of dried herbs or 0.925 L of extract per liter of solvent (water).

Determination of dry matter of extracts was performed by drying of exactly weighed amount of fluid extract (approximately 5 g) in a Petri dish in a drying oven at 105°C until the mass becomes constant. After it was cooled in a desiccator for 30 minutes, the residue was weighed and the dry matter (%) was calculated as mass of residue/mass of fluid extract*100.

Determination of total phenolics

The amounts of total phenolics (TPC) in extracts were determined according to the Folin-Ciocalteu method (Singleton and Rossi, 1965). Briefly, 0.5 mL of diluted extracts were mixed with 2.5 mL of 10-fold diluted Folin-Ciocalteu’s phenol reagent and allowed to react for 5 minutes. Two milliliters of sodium carbonate solution (75 g/L) was added to the mixture and then shaken. After 2 h of reaction at room temperature, the absorbance at 760 nm was measured. The calibration curve was prepared with gallic acid solution, and the results were expressed as milligrams of gallic acid equivalents per liter of sample (mg GAE/L).

DPPH radical-scavenging activity

DPPH radical-scavenging activity of extracts was estimated following the slightly modified procedure described by Kaneda et al. (Kaneda et al., 1995). Every diluted extract sample (0.2 mL) was added to the DPPH working solution (2.8 mL) (mixture of 1.86 x 10^{-4} mol/L DPPH

in ethanol and 0.1 M acetate buffer (pH 4.3) in ratio 2:1 (v/v)). The absorbance at 525 nm was measured after the solution had been allowed to stand in the dark for 60 min. The Trolox calibration curve was plotted as a function of the percentage of inhibition of DPPH radical. The results were expressed as millimoles of Troloxequvivalents per liter of sample (mM TE/L).

FRAP assay

The FRAP assay was performed according to the procedure previously described by Benzie and Strain, with some modification (Benzie and Strain, 1996). The FRAP reagent solution was made by mixing acetate buffering agent (pH=3.6), TPTZ (10 mM TPTZ solution in 40 mMHCl) and $FeCl_3$ x $6H_2O$ in volume ratio 10:1:1, respectively). All samples, standards and reagents were pre-incubated at 37°C. An aliquot of each diluted extract sample (0.1 mL) was mixed with distilled water (0.3 mL) and FRAP reagent (3 mL). After the reaction at 37°C for 40 min, the absorbance at 593 nm was measured. The calibration curve was prepared with Trolox solution and the results were expressed as millimoles of Troloxequvivalents per liter of sample (mM TE/L).

Statistical analysis

All experimentswere done in triplicate and obtained results are expressed as mean ± standard deviation (SD). Analysis of variance and significant differences among means were tested using ANOVA and Tuckey's HSD test ($p \leq 0.05$). Statistical analyses were performed with the statistical program Statistica 12.

Results and discussion

In this study, 9 different herb extracts was obtained. Table 1 shows an overview of the produced extracts, as well as the applied water temperature, extraction time and dry matter of extracts. The dry matter is a general parameter which measures the yield of extraction process and in obtained extracts was in the range from 0.93 to 1.93 %. The extraction yield was the highest in the extracts produced by extraction at 100°C, with no statistically significant differences between samples HE100/6, HE100/12 and HE100/24.The results indicate that increasing the extraction time is only relevant for the extraction at 20°C, because a longer extraction time did not influence the yield at 100°C and at 60°C after 12 hours. This means that the steady state between herbs and solvent (water)was reachedmore quickly at the higher temperature. Hinneburg and Neubert was obtained similar results during the extraction of buckwheat (*Fagopyrumesculentum*Moench) (Hinneburg and Neubert, 2005).

Table 1. Herb extracts overview

Extracts	Water temperature	Extraction time	Dry matter (%)
HE20/6	20	6	0.93±0.02
HE20/12	20	12	1.24±0.01
HE20/24	20	24	1.41±0.02
HE60/6	60	6	1.73±0.01
HE60/12	60	12	1.81±0.01
HE60/24	60	24	1.82±0.01
HE100/6	100	6	1.91±0.01
HE100/12	100	12	1.93±0.01
HE100/24	100	24	1.92±0.02

The total phenolic content and antioxidant properties of extracts are presented in table 2. Antioxidant capacity of samples was strongly and statistically significantly correlated with total phenolic content. All extracts was the very reach source of phenolic compounds, with the

total phenolic content in the range from 2048.82 to 4938.18 mg GAE/L. The results of the ANOVA test (table 3) indicates that observed factors (water temperature and extraction time) had a very significantly influence on the phenolic content and antioxidant activity of samples. The interaction of factors (temperature*extraction time) on the measured values was also very significant, which means that the impact of one factor depends on the level of the other factor.

Table 2. Total phenolic content and antioxidant properties of herb extracts

Extracts	TPC (mg GAE/L)	DPPH (mM TE/L)	FRAP (mM TE/L)
HE20/6	2048.82±10.10^{a}	14.62±0.13^{a}	13.49±0.09^{a}
HE20/12	2615.26±8.68^{b}	20.21±0.12^{b}	19.13±0.17^{b}
HE20/24	2892.48±23.76^{c}	21.79±0.14^{c}	21.11±0.14^{c}
HE60/6	4062.29±15.83^{d}	30.38±0.13^{d}	26.54±0.46^{d}
HE60/12	4340.80±21.99^{e}	33.85±0.07^{e}	30.50±0.31^{e}
HE60/24	4350.00±22.22^{e}	33.94±0.07^{e}	31.03±0.12^{e}
HE100/6	4726.50±9.42^{f}	36.16±0.08^{f}	34.53±0.16^{f}
HE100/12	4938.18±13.67^{g}	38.88±0.10^{g}	38.39±0.37^{g}
HE100/24	4901.24±4.13^{g}	38.79±0.09^{g}	38.65±0.06^{g}

Values represent means of triplicate determinations ± standard deviation. Different letters in same column denote a significant difference according Tukey's test, $p < 0.05$.

Table 3.The results of analysis of variance

Factors	TPC		DPPH		FRAP	
	F	p	F	p	F	p
Temperature	52645.28	0.00	77792.85	0.00	14147.31	0.00
Extraction time	1912.09	0.00	4749.12	0.00	1258.82	0.00
Temperature*extraction time	382.87	0.00	390.66	0.00	46.62	0.00

F - sample values applied test; p - level of significance (p≤0.05, difference is significant)

Water temperature had the very significant influence on the TPC of samples, where the best results were achieved with the temperature of 100°C. At 20°C, extraction time was important factor, and TPC and antioxidant activity was increased with prolongation of the process. However, after 12 hours at 60 and 100°C extraction time did not significantly effect on the TPC and antioxidant activity of extracts. Based on the results, it can be concluded that optimal parameters of this herbs mixture extraction is: water temperature 100°C and extraction time 12 hours.

Conclusions

The results obtained suggest that the extraction yield, TPC and antioxidant activities was the highest in the extracts produced by extraction at 100°C,with no statistically significant differences between samples HE100/12 and HE100/24. The steady state between herbs and solvent (water) was reached more quickly at the higher temperature, and because of that increasing the extraction time is only relevant for the extraction at 20°C. Extracts produced at 100°C are very rich source of phenolic compounds with considerable antioxidant activity. Therefore, these aqueous extracts are a very good base for development of different types of soft drinks with increased functional value.

Abstract

Variability of grain weight spike^{-1} was studied in four triticale genotypes: 'KG-20', 'Tango', 'Odyssey' and 'Favorit', grown over a two-year period under four mineral nitrogen fertilizer treatments, 0, 40, 60 and 80 kg N ha^{-1}. The experiment was set up as a randomized block design in four replications. Averaged across genotypes, grain weight spike^{-1} increased with increasing nitrogen rate. On average, grain weight spike^{-1} in both growing seasons and under N treatment was highest in 'Favorit' and lowest in 'Tango'. Nitrogen fertilization made the largest contribution to the total phenotypic variance of grain weight spike^{-1}, cultivar was a considerably smaller contributor, and a low percentage was assigned to cultivar x nitrogen interaction. The results indicate that the value of the trait is significantly dependent on cultural practices.

Key words: *triticale, grain weight, spike, nitrogen*

Introduction

The combination of the high yield potential and good grain quality of wheat with the resistance/tolerance to biotic and abiotic stresses of rye resulted in the creation of a new small grain crop named Triticale (*x Triticosecale* Wittmack). Triticale breeding programs are mostly focused on major economic traits such as grain yield, biomass yield, nutritional value, earliness and grain filling percentage.

Triticale has moderate soil requirements and a good tolerance to low pH (about 5.0), with many genotypes showing better adaptation to acid soils compared to wheat cultivars (Oettler et al., 2000). As a new promising plant, triticale can also give satisfactory yields at high altitudes (Stošović et al., 2010). Moreover, triticale is highly tolerant of unfavourable weather conditions (Nožinić et al., 2009).

In recent years, triticale yields have ranged from 4 to 10 t ha^{-1}. Grain number per spike and grain weight per spike as direct yield components are determined by gene action under the influence of the environment (Mladenov et al., 1998; Malešević et al., 2010). Triticale is characterized by a high number of grains per spike and high grain weight per spike and per plant (Benbelkacem, 2002; Milovanović et al., 2006, Kondić et al., 2013).

To obtain high yields and good grain quality in triticale, special importance should be given to cultivar choice and proper cultural practices, particularly optimum nitrogen fertilization. Increasing nitrogen fertilizer rates generally increases grain yield in triticale (Stošović et al., 2010). However, high N rates may lead to moisture deficit stress due to intensive vegetative growth drawing on soil moisture reserves to the detriment of subsequent grain fill. Increased nitrogen application rates in small grains cause more intensive vegetative growth, more spikes m^{-2}, fewer grains per spike and variable grain weight (Paunović et al., 2006; Madić et al., 2013). The soil moisture x nitrogen level interaction is the main determinant of grain yield (Gonzales Ponce et al., 1993).

The objective of this study was to evaluate the effect of increasing mineral nitrogen rates applied during the growing season on grain weight per spike as a direct yield component in four triticale cultivars (genotypes).

Materials and methods

An experiment to analyze grain weight per spike in triticale was set up at the farm of the Secondary School of Agriculture, Kraljevo (the experimental field of the Faculty of Agronomy, Čačak) during the growing seasons 2012/13 and 2013/14. The soil at the experimental location had poor physical properties, an acid reaction (pH_{H2O} = 4.7), the content of humus 2.20%, readily available phosphorus 8.0 mg 100^{-1} g soil and potassium 14.0 mg 100^{-1} g soil.

Four triticale cultivars ’KG-20', 'Tango', 'Odyssey' and 'Favorit' were tested. The experiment involved an untreated control (0) and three mineral nitrogen (N) fertilization treatments: 40 kg N ha^{-1} (N40), 60 kg N ha^{-1} (N60) and 80 kg N ha^{-1} (N80). The N rates were applied through mineral fertilizer KAN (27% N) at the beginning of March in the early stage of intensive growth (jointing).

The experiment was laid out in a randomized block design with four replications and plot size of 5 x 1 m (5 m^2). Seeding was performed by a small mechanical drill in the second third of October at a spacing of 12 cm between rows and 3 cm within the row. At full maturity, 30 primary spikes were sampled from each plot and grain weight per spike was measured.

The results were subjected to a two-way analysis of variance (with cultivars and nitrogen as factors) using SPSS software (1995). Individual differences between means were evaluated by the LSD test.

Results and discussion

Grain weight per spike is a yield component that plays an important role in the productivity of triticale. It is a highly heritable quantitative trait and as such it is of great importance in the breeding process as well. Many authors have reported high grain weight per spike and per plant in triticale (Milovanović et al., 2006; Đekić, 2012; Kondić et al., 2013).

Grain weight per spike as a direct grain yield component is dependent on soil fertility, nitrogen nutrition, plant density, productive tillering, spike length and grain number per spike (Kovačević et al., 2006; Paunović et al., 2006; Izsaki et al., 2007). Grain weight per spike is mostly governed by grain number per spike, grain size and grain shape (Amin et al., 1995).

Table 1. Analysis of variance for grain weight per spike in triticale cultivars in 2013 and 2014

		Years					
		2013			2014		
			Variance components			Variance components

Total	63						

** F –test significant at 0.01, ns F-test non-significant

The analysis of variance for grain weight per spike in triticale showed significant differences among genotypes, as well as among nitrogen application rates in both years (Table 1).

In both years, N accounted for the largest percentage of the total phenotypic variance of grain weight per spike, genotype made a considerably smaller contribution, and the lowest proportion was due to the genotype x nitrogen interaction. This suggests that the value of the trait is significantly dependent on cultural practices.

In the first year, the tested cultivars exhibited significant differences in grain weight per spike: it was highest in the lines ’Favorit’ and ’Odyssey’, followed by ’Tango’, and lowest in ’KG-

20’ (Tab. 2). Significant differences in grain weight per spike among the tested cultivars were also observed in the second year: the highest values were found in ’Favorit’, followed in decreasing order by ’Odyssey’, ’KG-20’ and ’Tango’ (Tab. 2). In the first year, increasing N application rates to 60 kg N ha^{-1} resulted in a significant increase in grain weight per spike (Tab. 2), in all cultivars.

In the second year, grain weight per spike increased in all genotypes with the N rate increasing to 80 kg ha^{-1}. Numerous studies have shown that increased N rates lead to a significant increase/decrease in grain weight per spike (Paunović et al., 2007 and 2008; Knežević et al., 2007).

Table 2. Grain weight per spike (g) in triticale cultivars under different nitrogen application rates (kg N ha^{-1}) in 2013 and 2014

		Year	
		2013	2014
Cultivar (A)	KG-20	1.02c	1.28c
	Tango	1.08b	1.21d
	Odyssey	1.12a	1.32b
	Favorit	1.14a	1.47a
Nitrogen (B)	0	0.97c	1.18d
	40	1.07b	1.25c
	60	1.15a	1.35b
	80	1.11a	1.39a
ANOVA	A	**	**
	B	**	**
	AxB	ns	ns

Means within line and nitrogen rate columns followed by the same lowercase letters are not significantly different at 95% according to the LSD-test

** F –test significant at 0.01, ns F –test non-significant

Moinuddin and Afridi (2008) found that the increase in mineral N fertilizer rates up to 200 kg N+ 40 kg P ha^{-1} had a positive effect on grain yield in triticale, whereas further increases caused a progressive decrease in the positive response (with overfertilization also leading to negative effects). Harmoney (2005) also reported a favorable response of triticale (grown for green forage) to increasing N rates up to a certain level.

Conclusions

Grain weight per spike significantly differed among the tested triticale cultivars in both years regardless of N application rates. The phenotypic variance components indicate that grain weight per spike is significantly dependent on cultural practices, since the total variance of the trait was mostly accounted for by mineral nitrogen fertilization, considerably less by cultivar and slightly by the cultivars x nitrogen interaction.

Increasing nitrogen application rates to 60 kg N ha^{-1} in the first year and to 80 kg N ha^{-1} in the second year led to an increase in grain weight per spike in all cultivars.

Significant differences among lines in both years across different nitrogen rates indicate that grain weight per spike is a genotype characteristic that may be used as a selection criterion for increased grain yield in triticale.

DETECTION OF EPISTASIS FOR PLANT HEIGHT IN HEXAPLOID WHEAT (Triticum aestivum L.) USING GENERATION MEAN ANALYSIS

Nataša LJUBIČIĆ[1]*, Sofija PETROVIĆ[1], Miodrag DIMITRIJEVIĆ[1], Nikola HRISTOV[2]

[1]University of Novi Sad, Faculty of Agriculture, Novi Sad, Serbia
[2]Institute of Field and Vegetable Crops, Novi Sad, Serbia

Abstract

In order to estimate the gene effects in the inheritance of the plant height, five winter wheat genotypes (Pobeda, Renesansa, Sara, Partizanka and Pesma) were selected. The above mentioned genotypes were diallel crossed and F_1, F_2, and Fbc_1 were obtained. The gene effects were estimated on the basis of generation mean analysis, using an additive-dominant model with three and six-parameters (Mather and Jinks, 1982). The adequacy of the additive-dominance model with three-parameters was tested using the Scaling-test and Chi-square ($\chi 2$) test. In the most crosses the value of the dominant gene effect was more significant than additive. The three-parameter model was adequate for the three crossing combination: Pobeda/Pesma, Renesansa/Pesma and Sara/Pesma. In the remaining crossing combinations tests showed the presence of epistatic effect which suggested that three-parameter model was not adequate. The application of six-parameter models was fitted for explaining genetic variation for the plant height and indicated the presence of various epistatic effects. The inheritance of the plant height was influenced by additive×additive and dominance×dominance type of non-allelic interactions. Duplicate gene interactions were also seen functioning in controlling plant height in most crosses. The best fit model indicated a very similar gene effects which were presented by a model with six-parameters. Epistasis played a considerable role in controlling plant height of wheat which revealed that epistatic gene effect cannot be ignored in establishing a breeding program to improve wheat populations for this trait.

Keywords: *wheat, plant height, gene effects.*

Introduction

Considering the importance of wheat production in agriculture, the main aim in plant breeding programs is to create the wheat genotypes with a high genetic potential for the grain yield (Petrović et al., 2012). As an efficient breeding program requires understanding the nature, magnitude of gene effects and their contribution to the inheritance of the yield and yield components, in order to increase the genetic potential of wheat, it has been developed numerous different analysis methods. Among these, plant breeders often use generation mean analysis to get information about gene action which is controlling the traits. Generation mean analysis is a simple and useful technique for estimating gene effects for a polygenic trait. Since it has been reported that epistatic gene action is a non-trivial factor in the inheritance of plant characters (Goldringer et al., 1997; Erkul et al., 2010), the greatest contribution of this analysis lying in an ability to estimate epistatic gene effects such as additive×additive (i), dominance×dominance (j) and additive×dominance (l) effects (Singh and Singh, 1992). A large number of genetic studies have been made to investigate the genetic basis of yield and yield components of wheat. In most of different crosses were found that dominance effects and epistasis have been more important and predominant than additive effects for grain yield and its components (Erkul et al., 2010; Kumar et al., 2013). Plant height is one of several yield components and directly affects the yield. Plant height is largely governed by multiple gene factors. The importance of epistatic effects in controlling plant height was observed by

many researches (Ilker et al., 2009; Khattab et al., 2010; Ojaghi and Akhundova, 2010; Tonk et al., 2011). Therefore, the present study was carried out to obtain information about the types of gene effects for the plant height of different bread wheat genotypes.

Materials and methods

Five varieties of hexaploid wheat (*Triticum aestivum L.*), namely, Pobeda, Renesansa, Sara, Partizanka and Pesma were diallely crossed. It was obtained the five basic generations: parent cultivars (P_1, P_2), first and second filial generations (F_1, F_2) and first backcrosses (BC_1) of ten cross combinations (Pobeda/Renesansa, Pobeda/Sara, Pobeda/Partizanka, Pobeda/Pesma, Renesansa/Sara, Renesansa/Partizanka, Renesansa/Pesma, Sara/Partizanka, Sara/Pesma and Partizanka/Pesma). The five generations and their parent were sown in a randomized block design, with three replications, in three growing seasons (2009/2010, 2010/2011 and 2011/2012). The trial was set up on the trial field of the Institute of Field and Vegetable Crops in Novi Sad, Serbia. The cultivars were sown in 2 m long rows with 20 cm of inter-row spacing and 10 cm spacing between plants in the row. The main sample consisted of 10 plants per replication. The plant height as a yield component was analyzed, at the stage of full maturity. The gene effects were estimated on the basis of Generation mean analysis, an additive-dominance model of three-parameters (Mather, 1949) and marked was according to Hayman (1960), where m = Mean effect, d = Additive gene effects, h = Dominance gene effects, i = Additive×additive epistatic effects, j = Additive×dominance epistatic effects and l = Dominance×dominance epistatic gene effects. The adequacy of the additive-dominance model could be tested in two ways, using the Scaling-test (A, B and C) and Chi-square ($\chi 2$) test. The simple genetic model (m, d and h) was applied when epistasis was absent, whereas in the presence of non-allelic interaction the analysis was proceeded to estimate the interaction types involved using the six-parameter genetic model i.e. (m, d, h, i, j and l) according to Mather and Jinks (1982). The type of epistasis was determined only when dominance (h) and dominance×dominance (l) effects were significant, when these effects had the same sign the effects were complementary, while different signs indicated duplicate epistasis (Kearsey and Pooni, 1996). The best-fit model was used for obtaining the degree of freedom. This model excludes gene effects which do not have a significant influence on the expression of the studied trait. The values of significant gene effects could be obtained using a matrix system.

Results and discussion

The additive-dominance model with three-parameter revealed that dominance effects (h) showed higher values than the additive effects (d), indicating that dominance gene effects play the major role in controlling the genetic variation of the plant height for all crosses (Table 1). The adequacy of the additive-dominance model was tested using Scaling test and Chi-square (χ^2) test. The results of these tests showed that the additive-dominance model, with three-parameter, was sufficient to explain genetic variation for the plant height for four crosses: Pobeda/Pesma, Renesansa/Partizanka, Renesansa/Pesma and Sara/Pesma. The results of the Scaling tests indicated that each of A, B or C were significant or highly significant for the plant height in the remaining six crosses: Pobeda/Renesansa, Pobeda/Sara, Pobeda/Partizanka, Renesansa/Sara, Sara/Partizanka and Partizanka/Pesma, which indicated the presence of non-allelic gene interaction for these crosses and revealed that additive-dominance model is inadequate for explaining the inheritance of plant height (Table 1).

Therefore, the six-parameter model was applied and it was fitted for explaining genetic variation for plant height (Table 2). Using the six-parameter model it was confirmed the presence of significant epistatic effects in all cross combinations, except the three cross combinations: Pobeda/Pesma, Renesansa/Pesma and Sara/Pesma. Also, it was revealed that dominance effects (h) showed higher values than the additive effects (d), indicating that dominance gene effects play the major role in controlling the genetic variation of the plant height for all crosses.The importance of dominance effects in controlling of the plant height was observed by Petrović (1995), Sarker et al. (2007) and Fethi and Mohamed (2010). However, Farooq et al. (2010) and Tonk et al. (2011) reported that additive gene effects were more important for plant height in wheat. In the cross combination: Pobeda/Renesansa, Pobeda/Partizanka, Renesansa/Sara, Renesansa/Partizanka and Partizanka/Pesma, was observed that highly significant dominant effect (h), significant epistatic effects additive×additive and dominance×dominance epistatic effect contributed significantly to the inheritance of plant height. In these cross combination was detected duplicate type of non-allelic interaction, since dominance effects (h) and dominance×dominance epistatic effect (l) were significant and in opposite sign. In this case success of the selection would be affected negatively by these interactions. These results are in agreement with those obtained by Sarker et al. (2007) and Khattab et al. (2010), who also observed the presence duplicate type of non-allelic interaction in the inheritance of plant height. Contrary to these results, the presence of non-allelic gene interaction caused by complementary genes indicated Novoselović et al. (2004). In the cross combination Pobeda/Renesansa and Pobeda/Partizanka was observed the less favorable case of duplicate type of epistasis. The sign of the value of epistatic effects

dominance×dominance (l) were negative, which causes reducing the effects of dominant gene, which causes decreasing phenotypic expression of the trait. These results are less favorable for breeders, than if the values of dominance×dominance epistatic effects (l) were positive, as the crosses Renesansa/Sara, Renesansa/Partizanka and Partizanka/Pesma. In these crosses epistatic effect in fewer amounts masked the phenotypic expression of the trait. Also, the favorable side of these crossing combinations lies in the fact that in these crosses was significant epistatic effects additive×additive (i), which increases the ability to successfully selection more superior genotypes. Beside of that genetic effect that can be fixed (additive) was not significant, reported significant epistatic effects additive×additive (i), could be a result of some preferred interaction between the genes which are controlling this trait. However, the results obtained here, revealed the importance of epistatic effects in the inheritance of the plant height and should not be ignored in establishment a new breeding program to improve wheat genotypes for this trait. The preponderance of dominance and dominance×dominance epistatic effects for the plant height in the present study reveals that the expression of this trait was largely controlled by many genes with small effects and dominant in their action. When non-additive effects are larger than additive, the improvement of the trait needs intensive selection through later generation. The favorable situation was observed in the cross combinations Pobeda/Sara and Sara/Partizanka, considering in this crosses only epistasis additive×additive (i) significantly controlled the inheritance of the plant height and this effect additionally draws gene effects in the direction to the additivity. When additive effects are larger than the non-additive, it is suggested that selection in early segregating generations would be effective. The results of six-parameter model also indicated that epistasis wasn’t found in the inheritance of plant height at the crosses Pobeda/Pesma, Renesansa/Pesma and Sara/Pesma, which suggests that for this crosses an additive-dominance model was adequate, which greatly makes easier the selection for this trait, given the fact that the presence of epistasis complicated procedures for improving quality of traits.

Application of the best fit model is indicated in a very similar gene effects which were presented by a model with six parameters. Interactions caused by the presence of complementary genes, in which significant values (h) and (l) had the same sign, for the trait plant height in this experiment has not been determined (Table 3).

Conclusions

Based on the present findings it can be concluded that epistasis is a non-trivial factor and plays a considerable role in controlling plant height of wheat in crosses: Pobeda/Renesansa, Pobeda/Sara, Pobeda/Partizanka, Renesansa/Sara, Renesansa/Partizanka and Partizanka/Pesma. Dominance and dominance×dominance type of interaction effects are more important than additive or additive×additive interaction effects in the inheritance of plant height. The preponderance of dominance and dominance×dominance epistatic effects for the plant height in wheat reveals that the expression of this trait was largely controlled by many genes with small effects and dominant in their action. Considering that non-additive effects are larger than additive, the improvement of this trait needs intensive selection through later generation and could be much slower in a selection program.

Abstract

Five winter wheat varieties (Pobeda, Renesansa, Sara, Partizanka and Pesma) have been selected for diallel crossing in order to estimate the mode of inheritance, gene effect and genetic variance components for the plant height in F_1 generation. The mode of inheritance was done on the basis of the significance of components of genetic variance and the regression analysis. The combining ability analysis indicated significant differences for the general (GCA) and specific (SCA) combining ability in the F_1 generation, which means that plant height had resulted from the genes with additive and non-additive impact. The best general combining ability was denoted in varieties Partizanka and Pesma and the best specific combining ability have shown in cross combination Partizanka/Pesma. The genetic components of variance, average degree of dominance and regression line indicated over-dominance in the inheritance of plant height.

Keywords: *wheat, plant height, diallel, regression.*

Introduction

Wheat is one of the most important crops in the world and its demand growing at approximately 2% per year, twice the current rate of gain in genetic yield potential (Reynolds et al., 2001). Since that grain yield is complex character influenced by many components, breeders normally use yield components to improve the grain yield, despite the fact that these components compensate each other in practice and increase in one cause a decrease in the other (Foroozanfar and Zeynali, 2013). Therefore, an efficient wheat improvement program requires an understanding of genetic mechanism involved in the expression of yield and yield components of plant material to be used in hybridization program (Shabbir et al., 2011). Plant breeders frequently use diallel analysis for testing a number of parental lines in all possible combinations. Diallel analysis is a suitable method for estimating of genetic parameters and provides early information on the genetic behaviour of these traits in the first generation (Farshadfar et al., 2012). Techniques for analyzing genotypes for all possible crosses include diallel analysis of variance, calculation of genetic components of variation, Vr/Wr regression analysis, as well as estimation general and specific combining ability effects and have been developed by Griffing (1956), Hayman (1954) and Mather and Jinks (1971, 1982). In the most of the diallel studies of wheat, genetic control of plant height, as one of several yield components of wheat, has been subject of numerous studies. Since that inheritance of plant height has complex nature, this question has been investigated in many its aspects (Zečević, 2005).

Therefore, the aim of this study was to obtain the information about inheritance of plant height in a 5×5 diallel cross of wheat. These results would be additional information in the selection of desirable parents for an effective breeding program to evolve new varieties of economic importance.

Materials and methods

Five winter wheat genotypes, (*Triticum aestivum L.*), Pobeda, Renesansa, Sara, Partizanka and Pesma, were crossed in all possible combinations following an 5×5 diallel mating system and it was obtained F_1 generation of progenies. The experiment was conducted at the trial field of the Institute of Field and Vegetable Crops in Novi Sad, according to random block design with three replications, in three growing seasons (2009/2010, 2010/2011 and 2011/2012). The cultivars were sown in 2 m long rows with 20 cm of inter-row spacing and 10 cm spacing between plants in the row. At the stage of full maturity, ten plants from each replication of hybrids and parents were selected randomly for recording data for plant height. Average values of three years trait analysis were used. Analysis of variance for parents and F_1 hybrids for the plant height was done according to Steel and Torrie (1980). General combining ability (GCA) and specific combining ability (SCA) was done following the Method 2 (parents and F_1 generation) Mathematical Model 1 of Griffing (1956). The regression analysis was conducted by the method of Mather and Jinks (1971). The components of genetic variance were analyzed following the models of Hayman (1954) and Jinks (1954).

Results and Discussion

The analysis of variance for plant height of wheat revealed highly significant differences among the replications and significant differences among genotypes (Table 1). Significant differences between replication indicated differences between years what was expected, given that the trial was conducted in three different growing seasons. Significant differences between genotypes suggested that the parents differ significantly and could be used efficiently for improvement of this trait. Using divergent genotypes in the crosses is preferable because selecting genetically divergent parents provides a wider genetic variability. These results are in accordance with earlier findings of Jadoon (2011) and Zeeshan et al. (2013).

Table 1. Analysis of variance for parents and F_1 hybrids for the plant height in a 5×5 diallel cross of bread wheat

[+]DF: Degree of Freedom, SS: Sum of Squares, MS: Mean Square, F: Level of Significance by the F test; Significant ($P < 0.05$), Highly significant ($P < 0.01$), Non-significant (ns)

Significant genotypic variation for this character was further partitioned into variation due to general combining ability (GCA) and specific combining ability (SCA) effects and presented in Table 2. The results of the analysis was indicated highly significant differences for the general (GCA) and significant differences for the specific (SCA) combining ability in the F_1 generation, meaning that plant height having resulted from the genes with additive and non-additive, i.e. dominant effects. The GCA/SCA ratio was equal and indicates that both kinds of gene effects were important in controlling the inheritance of the plant height of wheat. The present findings thus supported the results of Jadoon (2011); Farshadfar et al. (2013) and Zeeshan et al. (2013), which also showed the roles of both effects for plant height in wheat.

Table 2. Analysis of variance for combining ability for the plant height in a 5×5 diallel cross of wheat

E	28	237.99	2.83			
GCA/SCA				1.01		

+GCA: General Combining Ability, SCA: Specific Combining Ability, E: Error; DF: Degree of Freedom, SS: Sum of Squares, MS: Mean Square, F: Level of Significance by the F test; Significant ($P < 0.05$), Highly significant ($P < 0.01$), Non-significant (ns)

Estimates of general combining ability (GCA) were presented in Table 3. The GCA estimates revealed that the tendency of the largest positive value of GCA effects were observed in genotypes Partizanka and Pesma, suggesting that these genotypes contain more genes with additive effects or additive×additive interaction effects and could be a good parent for this trait. Findings of current study were similar to findings of Zeehsan et al. (2013). Genotype Renesansa was the poorest general combiner with maximum negative but not significant GCA effects. Negative GCA effects were also observed in genotypes Pobeda and Sara. However, if in breeding program short stature behavior is preferred, therefore, negative combining ability effects are preferred for plant height. In that case, the most appropriate are genotypes with the highest negative values of combining ability.

Table 3. Estimates of GCA effects for the plant height in 5×5 diallel cross of bread wheat

Parents	GCA values	Rank	SE	LSD 0.05	LSD 0.01
Pobeda	-0.826 ns	4			
Renesansa	-1.216 ns	5	0.900	1.82	2.43
Sara	-0.127 ns	3			
Partizanka	1.084 ns	1			
Pesma	1.083 ns	2			

+GCA: General Combining Ability, SE: Standard Error; LSD: Least Significant Difference test; Significant ($P < 0.05$), Highly significant ($P < 0.01$), Non-significant (ns)

Estimates of specific combining ability (SCA) are given in Table 4. Crosses which displayed high SCA effects for the plant height were obtained from parents with various types of GCA effects (high x high, high x low and low x low). The highest positive significant SCA effect was exhibited by the cross Partizanka/Pesma (high x high general combiner). Tendency of higher, but not significant values of SCA effects was also observed in crosses Sara/Pesma (low x high), Renesansa/Sara (low x low), Pobeda/Sara (low x low) and Pobeda/Pesma (low x high). The highest negative SCA effects was shown by the cross Renesansa/Pesma, followed by crosses Renesansa/Partizanka, Sara/Partizanka and Pobeda/Partizanka. The SCA effect represents the dominance and epistatic interactions which do not contribute remarkably in the improvement of self-fertilizing crops as wheat, except for the exploitation of hybrid wheat where non-additive genetic variability could be utilized (Javaid et al., 2001). The most important are greater SCA effects in crosses which were involving both parents with high GCA, such as a cross Partizanka/Pesma, because they contain the additive×additive type of interaction which is fixable in later generations and can be used in future plant breeding. Greater SCA effects obtained in this cross, indicated the possibility of genetic improvement for plant height through pedigree selection and may be produce transgressive recombinants for this trait. Greater SCA effects obtained in crosses Sara/Pesma and Pobeda/Pesma which were involving one parent with high and other with low GCA, indicated the involvement of

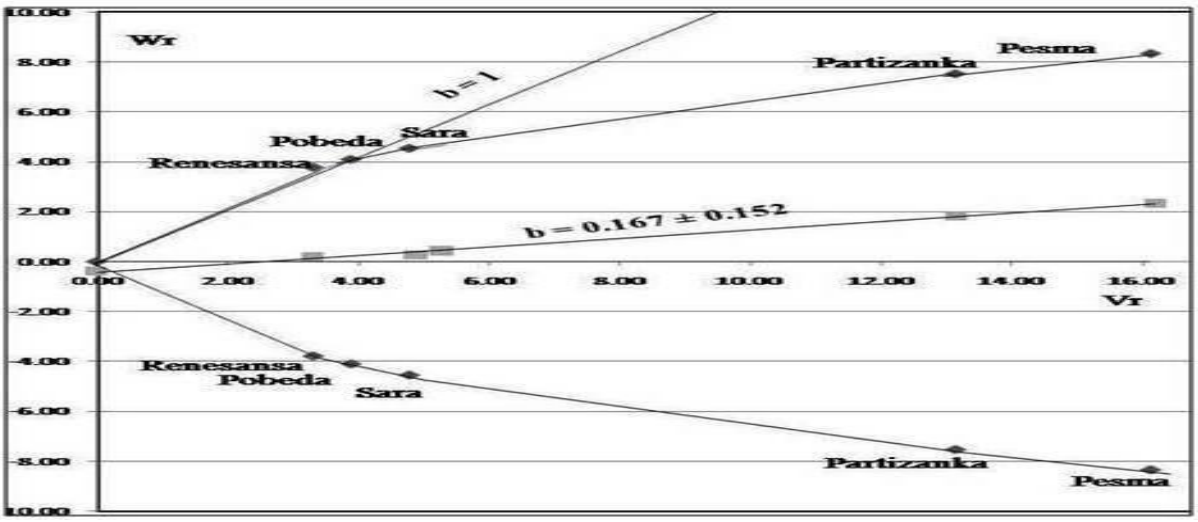
additive×dominance gene interaction in expression of this trait. Greater SCA effects obtained in crosses which were involving one parent with high GCA, was also reported by Ivanovska et al. (2003). Higher positive SCA effects exhibited by the crosses Renesansa/Sara and Pobeda/Sara which involving both parents with low general combiner, indicated the presence of non-allelic interaction at heterozygous loci. This interaction is unfixable, so it is suggested utilizing these crosses through single plant selection in the later generations (Hassan, 2004). Parents with high values of SCA are good combination of filial generation, which uses dominant gene action, but for wheat parents that show a high GCA are more important and are used in cases where the selection is performed in subsequent generations.

Table 4. Estimates of SCA effects for the plant height in a 5×5 diallel cross of bread wheat

							LSD	
Parents	Pobeda	Renesansa	Sara	Partizanka	Pesma	SE	0.05	0.01
Pobeda		0.462 ns	1.810 ns	-0.305 ns	1.357 ns			
Renesansa			2.033 ns	-2.714 ns	-3.752 ns	2.01	4.06	5.43
Sara				-0.867 ns	2.262 ns			
Partizanka					4.781*			

+SCA: Specific Combining Ability, SE: Standard Error; LSD: Least Significant Difference test; Significant (P < 0.05), Highly significant (P < 0.01), Non-significant (ns)

The regression analysis graph (Vr/Wr) for F_1 generations for plant height is presented in Figure 1. As it is seen in Figure 1, regression line intersected the Wr axis below the origin, indicated over-dominant inheritance of the plant height. Regression analysis (Vr/Wr) showed that regression coefficient in F_1 generation was significantly different from unity, suggesting the presence of non-allelic interaction for plant height. This result indicated the necessary to study effects of epistasis, as it may have a greater significance in some genotypes. Detection of epistasis suggested that variation for plant height of wheat was higher under polygenic control. The varieties Renesansa, Sara and Pobeda had higher dominant genes, but varieties Partizanka and Pesma, which were far away from the origin, had higher recessive genes. The arrays that correspond to parents were similarly distributed along the regression line and indicate that the parents were genetically divergent for the analysed trait (Fig. 1). These results suggest that selection would be difficult in the early generations for plant height due to over-dominance type of gene action. Similar results, which indicated over-dominance type of gene action, have been reported by Saleem et al. (2005) and Petrović et al. (2012).



b: Coefficient of Regression, Wr: Covariance, Vr: Variance

Figure 1.Vr/Wr regression analysis for the plant height of bread wheat

Genetics of the plant height, evaluated by calculation of the genetic components of variation is shown in Table 5. The analysis of the components of genetic variance indicated that dominant component (H_1 and H_2) was larger than additive (D). Unequal values of H_1 and H_2 suggested that positive and negative alleles were unequal among parent cultivars. The frequency of the dominant allele (u = 0.72) was greater than the frequency of recessive allele (v = 0.28), which is in agreement with the calculated F value (interaction additive×dominant effect), which is positive, as well as the value of $H_2/4H_1$. The average degree of dominance ($\sqrt{(H_1/D)}$ = 4.19) had greater values than 1, which indicated over-dominance type of gene action in the inheritance of the plant height, which was in accordance with the results obtained by regression analysis. The ratio of the total number of dominant against recessive alleles (K_D/K_R) was greater than 1, indicating the presence of more dominant alleles in inheritance of this trait. Preponderance of dominance effects suggested that selection for the trait in early generations may not be useful and it had to be delayed till late segregating generations. These results are in agreement with earlier findings of Zečević et al. (2005) and Jadoon (2011), while Minhas (2012) reported the predominant role of additive effects in affecting genetic mechanism of plant height and the involvement of partial dominance in the inheritance of this character.

Table 5. Genetic components of variation for the plant height of bread wheat

Components	Values	Components	Values
D	1.48	$H_2/4H_1$	0.20
H_1	25.88	u = p	0.72
H_2	20.72	v = q	0.28
F	1.17	$\sqrt{(H_1/D)}$	4.19
E	2.83	K_D/K_R	1.21

[+]D: Measures additive effect, H_1 and H_2: Measures dominance effect, F: Determines frequencies of dominant to recessive alleles in parents, E: Shows environment effect, $H_2/4H_1$: Determines proportion of genes with positive and negative effects in the parents, u: The values of dominant alleles, v: The value of recessive alleles, $\sqrt{(H_1/D)}$: The average degree of dominance, (K_D/K_R): Ratio of the total number of dominant against recessive alleles

Conclusion

The results revealed that there was significant genetic variation for the plant height of wheat among the genotypes and among the years. Significant GCA and SCA effects imply the role of both additive and non-additive gene actions in the genetic control of the trait. The largest value of positive GCA effects were observed in genotypes Partizanka and Pesma, suggesting that these genotypes contain more genes with additive effects or additive×additive interaction effects and could be a good parent for this trait. The highest positive significant SCA effect exhibited by the cross Partizanka/Pesma (high x high general combiner) indicated the possibility of genetic improvement for this trait through pedigree selection. The regression analysis in F_1 generations indicated over-dominant inheritance of the plant height, which was confirmed using the analysis of the components of the genetic variance. Regression coefficient was significantly different from unity, suggesting the presence of non-allelic interaction and indicated that variation for plant height of wheat is under polygenic control.

THE EFFECT OF VETCH SEED SIZE ON THE SEED QUALITY AND ON SEEDLING VIGOR

Rade STANISAVLJEVIĆ[1]*, Ratibor ŠTRBANOVIĆ[1], Lana ĐUKANOVIĆ[1], Dobrivoj POŠTIĆ[1], Snežana JOVANOVIĆ[2], Marijenka TABAKOVIĆ[2], Jasmina MILENKOVIĆ[3]

Abstract

Common vetch (*Vicia sativa*L.) in Serbia has the highest economic importance of the species *Vicia*. It is mostly cultivated jointly with cereals (oats, wheat, and triticale). It is rarely grown in pure culture due to flattening.

Producers have noticed that the market offer various sized seed. We decided to examine the connection between seed size with seed germination and vigor.

The paper presents two years results (2012 and 2013), of two cultivars of vetch seed (*Vicia sativa L*), and the three seed lots of each.

Seeds of each lot are divided into three fractions (C- small<3.5 mm; B - medium 3.5 to 5mm: A- large>5 mm. The germination and vigor of seeds are tested from all fractions (A, B, C).Germinated seeds were done in hot bed between the filter paper at 20°C in the dark; energy of germination was checkedon the fifth day, and the germination of the fourteenth day, in accordance with the ISTA rules.

Seed size had a significant impact both on the germination, and on the seedling vigor. The impact of the year, the party of seed and the varieties had no significant effect ($P \leq 0.05$). Between seed germination and seedling vigor was found high correlation (r).

Key words: *seed size, seed germination, seedling vigor, Vicia sativa*

Introduction

Common vetch (*Vicia sativa*) is a forage species with a long tradition of cultivation in Southeast Europe. The traditional way of use is the drying and haymaking. In recent years, often used for making haylage or silage, this has contributed to advances in the technology of conservation. In both modes of use,lodging is the problem in the phase of collecting. Therefore, it is grown mainly with cereals (wheat, oats, triticale), which increases the yield and partly solves the problem of collection but also the need to establish the optimum relationship between vetch and cereals (Mišković 1996; Yucel, andAvci, 2009; Karagićet al., 2011). For the projected ratio of legume andcereals, seed germination and seedling vigor (initial growth of stems and radicles) are of high importance.

On the other hand, the size of the seed is an important physical quality characteristic that often affect the initial growth of seedlings and in some cases on germination. For example, the leading agricultural crops (maize, rice) size of the seeds has been strongly influenced by genetics. Variation in seed size is due to the flow of nutrients to the seed in the mother plants therefore depending on the circumstances where the seed is located.

In literature there are a wide range of different effects of seed size on seed germination, however, these results differ substantially between species in the literature is insufficient data on the results of research of influence seed size on germination and seedling vigor beans(Kaydanand Yagmur, 2008;Kakhkiet al., 2008; Mut andAkay, 2010; Ambikaet al., 2014).The effect of vetch seed size on germination and vigor is not sufficiently explored, especially in Serbia

Therefore, the aim of this study was to determine the influence of seed size on germination and vigor, which would facilitate the choice of varieties to farmers according to size of seed. This would further determine the direction of breeders in creating new varieties.

Material and methods

In eastern Serbia was taken the seed of vetch (*Vicia sativa*),near Zaječar, 139 m asl, 43°58'N 22°18'E; with three lots (lot factor) of two cultivars (Neoplanta and Ovcepoljska, factor variety), for two years (2012 and 2013). Then the seeds are grouped into three fractions (C - small<3.5 mm; B - medium 3.5 to 5mm: A - large> 5 mm). Seed germination (%) was testedin the hot bed filter paper; 20°C - dark, fourteenth day was checked total seed germination (ISTA rules, 2003). By measuring each seedling (stem length – cm; radicle length – cm; fresh seedling weight- g) vigor was determined.

Statistical Analyses. Data were evaluated by analysis of variance (ANOVA) with Minitab 16.1.0 Statistics software package. When the *F*-test was significant, means were separated by Duncan's multiple range test at $p \leq 0.05$. An arcsine square-root transformation was performed on data percent. The correlation (r) between traits was established employing the Pearson's Correlation Test.

Results and discussion

Effect of variety, the seed lot and their interaction had no significant effect (F test; $P \geq 0.05$) on germination and vigor (Table 1). The reason is probably similar climatic conditions in 2012 and 2013 (table not shown) during critical phases of seed quality (filling, maturing and seed harvesting). Also, during both years in both varieties were applied the same breeding technology. The seed lot has no significant effect on germination in the grass species of *F. pratensis, F. arundinacea, F. rubra, D. glomerata* (Stanisavljević et al., 2013, 2014).

On the other hand, seed size showed a significant influence on seed germination and seedling vigor (Table 2). Between germination of large fractions (A 95%) and middle fractions (93% B), difference of 2% was not statistically significant ($P \geq 0.05$). Between middle-fractions (B) and fine fractions (C) difference of 3% was not statistically significant ($P \geq 0.05$). But, between the large (A) and fine fractions (C), achieved the difference of5%, which was statistically significant ($P \leq 0.05$).

The results ofbetter seed germination in larger seeds are consistent with the results obtained by Kaydan and Yagmur, 2008 with triticale; Kakhki et al. (2008)with wheat;Mut and Akay(2010)with oats and Sulewska et al.(2014)with maize. Overall, we should expect stronger initial seedling growth (vigor) because of higher feed into larger seed, which was necessary for the initial growth of seedlings.

In the fodder production, vigor (initial growth stems, radicles, and seedling weight) have high importance for the establishment of relations projected in grass-legume forage mixtures (Stanisavljević et al. 2011, 2013, 2014).

In our studies, from seed fraction A, rising ofstems (24.52cm), radicles (15.24cm) and weight of seedlings (40.26g) are significantly stronger compared to seedlings resulting from seed fraction B (22.87cm stem, 2.14cm radicle, seedling weight 36.12g). Also, vigor in fraction B was significantly ($P \leq 0.05$) higher than seedlingvigor obtained from fraction C (20.23cm stem, 13.15cm radicle, seedling weight 31.97g); (Table 2). The results are consistent with general conclusion that, in agricultural plant species higher seed weight gives stronger seedling which is advantageous, especially in the initial rise (Ambika et al., 2014).

Table 2. Effect of seed size on germination and vigor (average of two years, two varieties and the three seed lots).

Seed size	Germination %	Seedling vigor		
		Stem length, cm	Radicle length, cm	Fresh seedling weight g

	II	-	542***	0.529***
	III	-	-	0.507**
Small	Germination (I)	0.504**	0.476**	0.482**
	II	-	0.447**	0.424*
	III	-	-	0,409*

Statistical significance level: *P≤ 0.05, ** *P*≤ 0.01, *** *P*≤ 0.001.

In the largest seed fractions (A) between germination and seedling vigor achieved the strongest correlation coefficient (r = 0.720 to 0.630, P ≤ 0.001;Table 3). Also, the germination of seed medium fraction (B) has achieved the same interdependence with vigor (r = 0.648 to 0.503; P ≤ 0.001). Between radicle length and seedling weight, correlation coefficient was not so high (r = 0.507; P ≤ 0.01).

Seed germination of fractions C, with all tested parameters of vigor, has also achieved positive, but lower dependence (r = 0.504 to 0.476; P ≤ 0.01). From this fractions, the lowest interdependence achieved between the weight of seedlings and radicle length (r = 0.409; P ≤ 0.05) and seedling weight and stemlength (r = 0.424, P ≤ 0.05;Table 3).

Conclusion

Large vetch seeds had a 5% higher germination than the small seeds and 2% higher germination than medium seeds. Large seedsachieved significantly stronger seedling vigor (stem 24.52cm,radicle 15.24cm, and weight of seedlings 40.26g) than medium seeds(stem 22.87cm, 14.2cm radicle, seedling weight of 36.12g.). Seedlings from small seedshad significantly lower vigor (stem of 20.23cm, radicle of 13.15cm, seedling weight of 31.97g.) thanmedium seeds.

Manufacturers prefer the larger seeds for better and stronger seedling vigor under field conditions. It is necessary to bear in mind the negative side of larger seeds, that it increases the sowing rate necessary for the realization of the optimum number of plants per unit area, which affects the price increase.

Abstract

In this paper are studied 15 cultivars of alfalfa (*Medicago sativa* L.) of different geographical origins. In the studied alfalfa cultivars were tested for correlations of some important traits in 2007. year. Morphological traits were studied: height of plants (cm), number of stems, number of internodes per stem, green mass yield per cutting and the total yield of green mass (g). In the first cut were recorded medium strong positive correlation between the height and yield of green mass (r = 0.76 *). Heritability properties of plant height was very high in the first year (2006, h = 80.52) in the first cut, while in the second year of investigation (2007, h = 56.96), in the second cut. Estimation of heritability properties for green mass yield varied according to age, the highest value was obtained in the first cut 2006. year (h = 72.75), indicating a high share of genotype, while the lowest value was obtained also in the first cut in the 2007. year (h = 29.55). Breeding material possesses desirable traits for breeding new cultivars and with the choice of an appropriate model of breeding possible selection activities cultivars for specific purposes.

Key words: *alfalfa, cultivar, correlation, trait.*

Introduction

Alfalfa is a perennial and most important for multiple cuts fodder plant, which gives high yields and excellent quality forage in different environmental conditions (Đukić and Erić, 1995). Depending on the genotypes, characterized by high variability in forage yield (CV=28.6%) (Štrbanović, 2010). It is grown in the world over an area of 33 million hectares, while in Serbia represented an area of about 190.000 hectares. Areal of alfalfa cultivation on all continents covers more than 80 countries, from moderately cold to the tropics. The wide geographical distribution of alfalfa is conditioned by its great adaptability to different climatic and soil conditions (Julier *et al*., 1995). During of breeding certain traits that are controlled by a larger number of genes often lead to undesirable changes in the direction of some other important traits, which is due to mutual correlation in characteristics caused by the attachment of genes or pleiotropic effect (Šurlan-Momirović *et al*., 2005). It is therefore important to know the properties of interdependence traits, or in what way and to what extent one trait affects the other, which will allow easier identification of criteria and predict the course of breeding (Falconer and Mackay, 1996). Particular attention should be paid to genetic correlation coefficients that determine relationships between traits based only on genotype, without the influence of environmental factors.

Material and methods

In this paper studied 15 cultivars of alfalfa (*Medicago sativa* L.). Nine of selected cultivars of alfalfa were of the US origin and six of selected cultivars of alfalfa were of Europe origin (Table 1). The experiment was placed at the experimental field of the Institute for forage crops in Globoder at an altitude of 149 m. Experiment was placed on soil type alluvial sediment and is characterized by good physical - chemical properties, has a neutral pH value

(about 7), which is very favourable for growing alfalfa. Sowing of individual plants was performed manually in the spring, at the beginning of April 2005. at a distance of 60 to 60cm. The experiment was a randomized block design with four replications, with 60 plants per variety. In the course of performing experiments implemented a complete agricultural technology. Morphological traits were studied: height of plants (cm), number of stems, number of internodes per stem, green mass yield per cutting and the total yield of green mass (g). Based on the analysis of variance have been calculated components of variance studied traits.

Genetic (σ_g^2) and phenotypic (σ_f^2) components of variance:

$$\sigma_g^2 = \frac{MS_2 - MS_3}{r}\ ; \qquad \sigma_f^2 = \sigma_g^2 + \sigma_e^2\ ; \qquad \sigma_e^2 = MS_3$$

On the basis of the components of variance is calculated heritability in a broader sense (x_b^2):

$$h_b^2 = \frac{\sigma_g^2}{\sigma_f^2} \times 100$$

The coefficients of genetic and phenotypic variation (CVG and CVF) were calculated as follows:

$$CV_G = \frac{\sqrt{\sigma_g^2}}{\bar{X}} \times 100 \qquad CV_F = \frac{\sqrt{\sigma_f^2}}{\bar{X}} \times 100$$

The analysis of covariance examined characteristics of the studied alfalfa cultivars, calculated coefficients of genetic and phenotypic correlations.

- genetic correlation coefficient

$$r_{g_{xy}} = \frac{COV_{g_{xy}}}{\sqrt{\sigma_{g_x}^2 \times \sigma_{g_y}^2}}$$

- phenotype correlation coefficient

$$r_{f_{xy}} = \frac{COV_{f_{xy}}}{\sqrt{\sigma_{f_x}^2 \times \sigma_{f_y}^2}}$$

Results and discussion

In the studied alfalfa, cultivars were tested for correlations of some important traits in 2007. year. Research in the first two cuts, which generate over 60% of the fodder and represent best performers and most importantly cuts alfalfa. Among individual characteristics were significant and highly significant correlation expressed genetic and phenotypic correlation coefficients (Tables 2. and 3.).

Table 2. Correlation coefficients of genetic and phenotypic traits studied alfalfa cultivars, 2007. the first cut.

Phenotype / Genotype	Height of plants	Number of internodes per stem	Number of stems	Green mass yield in the I cut	Total yield of green mass
Height of plants		0.57	- 0.57	0.76*	0.45
Number of internodes per stem	0.32		- 0.38	0.69	0.25
Number of stems	- 0.40	- 0.17		0.31	0.30
Green mass yield in the I cut	0.62	0.30	0.33		0.38
Total yield of green mass	0.46	0.17	0.29	0.31	

Table 3. Correlation coefficients of genetic and phenotypic traits studied alfalfa cultivars, 2007. the secund cut.

Phenotype / Genotype	Height of plants	Number of internodes per stem	Number of stems	Green mass yield in the I cut	Total yield of green mass
Height of plants		0.40	- 0.46	0.79*	0.44
Number of internodes per stem	0.21		0.02	- 0.33*	-0.22
Number of stems	- 0.14	0.24		0.49*	0.79*
Green mass yield in the II cut	0.65	- 0.35	0.44		0.32
Total yield of green mass	0.42	-0.15	0.57*	0.63	

In the first cut were recorded medium strong positive correlation between the height and yield of green mass (r = 0.76*). In the second cut were recorded medium strong positive correlation between the height and yield of green mass (r = 0.79*), number of stems and yield of green mass (r = 0.49*) and the number of stems and total yield of green mass (r = 0.79*). A

negative correlation was observed between the number of internodes per stem and yield of green mass (r = - 0.33*). For other traits calculated correlations were not significant. Radovic (2005) was found strong positive correlation between yield and number of stems (r = 0.66**), as well as medium strong correlation between the yield of green mass with the number of stems (r = 0.49*). Zonjić (1961) reported a high correlation between weight and plant height (r = 0.92**). In his research Zoric (1993) determined a strong correlation between the height of plants and yield of green mass (r = 0.69**), as well as number of stems and green mass yield (r = 0.78**). Strong positive correlations between height of plants and yield of green mass presented many authors in their research (Mijatovic, 1960, Zonjić, 1961, Ivanov, 1980, Hauptvogel, 1994, Katic, 2000). In examining the 36 alfalfa cultivars Varga et al., (1994), have determined a negative correlation between yield and number of internodes per stem (r = - 0.53**). The share of genetic variance is quite high for almost all the characters, which tells us that for the most part variation of the studied traits responsible genotype of the plant.

Plant height

Heritability properties of plant height was very high in the first year (2006) and reached h = 80.52 in the first cut, while in the second year of investigation (2007) reached h = 56.96, in the second cut. A very high share of genetic variation coefficient, which indicates that the value of phenotypic properties of plant height for the most part influenced by genotype.

In the estimation of heritability has a large influence plant density (Cristophe, 1973), so that with increasing plant density decreases heritability. Therefore, it can be concluded that the characteristics of plant height is highly heritable and that can be done on the basis of plant breeding level to improve the properties of yield (Table 4).

Table 4. The components of variance, heritability and coefficient of variation for plant height alfalfa cultivars studied from first to fourth cuttings in 2006. and 2007.

Trait	Height of plants							
	1. cut		2. cut		3. cut		4. cut	
Parameters	2006.	2007.	2006.	2007.	2006.	2007.	2006.	2007.

CV_F (%)	10.78	13.14	6.71	13.15	6.98	11.36	14.67	15.09

Number of stems

The heritability of the characteristic number of stems per plant was quite high in both study years. The highest value of the year 2006. showed in the third cut (h = 62.47), while in the second year of investigation (2007), the highest value was shown in the first cut (h = 57.11). Genetic coefficient of variation is quite high in both studied years. The highest values showed in the first cuts in both years, and was 20.98% in the year 2006., while in the 2007. year showed slightly higher value 25.31%. All this indicates that the phenotypic characteristic of component number of stems under the strong influence of genetic components. Sikora, (1974) for this property states that the genetic variance in total phenotypic variance was 89%. The

high heredity of this trait suggests that it can be used as selection criteria in the plant yield, because there is a strong correlation between the number of stems and plant mass (Table 5).

Table 5. The components of variance, heritability and coefficient of variation for stem number of alfalfa cultivars studied from first to fourth cuttings in 2006. and 2007.

Trait	Number of stems							
	1. cut		2. cut		3. cut		4. cut	
Parameters	2006.	2007.	2006.	2007.	2006.	2007.	2006.	2007.

CV_F (%)	28.51	33.49	21.02	23.82	23.73	27.22	24.87	33.15

Number of internodes per stem

Number of internodes per stem directly influences the increase of green mass and thus the quality of alfalfa, so that is a very important trait. The greatest value of this property as far as the heritability was found in the first cut of 2006. year (h = 58.81), while the lowest value recorded in the second cutting of 2007. year (h = 14.04) (Table 6).

Table 6. The components of variance, heritability and coefficient of variation for number of internodes per stem of alfalfa cultivars, studied from first to third cuttings in 2006. and 2007.

Trait	Number of internodes per stem					
	1. cut		2. cut		3. cut	
Parameters	2006.	2007.	2006.	2007.	2006.	2007.
σ^2_g	1.42	0.349	0.49	0.18	0.51	0.59

h^2_b(%)	58.81	15.53	35.76	14.04	51.49	40.22
CV_G(%)	7.58	4.19	6.03	3.28	5.47	7.81
CV_F (%)	9.88	10.62	10.09	8.77	7.63	12.32

Green mass yield per cutting and the total yield of green mass

Estimation of heritability properties for green mass yield varied according to age, the highest value was obtained in the first cut of 2006. year (h = 72.75), indicating a high share of genotype, while the lowest value was obtained also in the first cut in the 2007. year (h = 29.55). Similar values as heritability demonstrated genetic coefficient of variation, which is in the first cut of 2006. was 21.45%, while in the first cut of 2007. was 12.03%. Such results can be explained by the strong influence of climate, drought and actually very high temperatures. Jacquard and Hanan (1970) found that the size of heritability for green mass yield depends on the conditions in which the estimate is done, an example density of the plants, so they get a higher percentage of heredity in rare plant density (h = 77) compared to the compacted plant density (h = 54). Due to the differences in heritability and the total yield of green mass, we can conclude that the heredity of green yield in under the increasing influence of environmental factors (Tables 7. and 8).

Table 7. The components of variance, heritability and coefficient of variation for green mass yield per cutting alfalfa cultivars studied from first to fourth cuttings in 2006. and 2007.

Trait	Green mass yield per cutting							
	1. cut		2. cut		3. cut		4. cut

Trait	Green mass yield - total	
Parameters	2006.	2007.
σ^2_g	35345.6	60509.9
σ^2_f	65936.1	177206.1
h^2_b(%)	53.61	34.15
CV_G(%)	11.95	13.86
CV_F(%)	16.32	23.71

Conclusion

Significant differences were found both between and within the studied alfalfa cultivars for most traits depending on cuts and years of research. The recorded positive correlations in the first and second cuts in the second year (2007) research. In the first cut were recorded medium strong positive correlation between the plant height and yield of green mass (r = 0.76*). Similar results positive correlations were obtained in the second cut. The negative correlation in the second cutting was found between the number of internodes per stem and yield of green mass (r = - 0.33*). Analyzing the components of variance is a very high share of genetic variance in total, which indicates that the impact of environmental factors on gene expression is very low, that is, for the most part responsible genotype variability. This confirms the very high values for the coefficients of heritability in a broad sense, ranging from 34.28% to 72.76% for the total dry matter yield. Breeding material possesses desirable traits for breeding new cultivars, and with the choice of an appropriate model of breeding, possible selection activities cultivars for specific purposes.

Abstract

The main goal of the most maize breeding programs is to create superior inbred lines that could be used for getting newer, better commercial hybrids. It is necessary, by using suitable experimental methods, to investigate potential of every recently created population for possible adopting in long-term breeding programs. This paper presents the investigation of F_3 population 2002-30, created in the Department of Maize, Institute of Field and Vegetable Crops, Novi Sad. The investigation lasted for three years. At the first year, about 150 plants of the studied population were selfed and simultaneously crossed with the tester 1491x1496, in order to get complementary S_1 and HS progenies. After the harvest, 41 progenies of each type were selected by the random sample method. During the second and third year, trials were carried out in Aleksinac, Leskovac, and Kruševac, as three studied environments, in RCB design. Moderately strong and strong positive phenotypic correlation between yield components and grain yield was established, but between certain yield components negative correlation coefficients also were found. We found many significant positive, but also negative values of genotypic correlation coefficients; however, general tendencies were the same as for phenotypic correlation coefficients. Genotypic correlation coefficients of HS progenies were much greater than the phenotypic ones.

Key words: *maize, correlation, recurrent selection, yield components*.

Introduction

The main goal of the most breeding programs is to create superior inbred lines that could be used for getting newer, better commercial hybrids. It is necessary to evaluate, by suitable experimental design, potential of every new population for possible introduction in long-term breeding programs (Stojković, 2007). Choice of methods for dealing with a new synthetic population depends on level of favorable alleles, traits that selection is aimed for, their heritability, genotypic correlation between the most important traits, as well as on breeding goals, but a common characteristic of the all recurrent selection methods is selection and recombination of a lower number of superior progenies for next selection cycle (Deletić, 2003). Having in mind that studying intrinsic quantitative genetic parameters of every new population and their constant observing during selection process, in order to choose selection method and level, is hardly reachable in practice, every study of this type contributes to establishing general rules. Possible contribution of genes in achieving heterosis is usually determined by investigating half-sib progenies (i.e. test hybrids), while studying of S_1 progenies reveals additive effect of genes.

This study has been aimed to establish genetic and phenotypic interconnectedness among yield components, which is essential in considering selection for more than one trait, and for proper choice of selection methods. Selection for grain yield is a kind of selection for more than one trait, because it is a complex trait, highly dependent on yield components.

Material and methods

The object of this study was F_3 maize population 2002-30, created in the Department of Maize, Institute of Field and Vegetable Crops, Novi Sad (Serbia). During the first year of investigation about 150 plants of the population were selfed and simultaneously crossed with the tester 1491x1496, in order to get parallel S_1 and HS progenies. After the harvest, 41 progenies of each type (S_1 and HS) were selected for trials, by random sample method. During the second year a field trial was set in Aleksinac, and during the third year field trials were carried out in Leskovac and Kruševac (total three environments), in random complete block design with two replications, where the experimental plot area was 0.7x4.6 m. Number of plants per hectare amounted 62,112.

Grain yield is expressed as t/ha of grain with 14% of water, and the all plants of an elementary plot were used to determine grain yield and number of lodged plants. The other studied traits were analyzed on ten randomly chosen plants (i.e. ears) per progeny. A trait is expressed as the mean value of the investigated plants. Correlation coefficients, their standard errors and tests of significance have been calculated according to Falconer (1989), with the correction for negative values according to Deletić (2003).

Results and discussion

Correlation points to concordance degree of two or more traits. If genetic connection exists, selection for a trait will cause correlated response, i.e. change of the other traits mean value. For that reason, it is important to know this parameter for proper choice of selection methods.

Table 1. Phenotypic correlations (above diagonal) among the studied traits of S_1 progenies and their standard errors (below diagonal).

Traits	Grain yield	% lodged plants	Ear height	Plant height	Ear length	No of rows	Grains per row	1000 gr. mass

* $p<0.05$, ** $p<0.01$

Grain yield of S_1 progenies was in strong, positive phenotypic correlation with ear height (0.63**) and plant height (0.82**), and in moderately strong, positive correlation with ear length (0.46**) and number of grains per row (0.39**). Significant, moderately strong, positive phenotypic correlation was found between grain yield and 1000 grain mass (0.32*). Moderately strong and strong, positive phenotypic correlation between certain yield components was established, but negative phenotypic correlation coefficients also were observed. The strongest negative phenotypic correlation connection was found between percent of root and stalk lodged plants and plant height (-0.46*) (table 1).

Coefficients of genotypic correlation between grain yield of S_1 progenies and the other investigated traits were positive and highly significant, except number of grain rows per ear (0.07) and number of root and stalk lodged plants, where significant, moderately strong, negative correlation (-0.56**) was found. We also observed several significant positive and negative values of genotypic correlation, but general tendencies were the same as for phenotypic correlation coefficients (table 2).

Coefficients of phenotypic correlation between grain yield and the other traits of HS progenies were positive and moderately strong, significant for number of grain rows per ear (0.35*), and highly significant for plant height (0.50**). Moderately strong, positive phenotypic correlation was also observed between plant height and ear length (0.53**), plant height and number of grains per row (0.44**), and between ear length and number of grains per row (0.46**). Moderately strong, negative phenotypic correlation was observed between number of grain rows per ear and 1000 grain mass (-0.54**) and between number of grains per row and 1000 grain mass (-0.34*), while other coefficients of phenotypic correlation were not significant (table 3).

Table 4. Genotypic correlations (above diagonal) among the studied traits of HS progenies and their standard errors (below diagonal).

* $p<0.05$, ** $p<0.01$

Genotypic correlation coefficients of HS progenies (table 4) were much greater than the phenotypic ones. Thus, correlative connection was highly significant, strong, between grain yield and plant height (0.91**), as well as number of grain rows per ear (0.64**), but moderately strong between grain yield and ear length (0.51**). Highly significant genotypic correlation was also observed between ear height and plant height, plant height and ear length, as well as between plant height and number of grains per row. Negative, highly significant correlative connection of moderate strength was found between number of grain rows per ear and 1000 grain mass (-0.49**), as well as between number of grains per row and 1000 grain mass (-0.42**).

Although there is a large number of previously reported data concerning correlative connection among various quantitative traits, especially grain yield and other traits, even a glance at some of them (Deletić, 1999; Deletić, 2003; Anđelković, 2000; Rošulj, 1999; Nastasić, 2001; Burak and Broccoli, 2001; Vasić et al., 2001; etc) reveals impossibility of a detailed comparison between them.

Conclusion

In S_1 progenies grain yield was in positive phenotypic correlation with plant height, ear length, number of grains per row and 1000 grain mass. Positive phenotypic correlation between certain yield components was established, but negative correlation coefficients also were found, e.g. between root and stalk lodged plants and plant height.

When genotypic correlation coefficients of S_1 progenies are observed, general tendencies were the same as for phenotypic correlation coefficients.

Phenotypic correlation coefficients of HS progenies were positive between grain yield and grain row number per ear, as well as between grain yield and plant height.

Genotypic correlation coefficients of HS progenies were much greater than the phenotypic ones.

Abstract

Crude protein content is one indicator of red clover quality, which, among other things, is affected by the variability of soil properties. The aim of this study was to determine the effect of different soil types on the content of crude protein in red clover. The examination was conducted on six types of soil: chernozem, vertisol, eutric cambisol, humofluvisol, fluvisol and humogley (according to domestic soil classification). Sampling of plant material was carried out during May 2011, in the second year of red clover production. On the basis of these results it can be concluded that there are statistically significant differences in the content of crude protein between red clover plants, grown on different soil types. The highest protein content has red clover grown on chernozem (21.33%) and lowest on the fluvisol (14.33%). Soils, on which the protein content in red clover was higher, are characterized by good physical and chemical properties, a higher content of total nitrogen, primarily nitrogen fixation increased, as have the favorable conditions for microbial activity. This is primarily related to the pH value, because the greatest number of *Rhizobium* is in neutral and slightly alkaline soils. The expected results should be a guideline for the production practice, because the modeling of feed production, in different production conditions, raises the possibility of more intensive crop and livestock production.

Keywords*:* *red clover, crude protein, soil type*

Introduction

Protein content is one of the indicators of red clover quality. Variations in plant protein content are not conditioned only by plant species, but also by soil characteristics and applied growing technology (Živkov-Baloš et al., 1999).

Red clover is characterised by high protein content, which ranges from 186 to 264 g/kg of dry matter, depending on development stage and cultivar (Lugić et al., 2002; Lugić et al., 2006).

Red clover mainly satisfies its need for nitrogen (43-80%) by nitrogen fixation in a symbiotic association with the nodule bacteria *Rhizobium.* There are numerous factors that affect the number and size of nodules, as well as the quantity of fixed nitrogen: mineral fertilization, pH, temperature, moisture, soil aeration, etc. (Jakšić, 2015). Red clover averagely fixes 190 kg/ha per year, whilst it takes up around 3 kg on nitrogen to produce 100 kg of hay (Vučković, 1999).

Symbiotic microorganisms are more active in soils with favourable physical and chemical characteristics, which lead to higher protein content of red clover. It primarily relates to pH value, because the nodule bacteria are most abundant in neutral and slightly alkaline soils (Jakšić et al., 2013). In acid soils they are less abundant due to the lack of Ca and Al toxic effects (Govedarica & Jarak, 1995). In soils with pH below that 5.5, division of nodule bacteria slows down or nearly stops.

The aim of this paper was to study the effects of different soil types on crude protein content of red clover plants.

Materials and Methods

Studying effects of different soil types on crude protein content in red clover was conducted on six soil types (according to national classification): chernozem, vertisol, eutric cambisol, humofluvisol, fluvisol and humogley.

Soil samples were collected during May 2011 in second growing season of red clover. The testing was performed in Novi Sad, Žabari, Ratari, Kruševc, Šabac and Hetin in Serbia. Soil samples were in disturbed condition while taken by agrochemical probe from 0-30 cm depth. One representative soil sample consisted of 15-25 individual samples. Collected samples were air dried and milled by soil grinder to a particle size <2 mm according to SRPS/ISO 11464:2004. Total nitrogen content was determined by AOAC Official Method 972.43:2000, Microchemical Determination of Carbon, Hydrogen, and Nitrogen, Automated Method, in Official Methods of Analysis of AOAC International. The humus content was determined by Turin's method (JDPZ, Hemijske metode ispitivanja zemljišta, 1966). The content of calcium carbonate was determined volumetrically on Scheibler Calcimeter by method ISO 10693:1995. Active pH value was determined in soil-water suspension, while substitutional was determined with 1M KCl, potentiometrically according to method ISO 10390: 2005.

Plant material samples of red clover were collected in May, during flowering stage – first cutting. Fodder was cut manually at the beginning of flowering from an area of 10 m^2 by cutting plant at the height of 5 cm, in four repetitions. Nitrogen content was determined by AOAC Official Method 972.43:2000, Microchemical Determination of Carbon, Hydrogen, and Nitrogen, Automated Method, in Official Methods of Analysis of AOAC International. Crude protein content was determined indirectly via nitrogen content, multiplying with coefficient 6.25, which represents ratio of total nitrogen and crude proteins in legumes (Undersander *et al.*, 1993).

Results and Discussion

Basic chemical soil characteristics of all studied soils are shown in Table 1. According to average nitrogen content, chernozem and humogley were well provided, while the other types were medium provided with this nutrient element. Soils were acidic to slightly alkaline according to the soil pH, and non-carbonate to carbonate according to calcium carbonate content. Humus content characterised soils as low-humic to humic. Studied soil types had very low to optimal level of readily available phosphorus, as well as optimal to high level of readily available potassium.

Table 1. Basic chemical soil characteristics of studied soils

Soil type	pH-KCl	pH-H_2O	N (%)	$CaCO_3$ (%)	Humus (%)	P_2O_5 (mg/100g)	K_2O (mg/100g)
Chernozem	7.38	8.11	0.21	5.47	2.81	15.95	29.33
Vertisol	5.88	6.89	0.16	0.48	2.45	3.93	23.15
Eutric cambisol	4.76	6.05	0.13	0.22	2.25	1.93	23.56
Fluvisol	5.53	6.58	0.15	0.07	2.30	3.96	16.36
Humofluvisol	6.52	7.55	0.15	3.75	2.11	14.66	23.17
Humogley	6.43	7.30	0.26	0.91	3.59	9.48	16.08

Trial results show significant effect of soil type on red clover protein content (Table 2). The highest average content was determined in tested forage plants from chernozem (21.33%), while the lowest in plant dry weight from fluvisol (14.33%). According to Džamić and Stevanović (2000), nitrogen content in full flowering of red clover amounts to 16.25%. Protein content in Vasiljević et al. (2011) of red clover from chernozem soil ranged from

17.59% to 18.32%. Marković et al. (2007) confirmed higher protein content of red clover in second cutting on alluvial soil - 19.74%.

Table 2. Protein content (%) in red clower

Soil type	Protein content (%)
Chernozem	21.33 a
Vertisol	17.54 d
Eutric cambisol	18.02 d
Humofluvisol	18.93 cd
Fluvisol	14.33 e
Humogley	20.59 ab
Average	**18.46**

Treatments marked with the same letter do not have statistically significant differences (Fisher’s exact test 0.05).

In the trial of Stević et al. (2007) on vertisol (pH value of 5.1), crude protein content in red clover averagely amounted to 17.90%.

Soils with higher nitrogen and dry weight protein content have higher total nitrogen content, and higher nitrogen fixation, due to favourable conditions for microbiological activity. It primarily relates to pH value, because the nodule bacteria are most abundant in neutral and slightly alkaline soils (Jakšić et al., 2013). In acid soils they are less abundant due to the lack of Ca and Al toxic effects (Govedarica & Jarak, 1995). In soils with pH below that 5.5, division of nodule bacteria slows down or nearly stops.

Grewal and Williams (2003) confirmed that significantly higher crude protein content was determined on treatments with liming, while Stout et al. (1997) stated that increase of crude proteins from 9.2% to 16.3% was achieved by application of lime material of 5 t/ha of CaO on soil with 5.1 pH value.

Correlation analysis was used to determine significant positive correlation between protein content in red clover and readily available potassium content in soil (r=0,58*), while regression analysis determined statistically significant average change of protein content in plants that occurs during change of readily available potassium content in soil (Figure 1). Regression coefficient showed that protein content in plants increased by 0.16% when the content of readily available potassium in the soil increased by one unit. Potassium has a positive effect on nodule bacteria growth, nodule formation and their functioning, as well as on plant growth, which results in higher nitrogen fixation (Divito and Sadras, 2014). In addition, K affects the metabolism of N by helping protein synthesis (Ubavić & Bogdanović, 1995).

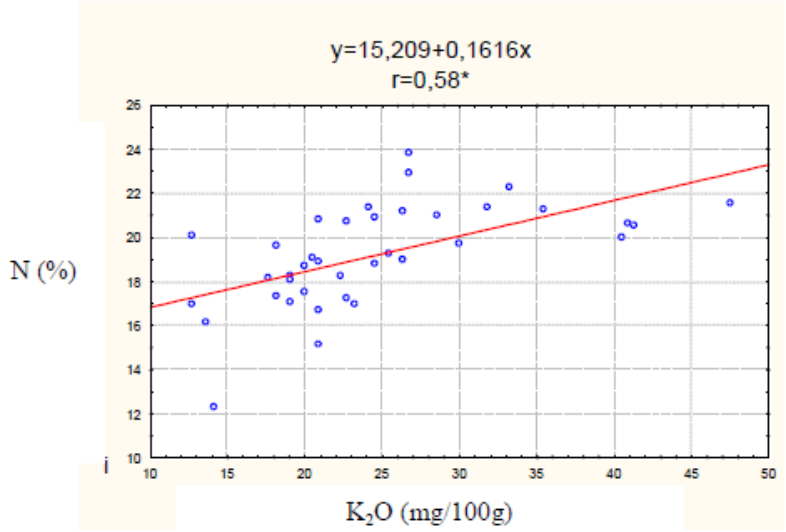

Figure 1. Dependence of protein content (%) in dry weight of red clover on readily available potassium content in the soil (mg/100g)

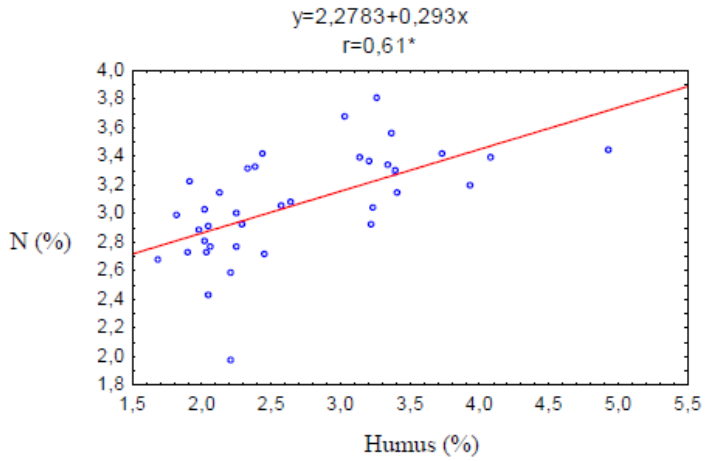

Figure 2. Dependence of nitrogen content (%) in dry weight of red clover on humus content (%) in the soil

Significant positive correlation between nitrogen content in red clover and humus content in the soil was determined (r=0.61*), while regression analysis was used to determine statistically significant average change in nitrogen content in plants, which occurs with change in humus content in the soil (Figure 2). Regression coefficient shows that the nitrogen content in plant increases by 0.29% when the humus content in the soil is increased by one unit. Presence of larger quantities of organic matter in the soil increases the content of elements necessary for plant nutrition, considering that their decomposition affects the nutrients to transform into mineral forms available to plants (Ubavić & Bogdanović, 1995). In addition, humus has a stimulating effect on biomass increase and macroelements uptake (Chen & Aviad, 1990).

Conclusions

The effect of soil type on crude protein content in the dry weight of red clover was significant. The largest average protein content was determined in studied forage plants grown on chernozem, while the lowest was in the dry weight from fluvisol.

More quality forage was obtained on soils with more favourable physical and chemical characteristics. Significant positive correlation between nitrogen content and humus content, as well as between proteins in red clover and readily available potassium in the soil was determined.

Abstract

The effect of storage was studied on grain metabolites wheat cultivars selected in Serbia – Evropa, Pobeda and Renesansa. The samples (500 ± 5 g, 11–14% moisture) were placed into sealed plastic containers of the same volume, labelled and stored at a temperature of 25 ± 2 ^{o}C for 12 and 24 months. During the 12 and 24 months of storage, there was a decrease on average in lipids (3.55% and 5%), crude cellulose (16.65% and 21.77%) and an increase in total ash concentration (10.2% and 12.39%) and dry matter (10.01% and 10.31%).

Storage duration caused a significant decrease in lipids and cellulose, when compared to freshly harvested grains ($p \leq 0.05$). Ash levels increased significantly ($p \leq 0.01$) with storage duration. Prolonging of storage resulted in increased dry matter in grains of all the investigated cultivars ($p \leq 0.01$).

Key words: *wheat, storage, metabolites*

Introduction

It is important to store freshly harvested wheat grains before processing them for their future use. Wheat is an important cereal crop in people's diet worldwide. Due to its wide-spread use, wheat is the most commonly stored cereal crop. It is estimated that an average adult needs 150 kg of wheat per year. Storage duration negatively affects gluten levels (Rasheed et al., 2014). It is necessary to provide good storage conditions, in order to avoid undesired physical and chemical changes that can occur in grains during storage. For efficient storage, grain moisture and the temperature in the storage facility are very important (Rehman 2006; Rehman et al., 2002). Wheat grains with less than 12% of moisture can be stored for a longer period of time. Grains reduce germination ability over time, whereas their nutrition properties stay at a satisfactory level. Grains should be protected from rodents, insects and external weather conditions. An outer layer of grains can contain thousands of fungal spores and bacteria inactive at lower moisture levels. If grains have 13.5%-15% of moisture, fungal spores will develop more slowly. Grains with increased moisture levels, 16%-23%, provide almost ideal conditions for uninterrupted fungal development. Aerobic bacteria require 20% of moisture for growth and development. A combination of increased moisture and respiration of grains, fungi and bacteria results in releasing heat and evaporation of water that stimulate additional microbiotic activities (Nummer et al., 2013). Such biomass is no longer suitable for further use. All of this can have very serious economic consequences.

Materials and methods

Materials and storage conditions

The study investigated three commercial wheat cultivars – Pobeda, Renesansa and Evropa. Renesansa was bred at the Institute of Field and Vegetable Crops in Novi Sad and produced on the experimental field in Rimski šančevi, while Evropa and Pobeda were produced in Bajina Bašta. Pobeda is a mid-late winter wheat cultivar, with genetic potential for 11 tha^{-1}of

yield. It belongs to B1-A1 quality group and it is quite adaptive. Evropa is a bread wheat cultivar with good chemical composition and a high level of gluten. Renesansa is an early-mid-winter cultivar, with good chemical composition. It belongs to bread wheat cultivars, B1-A1 quality group. In 2012, all three cultivars were harvested and their grains were hulled.
Standard grain sampling techniques (ISO 24333:2009) were used. The samples were protected from insect infestations without using any chemicals. Then, the samples (500 ± 5 g, 11–14% moisture) were placed into sealed plastic containers of the same volume, labelled and stored at a temperature of 25 ± 2 ^{0}C for 12 and 24 months. The relative humidity of the storage rooms was recorded but not controlled. Storage temperature of 25 ± 2 ^{0}C was chosen to resemble the adverse temperature often found in storage facilities in south-eastern Europe. At the end of the previously defined period, three containers of the same sample were randomly taken, and their concentration was mixed and tested. Thus formed samples were then ground in a laboratory mill (1 mm mesh size).

Chemical properties

The level of moisture in the analysed samples was determined according to the AACC International (2000). Total lipids and total ash were determined according to Kaluđerski and Filipović (1998). The level of crude cellulose (crude fibre) was determined according to Veender, using ‘‘Fibertec 2010’’ and the instructions from the manual: Fibertec 2010 system, User Manual, 1009 9130/rev. 1.3, FOOS Tecator, Sweden. The samples were ground in a laboratory mill (Knifetec 1096). All the samples were tested in three replications, and the results were expressed on a dry matter basis.

Statistical analysis

Testing the differences between the genotypes and storage duration, as well as their interaction was conducted with the variance analysis of a two-factorial trial model (ANOVA), the F test for group comparisons and the Tukey’s HSD multiple comparison test for the risk level of 5% and 1% (Hadživuković, 1977; SAS Institute Inc., JMP, 1995). The effect of each factor and interactions between them was determined with the partial eta-squared coefficient, and classified according to Cohen’s classification (Cohen, 1988). All calculations were done in Data Analysis Software System (StatSoft. STATISTICA v. 10.0, 2010).

Results and discussion

The authors recorded different changes in nutritional properties that occurred over different periods of storage (12 and 24 months) in pre-defined conditions, at the temperature of 25± 2^{o}C. Storage duration and the temperature corresponded to the conditions commonly seen in storages in south-eastern Europe. Table 1 shows the levels of dry matter, ash and primary metabolites in the wheat grain samples stored at the constant temperature, for different periods of time. Dry matter in all the samples significantly decreased ($p < 0.01$) during 12-month and 24-month storage, by 10.01% and 10.31%, respectively. The obtained results are in accordance with a previous study (Rehman, 2006) that investigated changes in nutritional properties of maize, wheat and rice grains during storage. The total level of crude ash in all genotypes increased ($p < 0.01$) during storage, and significantly increased after 24 months. Data analysis showed the cultivars differed significantly in lipids and cellulose levels in grains.

Table 1. Investigated parameters, by different storage duration

Storage duration (months), B	Genotype, A	Contents (g kg^{-1})			
		Dry matter	Lipids	Ash	Cellulose
0	Evropa	871.17 $^{e\ a}$	21.93 $^{a\ b}$	14.97 $^{d\ c\ a}$	39.02 $^{a\ e}$
	Pobeda	872.83 $^{e\ b}$	20.84 ^{c}	15.95 $^{d\ b}$	38.27 $^{a\ d}$
	Renesansa	873.59 $^{e\ a}$	20.27 ^{c}	15.11 $^{d\ a}$	37.25 $^{b\ e}$
12	Evropa	891.60 $^{d\ ab\ c\ bc}$	20.85 ^{b}	15.94 $^{d\ c\ b\ c}$	33.03 $^{c\ d\ d\ b}$
	Pobeda	892.83 $^{d\ d}$	19.54 ^{d}	16.15 $^{d\ c}$	29.67 $^{e\ c\ c}$
	Renesansa	897.07 $^{b\ cd}$	18.38 ^{e}	16.73 $^{c\ b}$	28.72 $^{e\ d}$
24	Evropa	895.67 $^{b\ de}$	19.09 ^{d}	16.81 $^{c\ c\ b}$	30.02 $^{d\ a\ b\ d\ a}$
	Pobeda	893.70 $^{c\ e}$	17.97 ^{e}	17.19 $^{c\ c}$	28.43 $^{e\ b}$
	Renesansa	900.54 $^{a\ e}$	16.96 ^{f}	18.73 $^{a\ c}$	26.02 $^{f\ a}$
$HSD_{AB\ 0.05}$		3.66	0.95	1.63	1.86
$HSD_{AB\ 0.01}$		4.15	1.08	1.85	2.11

The grains of Evropa cultivar had significantly higher ($p \leq 0.01$) levels of lipids than the grains of the other two cultivars. Conversely, Pobeda and Renesansa had significantly higher ($p \leq 0.01$) levels of cellulose than Evropa. The results of previous studies (González-Torralba et al., 2013) on related topics indicate some changes that can affect negatively the quality of flour made from wheat grains stored for a longer period of time.

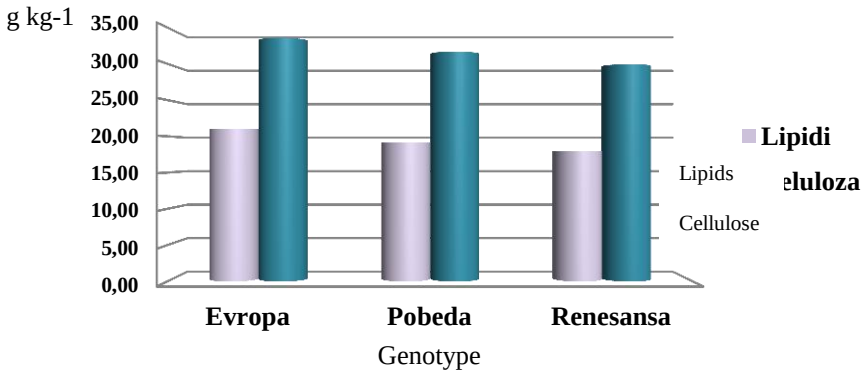

Figure 1. Lipids and cellulose in wheat grains, by genotype

When compared to freshly harvested samples, lipids and cellulose in grains of all the cultivars decreased significantly ($p \leq 0.05$) after 24-month storage (Figure 2). Previous studies (Rasheed et al., 2015) on monitoring the conditions of primary metabolites indicate there are some factors that can negatively affect the properties of mill products and the results of tests conducted during the process of making wheat bread.

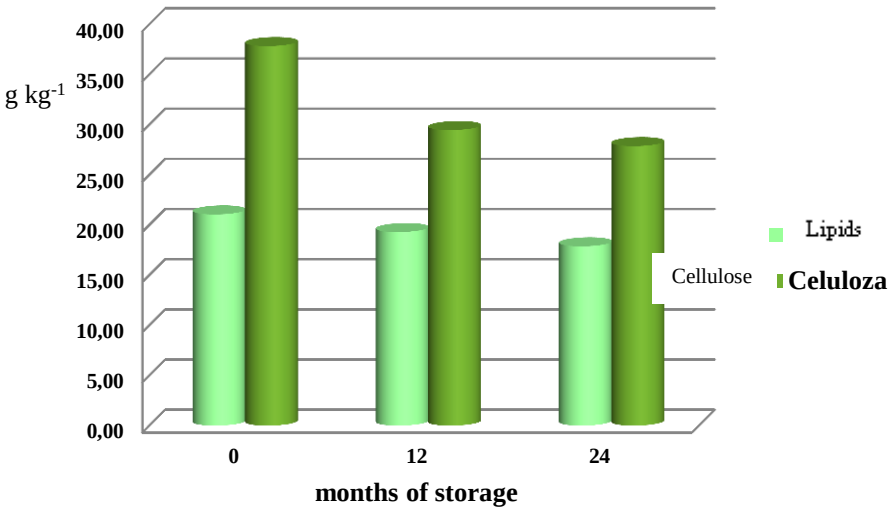

Figure 2. Lipids and cellulose in wheat grains, by storage duration (months)

In this study, ash levels in the grains were significantly ($p \leq 0.01$) affected by storage duration. Prolonged storage resulted in significantly increased ($p \leq 0.01$) ash levels (Figure 3).

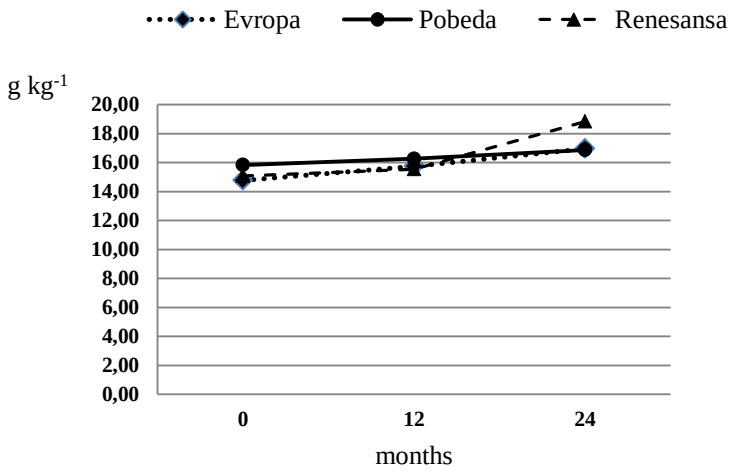

Figure 3. Storage duration and ash levels in the grains of the investigated wheat cultivars

These data are in line with the results of the previous study (Rakić et al., 2014) on storage of oat grains.

Conclusions

When it comes to lipids and crude cellulose, the nutritional properties of wheat grains changed during storage under the tested conditions. The levels of dry matter and total ash increased, when compared to the freshly harvested grains.

The results of this study show that wheat grains can be stored for 24 months under controlled storage conditions.

Abstract

The aim of the study was to determine the optimal ratio of male sterile (cms-S) to male fertile components of the hybrid ZPSC 341, in order to obtain the maximum yield in the commercial production. The present study encompassed observance of effects of different proportions of fertile to sterile plants on grain yield of the hybrid ZPSC 341. The three-replicate trial was set up according to the randomised block design. Twenty one mixtures with 0, 5, 10, …up to 100% of fertile plants mixed with the sterile variant of the hybrid ZPSC 341 were made. The original fertile hybrid ZPSC 341 was three times included into the trial as a check (hand-pollinated ZPSC 341, ZPSC 341 F1 and reciprocally crossed ZPSC 341), so as to control reliability of the trial. Yield, variations in yields and effects of fertile and sterile cytoplasm of the hybrid on yields were observed. The effect of the percentage of fertility, i.e. of sterile to fertile variant ratio on yield was determined. Gained results show that the highest average yield (16.071 t ha^{-1}) was achieved with 90% of fertility, in contrast to the hybrid with 30% of fertility in which the lowest yield (14.112 t ha^{-1}) was recorded.

Key words*: cytoplasmic male sterility ,maize, yield*

Introduction

Maize, due to its morphology, is a plant very suitable for the production of hybrid seed in large quantities, because hybridisation is relatively easily achieved by sowing parental components in alternate rows and by detasseling, i.e. removal of pollen-producing flowers (tassels) from female plants immediately after their exsertion. In such a way the following is achieved: pollen of solely male parents (which are not detasseled) circulates in the field, and hybrid seed is produced on female (detasseled) plants.

In order to achieve total hybridisation it is necessary to remove all tassels in female rows in due time (prior to pollen shed). This requires a great many workers, who have to be engaged in a relatively short period of time (10 to 30 days). Besides the provisions of detasselers it is necessary to provide appropriate control and super quality control of the work performed.

The machine cutting off tassels is the simplest solution to the problem of detasseling in maize hybrid seed production. Experiments with detasseling machines, cutters, had been performed by many researchers (Dungan and Wudworth, 1939; Borgeson, 1943; Kiesslbach, 1945; Bauman, 1959; Hunter et al., 1973 and others), and obtained results were summarised by Huey (1971) and Trifunović (1975). H u e y (1971) states that mechanical cutters of tassel are not usable under poor weather conditions, do not solve the problem of removing tassels on tillers and plants lagging in growth, and at the same time it is not possible to reduce the average number of leaves lost per plant bellow 2-3 even with the most careful work.

The possibility for an effective solution to the problem of detasseling in hybrid seed production has emerged with the discovery of cytoplasmic male sterility in maize. Using the

sterile male version of the female component completely eliminates the need for detasseling, then the number of workers needed for control tasks is minimised, production quality is improved and costs and associated risks are significantly reduced, and finally, in this way, the seed production becomes very attractive for producers.

The first description of male sterility was given by Rhoades (1931). Further investigations showed that sterility was caused by cytoplasmic factors.

Considering that the highest possible yields, with other favourable agronomic traits, are the principal aim of commercial production and in the light of increasingly strong competition in the seed maize market, it is necessary to evaluate the effect of maize sterility on grain yield of ZPSC 341, one of leading hybrids at the Maize Research Institute, Zemun Polje, and to determine the optimal ratio of sterile to fertile component for the need of commercial production of this hybrid.

Material and methods

In order to determine the optimal ratio of sterile to fertile variant of the hybrid ZPSC 341 in the commercial production, 21 mixtures with 0, 5, 10, up to 100% of fertile plants mixed with the sterile variant of the hybrid ZPSC 341 were made. The original fertile hybrid ZPSC 341 was three times included into the trial as a check (hand-pollinated ZPSC 341, ZPSC 341 F1 and reciprocally crossed ZPSC 341), in an attempt to control reliability of the trial.

Material and methods of setting up field trials

The three-replicate trial was set up according to the randomised block design in the location of Pančevo in 2013. The elementary plot consisted of two rows with 0.7-m inter-row distance, 10 hills per row, 0.37-m inter-hill distance and 2 plants per hill. The size of elementary plot amounted to 5.18 m².

The trial was set under conditions of dry-land farming. Sowing was performed at the optimum time (from April 5 to May 1). Standard maize cropping practices were applied.

The total number of plants, separately of fertile and sterile plants, was recorded for each elementary plot during the growing season when pollination was completed.

Harvest was done in the time of full maturity. The yield of fresh ear maize was measured at harvest for each hybrid per replicates and each elementary plot. The submitted sample consisting of five ears was measured with the technical balance in the laboratory.

Methods of experimental data processing

Statistical data processing encompassed the following: analysis of variance according to the randomised block design, regression and correlation analyses of grain yield and percentage of fertile plants in the hybrid ZPSC 341, so as to determine changes in grain yields in relation to the percentage ratio of sterile to fertile plants (according to Hadživuković, 1991).

Results and discussion

Table 1. Average yield and its variation interval for the check and different levels of fertility percentage

Ordinal number	% Fertility	Average yield (t ha^{-1})	95-% interval of confidence for mean yield	
			Lower limit	Upper limit
1	Hand-pollinated ZP341	14.980	13.637	16.322
2	ZP341F1	13.952	13.744	14.159
3	ZP341Rec.	14.718	12.232	17.204
4	0%	14.260	12.369	16.150
5	5%	14.590	13.687	15.494
6	10%	14.235	13.328	15.142
7	15%	14.294	12.489	16.098
8	20%	15.137	14.045	16.230
9	25%	14.903	12.764	17.043
10	30%	14.112	12.743	15.481
11	35%	14.669	14.286	15.051
12	40%	14.515	13.711	15.320
13	45%	14.435	12.901	15.970
14	50%	14.503	10.921	18.085
15	55%	14.916	14.562	15.270
16	60%	15.279	13.604	16.953
17	65%	15.237	14.029	16.446
18	70%	14.713	11.857	17.569
19	75%	14.804	11.850	17.758
20	80%	14.925	14.632	15.217
21	85%	15.151	12.749	17.552
22	90%	16.071	15.625	16.517
23	95%	15.435	14.694	16.175
24	100%	15.269	13.678	16.860

Table 1 shows that the most yielding hybrid (16.071t ha^{-1}) had 90% of fertile plants, while the hybrid ZPSC 341F1 was the least yielding (13.952 t ha^{-1}).

According to the stated, it may be concluded that edaphic and climatic conditions in the given location had a crucial effect.

The conclusion made by comparison of average yields (14.796 t ha^{-1}) obtained in the location of Pančevo and yields of hybrids ZP 360 and ZP 434 (14.160 and 14.260 t ha^{-1}) recorded by Videnović et al. (2000) in the location of Sombor, is that achieved average yields were approximately equal.

Furthermore, studies of the most recent the 5th and the 6th generation of ZP hybrids carried out by Jovanović et al. (2007) show that the highest yields in Serbia were recorded in the following hybrids: ZP 684 (9.50 t ha^{-1}), ZP 544 (9.23 t ha^{-1}) and ZP 434 (9.21 t ha^{-1}). The hybrids ZP 341 (10.02 t ha^{-1}) and ZP 434 (9.50 t ha^{-1}) were the most yielding in the region of Banat, while the highest yield in the region of Srem was achieved with the hybrid ZP 434 (11.34 t ha^{-1}). Moreover, based on long-term studies on medium late maturity hybrids with a

shorter growing season carried out by the group of researches, it was concluded that given hybrids had significantly lower grain moisture content (16-18%).
Based on everything stated, it may be concluded that the 5th generation of ZP hybrids (FAO 300-400) expressed exceptional yielding and yield stability. Additionally, these hybrids are characterised by a shorter growing period and significantly lower grain moisture at harvest, which is great advantage due to reduced costs of maize drying and storage.
Results presented in Table 2 point out that different ratios of sterile to fertile components in the seed mixture used in sowing do not significantly affect achieved yields (r=0.390).

Table 2. Correlation coefficient of yield and fertility percentage

Ordinal number	Location	r_{xy}
1	Pančevo	0.390

Furthermore, we were not able to determine a relative importance of each independent variable for depended variable - yield (Table 3). Insignificant effects of various ratios of fertile to sterile components are noticeable through low regression coefficients (ß). Their contribution to the changes in yields amounts to only 15.2 % (R^2).

Tabela 3. Values of parameters of squares regression model and coefficient of determination

Location	β_0	β_1	β_2	R^2
Pančevo	-4E-05X^2	0.0118X	10.049	0.152

According to the coefficient of determination, a small percentage dependence can be observed, pointing to the fact that a high percentage of variance affecting yield variation was not encompassed.
The coefficient of determination for the location of Pančevo (0.152) is presented in Figure 1.

Figure 1. Calculated squares regression equation for the location of Pančevo.

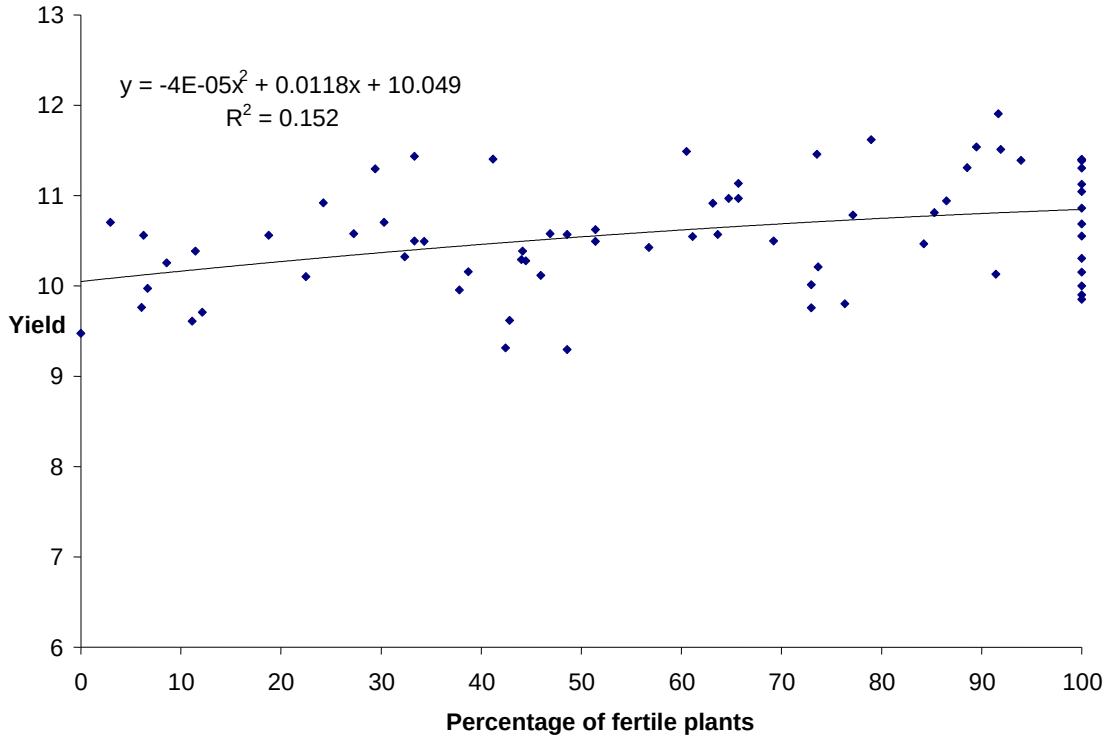

Figure 1 does not show regularity of effects of percentage of fertile and sterile plants on yields, which points out to the possibility of their independence.

Conclusion

Issues related to the commercial seed production of the hybrid ZPSC 341 and effects of different percentages of fertile and sterile plants on yield of this hybrid were observed in this study.

According to obtained results, the following may be concluded:

The location statistically significantly affected maize grain yield;
Environmental conditions significantly affected yield variation
The highest recorded yield amounted to 16.071 t ha^{-1}
The lowest recorded yield amounted to 13.952 t ha^{-1}
The most favourable ratio of fertile to sterile variant was 90% of fertile to 10% of sterile plants;
The least favourable ratio was with the participation of 30% of fertile plants (14.112 t ha^{-1})
Although correlation coefficients were positive, there was no statistical significance of yield and percentages of fertile and sterile plants.

Although obtained results do not show the optimal ratio of sterile to fertile variants of the hybrid ZPSC 341 for its commercial production, there are sufficient reasons to assume that the previously applied 75% to 25% ratio of fertile to sterile variants is the optimal one for the commercial production of the hybrid ZPSC 341.

Abstract

The effects of fertilization and tillage on grain quality trait and yield of maize hybrid was evaluated. An experiment was laid out in split plot design, having three replication, with following treatments: no-tillage (NT), reduced tillage (RT) and conventional tillage (CT), and three levels of fertilization (F1 - no fertilizer; F2 – 50 kg N/ha + 50 kg P/ha + 50 kg K/ha in fall, + 33.5 kg N/ha in spring; F3 - in 50 kg N/ha + 50 kg P/ha + 50 kg K/ha fall+ 93.5 kg N ha in spring), during 2014 at MRI Zemun Polje. The highest yields were observed with CT (12.19 t/ha), while the averages with RT and NT were lower (10.57 t/ha and 9.68 t/ha, respectively). The lowest yield was in F1 fertilization treatment 8.66 t/ha, while the yield was raised with amount of applied fertilizer (11.66 t/ha and 12.02 t/ha, respectively). The results of the influence of the amount of the applied fertilizers on protein content showed that the highest protein content have been obtained with treatment F2 (8.31%) followed by treatment F3 and F1. The average protein content at NT was 7.91%, while at RT, the protein content was 8.12% and at CT 8.17%. Also the highest oil content as well as starch content was with CT. The effect of fertilization on oil content is inconsistent, the highest content was in F2 treatment, 3,88%. The lowest protein, oil and starch content were in treatment without fertilizer. This experiment will continue.

Key words: grain quality, fertilizer, maize, tillage, yield

Introduction

Maize, the most important cereal crop of the world, is used for three main purposes as human food, feed for poultry and livestock, as well as for industrial processing. Maize grains have great nutritional value as they may contain 70-75% starch, 8-10% protein, and 4-5% oil. For successfully maize production optimal inputs are required. These include the use of adapted cultivars, appropriate tillage practice, application of fertilizers at amounts required for yielding potential, proper weed and disease control.

It is known that tillage affect soil properties, growth and yield parameters of maize. According to Khurshid et al., (2006) among the all crop production factors, tillage contributes up to about 20%. Tillage influences soil physical, chemical and biological properties, which in turn affect crop productivity (Anikwe and Ubochi, 2007). However, in Serbia is prevailing conventional or classical soil tillage system including considerable consumption of time, energy and human work.

Fertilizer incorporation is one of the most important farming operations needed to correct deficiencies in the soil in order to ensure proper growth and functioning of crops with the aim of increasing yield. Inadequate fertilizer rates lead to poor crop growth and reduced yields. On the other hand, over-fertilization leads to increased green biomass production and to lower grain yield and environmental pollution. Maize is particularly sensitive to soil nutrient deficiencies of both the major and minor nutrients and requires adequate supply of nutrients particularly nitrogen, phosphorus and potassium for good growth and high yield. Videnović et al (2011) studied effects of different tillage systems and level of fertilization on the yield of

the maize hybrid ZP 704 during ten years and find out the benefits of conventional tillage under the presented agro-ecological conditions, irrespective to the amount of applied fertilizer.

The chemical composition of maize grain is affected by many factors as fertilization, plant density, growing site etc. (Thomison et al., 2004). Higher protein content was obtained by conventional tillage in regard to no tilled soils (Andrija et al.,2009; Sessiz et al., 2010). According to Khan et al. (1992) grain protein, starch, and oil contents were not significantly affected by the different sowing methods. Javed et al. (1985) reported the stimulating effect of NPK fertilizers on protein content. Holou and Kindomihou (2014) studied the influence of fertilizer on protein, oil and starch in maize grain and find out that N fertilizers (up to 179 kg N/ha) increased protein and starch content in maize kernel.

The objectives of present study were to determine the impact of different tillage practices with different level of fertilizer on chemical composition and maize grain yield.

Material and methods

The field experiments arranged in a split plot design with three replicates were conducted during 2014 in Zemun Polje, in the vicinity of Belgrade in Serbia (44°52'N, 20°20'E), on a slightly calcareous chernozem. The maize hybrid ZPSC 606 was sown. The plant density was 59,524 plants/ha. The following tillage systems were investigated: NT – no-tillage, RT – reduced tillage and CT – conventional tillage. In the NT variant, sowing was performed directly with a drill. In the RT treatment, tillage was performed with a rotavator in the autumn to a depth of 10–12 cm and sowing was done with a conventional drill. The CT variant consisted of shallow plowing to a depth of 15 cm, immediately after wheat harvesting in 2013, primary tillage in the autumn to a depth of 25 cm, seedbed preparation in the spring with a Rau-combi (composed of a harrow, cultivator and rollers). The fertilizer treatments include: control F1 without fertilization; F2 – 50 kg N/ha + 50 kg P/ha + 50 kg K/ha in fall, + 33.5 kg N/ha in spring (up to 180 kg N/ha according to N-min); F3 - in 50 kg N/ha + 50 kg P/ha + 50 kg K/ha fall+ 93.5 kg N ha in spring (up to 240 kg N/ha according to N-min). The maize grain yield was measured at the end of the growing cycle from the two inner rows and calculated with 14% of moisture. The collected grain in harvest maturity was analyzed using Near Infrared Reflectance Grain Analyser (NIR), Chopin Technologies Infraneo. The seeds were analyzed for starch, protein and oil content. All observed data were analyzed using the analysis of variance (ANOVA). Treatment means were compared using the Fisher’s least significant difference (*LSD*) test ($P = 0.05$).

Results and discussion

A significant difference was observed in grain yield and seed chemical composition according to application of different tillage systems and level of fertilizers. The statistical analysis showed significant effects of tillage and amount of fertilizers on maize yield (Table 1). Soil tillage has also significant effect on starch content and no significant effect on protein and oil content (Table 2). Contrary, amount of applied fertilizers have significant effect on protein and oil content and non significant effect on starch content. Interaction between soil tillage and amount of fertilizers was significant for all traits.

Table 1. Influence of tillage systems and levels of applied fertilizers on grain yield

Treatment	T1	T2	T3	Average

	F	T	FxT	
LSD 0.05	0,613	0,416	0,357	

Major differences between the tillage systems were noticed in F1 treatment. Results indicated the advantage of the CT system for grain yield (Table 1). The highest average yield was observed with CT 12.19 t/ha (100.00%), while the yield was lower with RT 10.59 t/ha (82.09%) and NT 9.67 t/ha (74.96%). Lower maize yields in no-till systems compared to conventional tillage systems are widely documented in other similar studies (Pederson and Lauer 2003, Boomsma *et al.* 2010, Videnovic *et al.*2011). Authors often report higher yields that can be achieved with conventional tillage in comparison to other non-conventional tillage systems (reduced, conservation and no-till). Borin and Sartori (1995), reported that among conventional tillage, minimum tillage and no-tillage in maize, the highest yield had been

obtained with the conventional tillage. Maurya (1988), also reported lower maize grain yield achieved with no-till system than with conventional tillage.
Yield reduction on the unfertilized plots compared to the F2 was the greater under conditions of no-till (37%) than on the reduced tillage (30%) and conventional tillage (20%). Averagely, the lowest yield was achieved with F1 treatment 8.66t/ha (100.00%), while the yields were higher in F2 (11,77 t/ha or 135,91%) and F3 treatments (12,02 t/ha or 138,79%). Kovačević et al. (2008) found out that different levels of P and K fertilization had a significant impact on maize yield. Similarly, lower yield was found in maize when the crop was subjected to the case of high N doses (Moser et al., 2006).
The effect of the interaction between the soil tillage and the amount of the fertilizers was significant at the RT and CT treatment for all fertilization levels. At the NT treatment a significant difference was observed between F1 and F2 and between F1 and F3, while there was no difference between F2 and F3. These results are in agreement with those reported by Shata et a*l*. (2007) and Sial et al. (2007). Adeniyan and Ojeniyi (2005) also harvested higher maize grain yield with the application of mineral and organic fertilizers.
The influence of tillage systems and level of fertilizers on chemical composition of maize seed was shown in Table 2. The results indicated that the effects of fertilizers level on the protein and oil content was significant. The protein content varied from 7,40% in NT-F1 treatment to 8,34% in CT-F2 treatment. Maximum protein content was recorded in CT system, as compared to RT and NT system, but differences between tillage systems are not significant. Comparing the protein content in regard to different fertilizer treatments (F1, F2, F3) for NT, RT and CT, the statistical differences were significant. Maximum protein content was obtained for F2 treatment in all three tillage variants. Application of nitrogen fertilizer had significant effect on maize seed protein content. Maize plots with fertilizer application had significantly ($P < 0.05$) higher protein content of 7,4% than maize plots without fertilizer application. According to Stone et al., (1998) and Hammad et al. (2011) low and high nitrogen dose have adverse effect on quality of maize. Khan et al (2008) reported higher N contents in the leaves being translocate and converted into proteins during kernel filling, suggesting that increased leaf area index, with increasing N availability, were the possible reasons for improved seed protein contents. The tillage system has no significant effect ($p \geq 0.05$), but fertilizer level showed significant ($p \geq 0.05$) effect on oil content. Oil content ranged between 3,74% to 3,92%. The average oil content was the highest in F2. Maximum oil content was in CT system with F2 level of fertilizer.
The tillage system had a significant ($p \geq 0.05$) effect, while fertilizers level had a no significant ($p \geq 0.05$) effect on starch content. In NT variant maximum starch content is obtained with F3 treatment, and in RT and CT with F2 treatment. In NT treatment average starch content was 71.55% followed with 72,02% in CT and 72,64% in RT. Maximum starch content has combination of RT variant and F2 level of fertilization. Maize grown without N fertilization promotes the greatest concentration of kernel starch, than kernels grown with the maximum N supply (Seebauer et al., 2010).

Conclusion

The combined effects of tillage systems with different level of fertilizers showed the significant effect at $p \leq 0.05$ for all traits. For the treatments F2 and F3 the differences were less expressed; hence, an appropriate application of fertilizers can reduce the differences appearing between the soil tillage systems. The treatment CT with F2 produced maximum protein and oil content followed by treatment RT+F2. Maximum yield was obtained with CT+F3 and starch content with CT+F2.The plants grown under CT treatment gave the highest grain yield, followed by RT treatment, while the plants grown under NT treatment gave the lowest grain yield.

Abstract

Anatomical aspects are an integral part of the resistance of plants to abiotic and biotic factors, influencing yield of cultivated plants. Plant anatomy is an important tool in agricultural research since understanding anatomical background of the mechanism of stress resistance is important for optimization of cultivation practices and for selection of new varieties in order to achieve higher productivity in stress conditions.

In this paper we present principals of techniques that are commonly used in plant anatomy research: brightfield light microscopy, fluorescence microscopy, polarization and electron microscopy, including some methods for chemical identification (histochemistry) and chemical imaging such as infrared and Raman microscopy with emphasis on some of their advantages and limitations and application in agricultural research. We here provided review on the methods most frequently used in crop plants investigations with emphasis on the research done at the Faculty of Agriculture University of Belgrade. We also present the methods currently used for imaging, measurements and image analysis using various software.

Keywords: *light microscopy, electron microscopy, fluorescence microscopy, chemical imaging, image analysis*

Introduction

Abiotic factors have a significant impact on the growth and development of cultivated plants and can influence to a large extent their yield. Drought is considered as one of the most common abiotic stress factors, and the following properties of leaves are referred as the adaptation of plants to water deficit: greater number of stomata per unit area, smaller epidermal cells, thicker cuticle, smaller mesophyll cells, compact leaf mesophyll, more layers of cells in the leaf mesophyll, thicker leaves, size and functionality of vascular tissues, etc. (De Micco and Aronne, 2012, Quarrie et al. 2006).

Anatomical studies may provide an answer to questions concerning the influence of biotic factors on plants, nature and intensity of the damage caused by the activity of herbivorous organisms (insects, nematodes ...), pathogens (bacteria, fungi, viruses ...) or parasitic plants, and possible non-specific and specific defense reaction of plants on these organisms (De Cal et al. 2000, Rančić et al. 2006, Pećinar et al. 2011). Anatomical study of the roots of plants, especially in cases where there are symbiotic relations (mycorrhiza and nitrogen fixation) are important for understanding the adoption of water mineral substances (Dreyer et al. 2010). Studying the flower nectaries can provide the basis for a better understanding of possible mechanisms of nectar secretion and different aspects of attacking pollinators (Nedić et al. 2013, Mačukanović-Jocić et al. 2007). In addition, studies of viability and germination of pollen and cytological and histological study of fruit development (Rančić et al. 2010a, Pecinar et al. 2013) are directly related to the potential increase in yields of cultivated plants. Also, anatomical investigations could have scientific value in terms of our general understanding of the parasite-host interaction (Rančić and Božić, 2004), as well as a practical one by providing data that are essential for a more efficient application of adequate control. In addition, for agriculture are also important anatomical characteristics of weed species

(Vrbničanin et al. 2007, Božić et al. 2008). Anatomical studies are important in studying the mechanisms of action of certain herbicides. Knowledge of population variability in the anatomy of weed species, as well as differences between individuals of the same species may be important for herbicide resistance and thus affect their control. Specific morphological features of plants, such as cuticle on the leaves, the presence of different types of hair, number of stomata per unit leaf area, affect the adoption of herbicide by leaf surface (Solymosi and Nagi, 1998; Grangeot et al.. 2006), and thus the expression of their efficiency. In *Cirsium arvense* (L.) Scop. it was shown that the various varieties differ in sensitivity or resistance to the herbicide (Hodgson, 1970; Zand i sar., 2002; Vrbničanin i sar., 2004).

Microscopy techniques

Microscopy techniques are usualy divided into three well-known branches*:* optical, electron, and scanning probe microscopy. The techniques that are commonly used in anatomical studies of plants are optical and electron microscopy, although increasing importance of techniques that allows microanalysis and which in addition to information about the structure provide information on the chemical composition. Methods involving the use of nanomikroscopes (scanning probe microscopy) are still not used a lot in plant anatomy.

Optical microscopy

The first invented and still the most common type of microscope in biological speciment research is optical microscope, referred also as light microscope. It uses visible light and a system of lenses to magnify images of small samples and could be based on transmitted or reflected light.

In transmitted light microscope (compound microscope) sample is illuminated from the side that is opposite to the lens, and sample should be transparent enough to enable light to pass the observer's eye. That is the reason why samples are usually cut on very thin sections before observations. Sometimes it is possible to observe the whole plant organ but only if it is transparent enough to allow passing of the light, therefore an alternative to the cutting can be tissue clearing that is most commonly used in studying intact structures in flowers. The transmitted light microscope is used for observation of samples whose size is from a few micrometers to a few millimeters. This microscope is useful for observing plant internal structures, different cell types, some organelles (plastids, nucleus and vacuoles) and metabolic products such as crystals of calcium oxalate or starch. As this type of microscope has a very low contrast, most of the samples require additional staining. Maximal resolution in light microscopy is approximately 0.2 micrometers, what limits the practical magnification is up to 1500 times. This type of microscopy is the most widely used in the investigations of the crop vegetative organs such as stem (Fig. 1a) and leaf (Fig. 1b).

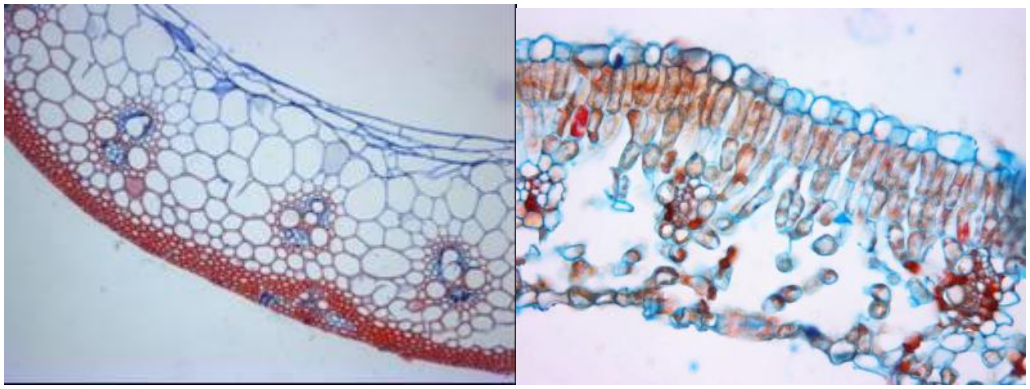

Figure 1. Transversal section stained with safranin and alcian blue: a) wheat stem and b) apple leaf

In reflected light microscope (stereomicroscope) sample is usually illuminated from the same side as the lens, so the sample does not need to be transparent. It is a lower powered microscope comparing to transmitted light microscope, but it provides a stereoscopic view of the sample and is valuable in situations where three-dimensional observation is required. Stereomicroscopes is useful for observation of larger samples (up to a few centimeters) and when micromanipulation of the specimen is required. In some circumstances, reflected and transmitted light sources could be combined to take advantage of particular specimen characteristics in a manner that most effectively reveals the features of interest.

Darkfield microscopy

Darkfield microscope is transmited or reflected light microscope which has a filter enabling illuminating the sample with light that will not be collected by the objective lens, what produce black background with bright objects on it. Darkfield microscopy is used to enhance the contrast of unstained samples. and is especially useful for observing living cells or for finding cells or organels (chloroplasts, mitochondria) in suspension. The tissue needs to be strongly illuminated, which may damage delicate samples

Polarizing Microscopy

Polarized light microscopy is optical microscopy which include illumination of the sample with polarized light to investigate its optical properties. Polarized light microscopy can be used both with reflected and transmitted light. Polarization provides information on absorption, structure and composition of the samples and this type of microscopy is suitable for study of crystalline and fibrous structures, which rotate part of polarized light and thus become more visible. The polarizing microscope could be applied to observe section of fresh, unfixed materials, and it is especially suitable for the study of starch grains of different plants species (Fig. 2).

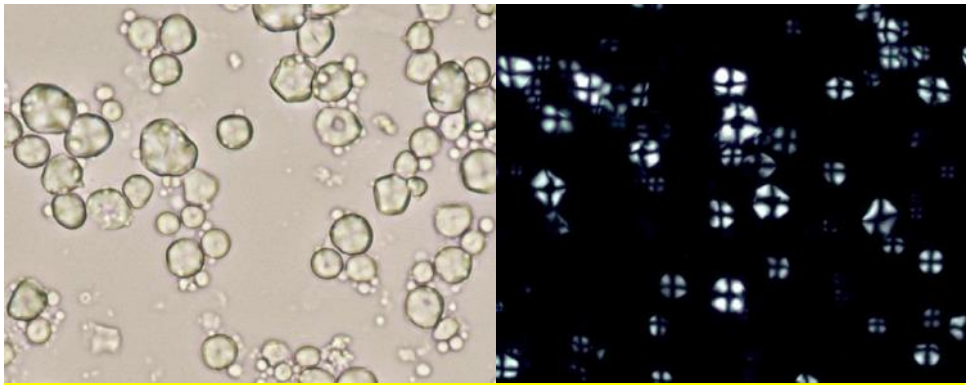

Figure 2. Corn starch grains observed in the bright field microscopy (a) and polarized light microscopy (b)

Phase contrast microscopy and Differential interference contrast (DIC) microscopy

Phase contrast is an optical microscopy illumination technique that shows differences in refractive index as difference in contrast. Due to improving image contrast it reveals many cellular structures that are not visible with a simpler bright field microscope, so it could be used for observing unstained, transparent samples. Similar to Phase contrast microscopy is

Differential interference contrast microscopy also known as Nomarski Interference Contrast (NIC) or Nomarski microscopy which requires a polarized light source to function. DIC is capable to enchance contrast even more, but is unsuitable for thick samples, such as tissue slices and highly pigmented cells.

Fluorescence microscopy

Fluorescence is an optical phenomenon in which light from shorter wavelength is absorbed by the substance and then emitted as longer wavelengths light. Fluorescence microscope is designed for observation of the samples which fluoresce in its natural form (primary fluorescence or autofluorescence) or fluoresce when treating some fluorescent chemicals (secondary fluorescence). A fluorescence microscope works on the same principle as an ordinary light microscope, but as a source of short wavelength of light used mercury or xenon lamp. Fluorescence microscopy is a powerful tool for the study of plant structure. The main value of this technique is the ability to detect substances that are present in very low concentrations. Using the epi-fluorescence it is possible to observed surface of the samples that are relatively large and it is not necessary to be transparent. Many compounds in plants such as chlorophyll, lignin, suberin and phenolic compounds have the ability to exhibit autofluorescence, so it is possible to identify some of these substances very easily, even on hand sections without staining (Fig. 3). Samples which do not have the property of autofluorescence should be pretreated with special fluorescent dyes (fluorochromes). Many specific fluorescent probes have been developed to allow observing large number of different macromolecules, such as callose in phloem or nucleic acid.

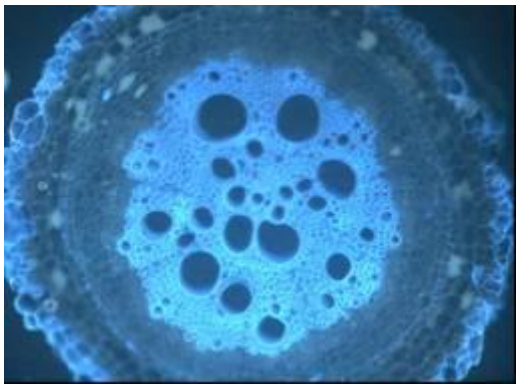

Figure 3. Cross-section of tomato root in epifluorescence microscope (blue- autofluorescence of lignin)

Fluorescent dyes are especially suitable for vital staining, because the very small amount of the fluorescent substance can be detected by fluorescence microscopy. In the indirect technique fluorochromes are used first to bind to the protein or some other molecule, and after that protein carrying fluorescent dye binding to the receptor site in the tissue sample. This reaction is the basis of the immunofluorescence. Developing of fluorescent probes, as well as improvements in optical microscopes and light sources (laser), as well as computers and appropriate software, enabled design of confocal microscopes, special type of fluorescence microscope which enabling optical sectioning of the sample and subsequently 3D reconstruction of obtained pictures.

Electron Microscopy

The electron microscope uses a beam of electrons instead light to create an image of the sample. The most important variants of electron microscopy are transmission electron microscopy and scanning electron microscopy.

In Transmission Electron Microscope (TEM) the electrons in the primary beam are transmitted through the sample. TEM has a very large magnification range (up to 50 million times) and the ability to obtain images of very high resolution, better than 50 pm.. In plant anatomy research, TEM is mainly used for analyzing the internal structure of the cells - cell organelles. Samples prepared for electron microscopy must be very thin, about 100 nm or less. Electron microscopy is not capable for observing living cell because all life processes in the sample must be stopped by quick freezing or chemical fixation. Sample preparation in addition to fixation involves chemical dehydration too and embedding in the plastic or resin that allows cutting of very thin (ultrathin) section. Cutting embedded material requires specific microtome called ultramicrotome, which instead of a metal blade have glass or diamond knives. Visualization and contrasting preparation for electron microscopy is achieved by the addition of heavy metal salts, which bind to cellular components, what manifested as different in their densities. Transmission electron microscopes produce two-dimensional, black and white images (Fig. 4), but by combining a large number of 2D images in softvares is possible to get a 3D view. Proteins or other molecules can be located by applying antibodies conjugated to gold particles.

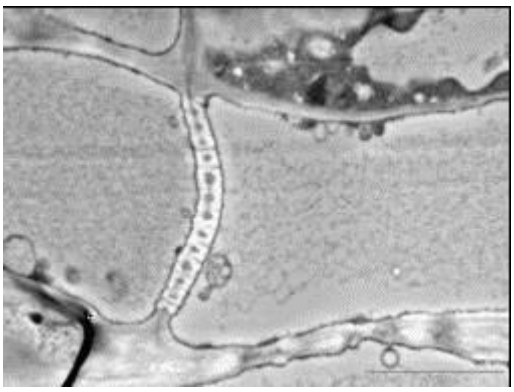

Figure 4. Longitudinal section of sieve tube and sieve plate in tomato pedicel observed in TEM

In Scanning Electron Microscope (SEM) images are produces by detecting secondary electrons which are emitted from the surface due to excitation by the primary electron beam. Comparing to TEM which have much better resolution and magniffication (up to about 500.000 times), SEM has a much greater depth of view, provide us with 3D, topographical information about the sample surface (Fig. 5). Preparing samples for SEM is easier than for TEM and since the sample could be up to a few centimeters sized, thin sectioning is not necessary. Most biological samples need to be dehydrated and coated in a conductive material before being placed in the SEM. If combined with x-ray microscopy, beside topography information, SEM could be capable of to provide precise information of the chemical composition of the material near its surface (elemental analysis).

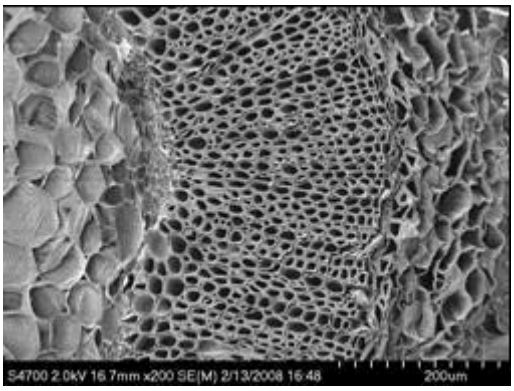

Figure 5. Tomato pedicel transfersal section observed in SEM

Scanning probe microscopy

Scanning probe microscopes are very powerful microscopes which could be used to investigate surfaces with atomic resolution. There are several types of Scanning probe microscopes: atomic force microscopes, scanning tunneling microscopes etc. and they use very sharp probe to scan the surface of a sample. The probe in these microscopes does not touch the surface but traces the specimen nanometers above the surface. During this scanning process, a computer gathers data of the interaction of a scanning probe with the surface of the sample to generate an image. In addition to visualizing nanoscale structures, some of these microscopes can be used even to manipulate individual atoms. Although there are some examples of using nanomicroscopes in biological research, e.g. for the investigating surface of a living cell, these microscopes have much more used in material science research.

Selected anatomical methods and examples of their application in agricultural research

Methods for studying epidermis

The surface of the leaves and other plant organs can be observed directly by stereomicroscope - light microscope using reflected light, or by fluorescence microscope or scanning electron microscope. For transmitted light microscopy slides are usually prepared by the method which includes peeling off the epidermis (Weyers and Travis, 1981) or making imprint by applying clear nail polish (Fig. 6) (Miller-Rushing et al. 2009). This methods enabling studying epidermal cell shape, size as well as abundance of atypical epidermal cells: glandular and nonglandular trichomes, stomata etc.

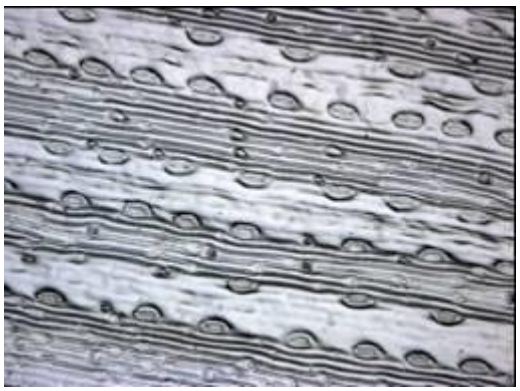

Figure 6. Nail polish imprint of leaf surface of wheat

Methods for studying hydraulic network

Apoplastic water flow through the plant can be traced by infiltration of different dyes dissolved in water. The dye could be infiltrated into xylem tissue by immersing freshly cut basal part of the stem into the staining solution. After some time, due to transpiration, dye will be sucked into xylem vessels. Since dye solution passes only through functional xylem vessels, comparing the area of stained and non-stained vessels it is possible to get information of the ratio of functional and non-functional xylem elements (Rancic et al. 2010b) (Fig. 7).

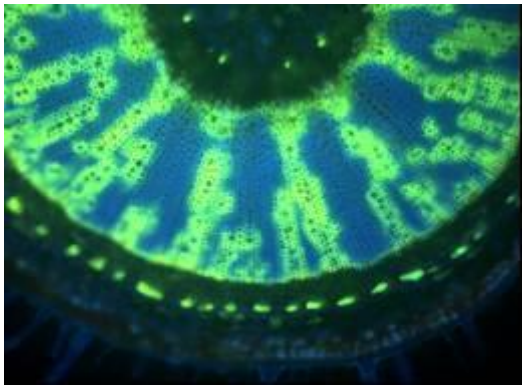

Figure 7. Functional analysis of xylem in tomato pedicel: blue-xylem autofluorescence; yellow - functional xylem

Simplastic water transport through the plant is possible to visualize using an aqueous solution of colors which transported by phloem over long distances, and which due to the characteristic of the cell membrane does not diffuse into the surrounding tissue (Rančić et al. 2011). Such dyes are usually added over the leaves, and through the stomata penetrate into the leaf parenchyma, and later were transported by phloem to other parts of the plant.

Methods for the investigation fruit anatomy and fruit cytology

Anatomical analyses of fruits could be used for monitoring development of certain plant organs. Histological researches performed by tissue sectioning (Fig. 8) or cytological analysis after tissue maceration (Fig. 9) could be used. Histological sections enabling observing different tissue layers in plant organ, while method of tissue maceration enabling dissolving median lamella connecting the adjacent cells and separating from each other, thus allowing us to study the three-dimensional aspects of the of cells. Mmethod of maceration could be used for investigation all tissue types, but the most offen is used for vascular tissue and fruit investigations (Pećinar et al. 2014).

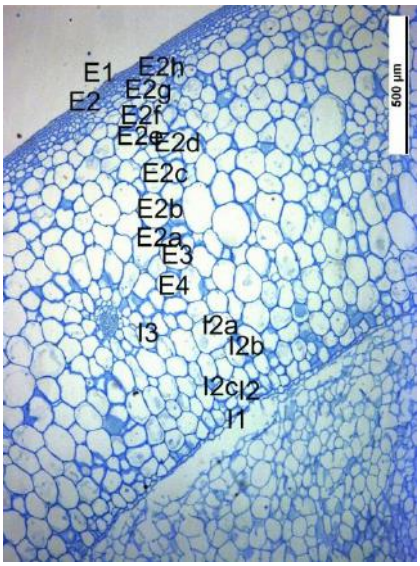

Figure 8. Transfersal section of tomato fruit pericarp

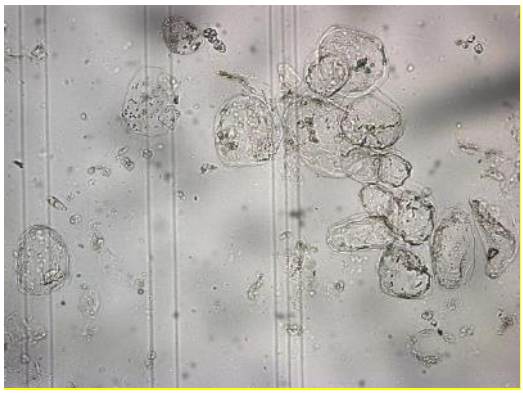

Figure 9. Macerated tissue of tomato fruit pericarp

Identification and localisation of different plant metabolites

Histochemical staining

Anatomical studies can also be used to assess the quality of the product. This could be achieved by application of histochemical staining, specific test for some group of compounds allowing to selected cell structures to be differentiated. These tests may indicate the chemical nature of the colored substance, and are often used for the identification and localization of various reserve materials (starch, proteins, lipids) (Fig. 10) or secondary metabolic products that play a role in the plant defense (different phenolic compounds, tannins, alkaloids, flavonoids) (Marin et al. 2006, Rančić et al. 2009, Rancic et al. 2013, Pljevljakusic et al. 2012).

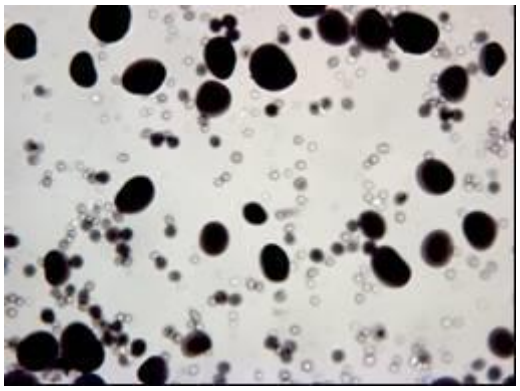

Figure 10. Wheat starch grains stained black by Lugol reagens

Microscopes for microanalysis

More recently are developed microscopes that enable not only a visualization of the sample but also chemical analysis of the sample (microscope for microanalysis). With these microscopes is possible to localize different molecules or groups of compounds in the sample and the technique is named chemical imaging. A special advantage of this method is that it is non-invasive and usually does not require staining or specific sample preparation.

Infrared microscopy

Infrared microscope is configuration of an optical microscope, a infrared spectroscope (usually Fourier Transform Infrared Spectrometer - FTIR) combined with and an infrared detector. Infrared spectroscopy study infrared radiation emitted by the molecules due to their vibration. Free atoms do not emit infrared radiation, but molecules after absorption infrared radiation begin to vibrate, and each molecule has a characteristic vibration, ie has a different infrared spectrum which can be used for the identification of the specific compounds. FTIR microscope is not suitable for observing water solutions and fresh plant samples, due to strong signal of water molecules vibration, but it is useful for dry samples (i.e. seeds). In infrared microscopes the spatial resolution is relatively low, limited to 1-3X the wavelength, what sets a practical spatial resolution limit of ~3-30 μm.

Raman microscopy

Raman microscope is very specialized optical microscope in which the sample is illuminated by monochrome light (the light source is a laser) and light scattered by the observed material is analyzed by Raman spectrometer. Analysis of scattered light could give information about the chemical composition of the material and could be analyzed at different points in the sample giving chemical image of the sample. Applications of this technique in the field of plant science are very far ranging, going from investigations on structural polymers to metabolites and mineral substances (Gierlinger and Schwanninger 2007, Agarwal, 2014). Non-destructive nature of Raman analysis along with none-to-minimal requirement of sample preparation makes it exceptionally useful for various investigations (i.e. cellulose and pectin: Atalla and Agarwal 1986; Gierlinger et al. 2010, carotenoids in tomato fruit: Qin et al. 2012; Baranska et al. 2006, starch, lipid and proteins in wheat grain Manfait et al. 2004) (Fig. 11). The informations provided by Raman are complementary to information obtained by infrared (IR) (Lang et al. 1986). In contrast to FTIR, Raman is useful for styding fresh plant samles rich in water and have better resolution (0.5-2 micrometers) but the main problems associated with the use of conventional Raman on plant materials is strong autofluorescence that is produced when phenolic compounds (i.e., lignin) are excited by visible light. This problem

could be overcome by using longer wavelenght laser source or NIR-FT-Raman (Agarwal, 2014).

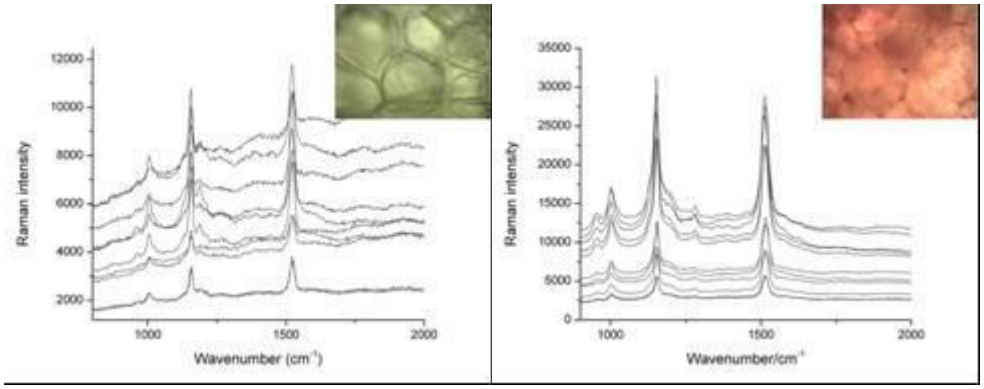

Figure 11. Raman spectra of tomato fruit obtained at 532-nm laser at two developmental stages. Figure 11a indicates on mature green, and Figure 11b on over ripe fruit stage.

Raman peaks appeared consistently at 1001 and 1151 cm^{-1} (indicating the position of C-C bond) in mature green fruit stage and ripe fruit. The third peak was gradually shifted from 1525 cm^{-1} (lutein at mature green stage) to 1513 cm^{-1} (lycopene at red stage), indicating the position of C=C stretching vibration of the polyene chain in carotenoids, owing to the loss of lutein and β-carotene and the accumulation of lycopene during tomato ripening.

Acquiring and measuring of microscopic preparations

At the same time with development of microscopy, different methods for measurement of microscopic objects have been developed. The simplest technique involved the direct comparison of the size of the object with a graduated scale in eyepiece, however the latest digital camera connected to the microscope, combined with powerful computer software, enables quick and easily performed microscopic measurement and automatic data analysis. Analysis of the picture varies widely depending on the type of the sample and research needs. Typical applications for automatic image analysis involves determining the edges of the objects (e.g. cell wall), counting the number of similar objects (e.g. nuclei), the measurement of area, length, volume and other characteristics (Fig. 12). Software for analysis of allows users to manipulate images in many different ways, such as creating 3D images, making video sequences that follow the movement of certain objects or its parts cells, etc. Progress in programming led to the development of software that enabled the fully automated operation of the microscope, which saves time and increases the quality of the research. In addition to commercial programs designed by the with eminent companies for the production and distribution of microscopes and related equipment (eg Nikon, Zeiss, Leica, Olympus ...), online could be find free programs for image analysis too, such as ImageJ (http: //imagej.nih.gov/ij/), Fiji (http://fiji.sc/), Icy (http://icy.bioimageanalysis.org/), Cell Profiler (http://www.cellprofiler.org /) and others. For the processing of spectra obtained by Raman or FTIR microscopy are commonly used Matlab and R softwere, while for primary processing of the spectra without additional statistical tests Origine, PeakFit and LabSpec softweres could be enough.

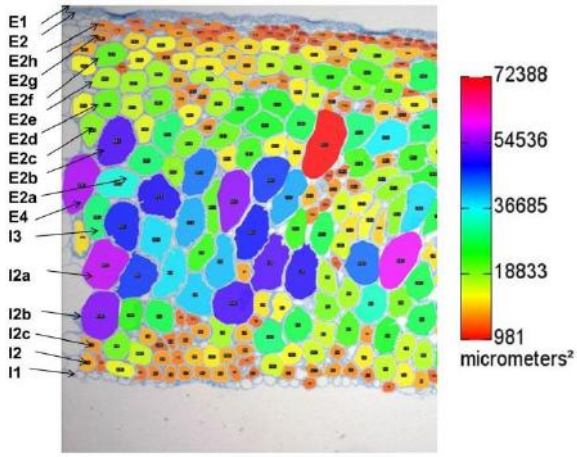

Figure 12. Tomato fruit pericarp cells automatically colored according to their size by the ROI color coder plugin of Image J software.

Acknowlegdement

Abstract

The interaction of genotype x environment on yield and 1000 grain weight and test weight at four KG cultivars of barley (Rekord, Jagodinac, Maksa and Grand) was researched in this paper. The experiment was established on the experimental field of the Small Grains Research Centre in Kragujevac (Serbia) during two growing seasons. The highest grains yield per area unit had, on an average, Jagodinac and Grand cultivars (6.647 t/ha and 5.919 t/ha). Average grains yield observed in the two-year period was the highest at Jagodinac cultivar (6.647 t/ha), while the lowest yield was obtained by Grand and Maksa cultivars (5.919 t/ha and 5.742 t/ha). The largest two-year average value of test weight was found in the cultivar Maksa (69.56 kg/hl), and lowest in cultivar Grand (64.87 kg/hl). During the both years of investigation the highest average value of 1000 grain weight achieved the Maksa cultivar (49.84 g and 47.85 g). The highest average 1000 grain weight was determined for cultivar Maksa (48.84 g). Very highly significant differences in 1000-grain weight and highly significant of grain yield and test weight at investigated barley were found in relation with the cultivar. During 2006-2007, statistically significantly higher grain yield per area unit as well as 1000 grain weight was achieved, compared with 2005-2006. Interaction of the year and cultivars on the yield and 1000 grain weight were statistically significantly. Investigations on genotype and environment interaction present the basis for further refinement and barley zoning.

Key words: *cultivar, grain yield, winter barley*

Introduction

Barley cultivars that were in production until the end of the eighties were characterized by the lower yields, good technological quality and higher stem sensitive on lodging. Due to lower resistance on lodging, that cultivars were grown at modest soils and therefore they had lower yields (Đekić et al., 2012.b). Agronomic cultivar value depends not only on its genetic potential for yield, but also on its ability to achieve genetic potential under different conditions of production (Mladenović et al., 2009). New varieties are characterized by good technological quality, better resistance on lodging and diseases, shorter stem and more efficient assimilates usage (Pržulj et al., 2004). Malting barley is expected to have 1000 grain weight of 40 and 46 g and test weight of 68 to 75 kg/hl (Paunovic et al., 2006). Yield is largely dependent on the genetic potential, which could be defined as yield of variety which was grown in conditions on which it had been adapted, with adequately amounts of water and nutrients and efficient control of pests, diseases, weeds and other stresses (Đekić et al., 2011). Yields considerably vary primarily as a result of agro-ecological conditions during the growing season (Đekić et al., 2014).

Barley is in the usage as an important component of beer and malt production, important and quality component in animal feeding, partially in human nutrition as well as a component in processing industry (Đekić et al., 2012.a). As a top-quality forage crop plant, barley is used as fodder unit in meals balancing in animal feed (Đekić et al., 2010).

The aim of this study was determination of the cultivars and ecological environmental factors influence on differences in stability and adaptability of cultivars regard the grain yield, 1000 grains weight and test weight of tested winter barley cultivars, as well as specificity cultivars exploring regard growing seasons conditions.

Materials and methods

Experimental design

During the 2005-2006 and 2006-2007 growing seasons, four cultivars of winter barley (Rekord, Jagodinac, Maksa and Grand), cultivated at the Center for Small Grains in Kragujevac (Serbia) were investigated. Experiments have been conducted in randomized block systems, with a plot size of 5 m^2 (2 m x 2.5 m) in five replicates. The usual techniques for barley production were applied, and it was done in the optimum sowing time in late October. 400 kg/ha of fertilizer NPK 15:15:15 was added in the fall on the investigated plots, while during the spring fertilization, 300 kg/ha (KAN) was supplemented. The following properties were analyzed: grain yield (t/ha), 1000 grain weight (g) and test weight (kg/hl).

Meteorological conditions

Kragujevac area is characterized by a moderate continental climate, which general feature is uneven distribution of rainfall by months. Data in Table 1 for the investigated period (2005-2007) clearly indicate that the years in which the researches were conducted differed from the typical multi-year average for Kragujevac region, regarding the meteorological conditions.

Table 1. Mean monthly air temperature and precipitation (Kragujevac)

Months	Mean monthly air temperature (°C)			The amount of rainfall (mm)		
	2005-06	2006-07	Average	2005-06	2006-07	Average
VIII	20.0	20.7	22.7	117.8	141.9	58.5
IX	17.4	17.7	16.6	115.6	57.4	62.7
X	11.5	13.3	12.5	49.0	16.7	45.4
XI	5.7	7.6	6.9	54.8	13.7	48.9
XII	3.4	3.5	1.9	47.9	51.9	56.6
I	-1.7	6.1	0.5	27.9	45.3	58.2
II	1.5	6.3	2.4	38.1	32.1	46.6
III	5.6	9.1	7.1	116.1	62.9	32.4
IV	12.7	12.1	11.6	86.3	3.6	51.9
V	16.4	18.2	16.9	29.6	118.4	57.6
VI	19.7	22.8	20.0	84.8	25.3	70.4
VII	23.0	24.8	22.0	22.4	10.1	71.5
Average	11.27	13.52	11.76	790.3	579.3	660.7

The average air temperature in 2005-2006 was lower by 0.49°C and 2006-2007 was higher by 1.76°C. The sum of rainfall precipitation in 2005-2006 was higher by 129.6 mm, where the sum of rainfall in 2006-2007 was 81.4 mm lower than the average of many years and with a very uneven distribution of precipitation per months. Spring months March and April in 2005-2006 were surplus of precipitation, what affected unfavorable on the crops. During the March in 2005-2006 it was 116.1 mm of rainfall, what was 83.7 mm more compared with the perennial average. Regard the high importance of sufficient rainfall amounts during the spring months, particularly May for small grains production, the distribution and amount of rainfall

over the growing season 2006-2007 were considerably more favorable, what resulted with increment of yields during that year. Apart from the rainfall deficiency during the spring months and the non-uniform distribution of rainfall across months, an increasing in average air temperatures was also observed.
Based on the fact that sufficient amounts of rainfall in these months are very important for the successful production of cereal crops it can be concluded that the years in which the researches were conducted were not favorable for the barley growing.

Soil and weather conditions

Before the commencement of the experiment soil samples were taken from the sample surface and the chemical analysis of soil was performed. On the basis of obtained results it was revealed that the soil belongs to the smonitza type, with relatively high clay content, and unfavorable physical properties. The humus content in the surface layer of soil was low (2.38-2.64%), and a substitution and total hydrolytic acidity were quite high (pH H_2O=5.99, KCl=4.56). The soil was medium provided with total nitrogen (0,11-0,13% N) and easily accessible potassium (10-14 mg/100 g soil K_2O), while the available phosphorus content was low (under 10 mg/100 g of soil P_2O_5).

Statistical Analysis

On the basis of achieved research results the usual variational statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Results and discussion

Average values of yield (t/ha), test weight (kg/hl) and 1000 grain weight (g) at investigated Kragujevac's winter barley cultivars grown at the Center for Small Grains in Kragujevac during two growing seasons, 2005-2006 and 2006-2007, are presented in the Table 2.

Table 2 Average values of investigated barley cultivars characteristics

Traits	Cultivar	2005-2006			2006-2007			Average		
		x	S	Sx	x	S	Sx	x	S	Sx
Grain yield (t/ha)	Rekord	4.940	0.356	0.159	5.272	0.669	0.299	5.106	0.535	0.169
	Jagodinac	6.242	0.443	0.198	7.052	0.557	0.249	6.647	0.638	0.202
	Maksa	5.184	0.695	0.311	6.300	0.503	0.225	5.742	0.820	0.259
	Grand	4.770	0.488	0.218	7.068	0.463	0.207	5.919	1.292	0.408
Test weight (kg/hl)	Rekord	66.30	2.086	0.933	63.79	3.490	1.561	65.04	3.016	0.954
	Jagodinac	70.81	2.627	1.175	66.37	5.050	2.259	68.59	4.459	1.410
	Maksa	70.35	1.038	0.464	68.77	1.178	0.527	69.56	1.337	0.423
	Grand	63.57	2.906	1.300	66.18	1.227	0.549	64.87	2.513	0.795
1000 grain weight (g)	Rekord	49.76	2.431	1.087	43.76	1.846	0.826	46.76	3.760	1.189
	Jagodinac	44.36	0.684	0.306	42.61	0.872	0.390	43.48	1.182	0.374
	Maksa	49.84	1.799	0.805	47.85	1.966	0.879	48.84	2.063	0.652
	Grand	39.16	0.865	0.387	37.56	1.545	0.691	38.36	1.451	0.459

During the first year of investigations, cultivar Jagodinac achieved the highest grains yield (6.242 t/ha), followed by Maksa (5.184 t/ha), while the lowest yield was at Grand cultivar (4.770 t/ha). During the second year of investigations (2006-2007), the yield of Grand cultivar was the highest with 7.068 t/ha, while the slightly lower yield was realized by Jagodinac

cultivar (7.052 t/ha). Average grains yield observed in the two-year period was the highest at Jagodinac variety (6.647 t/ha), while the lowest yield was obtained by Grand and Maksa cultivars (5.919 t/ha and 5.742 t/ha). Considerable variation in yield depending on years of research have established Jelić et al. (2007), Đekić et al. (2011) and Popović et al. (2011). Grain yield is a value, which is not only genetically determined but also dependent to a high degree on the growing conditions (Popović et al., 2011, Sabaghnia at al., 2013, Chamurliyski et al., 2015).

During the first year of investigations, cultivar Jagodinac achieved the highest test weight (70.81 kg/hl). The barley cultivar Maksa has achieved the highest test weight in both years of investigation compared to other tested barley cultivars (70.35 kg/hl and 68.77 kg/hl). The average two-year value of test weight at Maksa cultivar was 69.56 kg/hl, Jagodinac 68.59 kg/hl, Rekord 65.04 kg/hl, while the lowest average was at Grand cultivar (64.87 kg/hl). Grain of investigated barley cultivars was characterized by good physical characteristics; especially regard the test weight and 1000 grain weight. Realized average values of these characteristics in the study were slightly higher than the values obtained by Jelić et al. (2007) and Đekić et al. (2011).

During the both years of investigation (2005-2006 and 2006-2007), Maksa cultivar achieved the highest average 1000 grain weight (49.84 g and 47.85 g) compared with other tested barley cultivars. During the first and second years of investigation the lowest average value of 1000 grain weight achieved the Grand cultivar (39.16 g and 37.56 g).

Table 3 Analysis of variance of the tested parameters (ANOVA)

Effect of year on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F(df1,2) 1, 38	p-level

**Statisticaly significant difference (P<0.05) **Statisticaly high significant difference (P<0.01)*

Table 3 shows the impact of year, cultivar and interaction of year x cultivar on yield, test weight and 1000-grain weight. The ANOVA indicated very highly significant effects of the year and grain yield (F_{exp}= 18.6766***) and significant effects of the 1000 grain weight (F_{exp}=4.10989**). Our results are consistent with the results Madić et al. (2009), where the authors state that the growing conditions in the observed years had a significant impact on yield. Very highly significant differences in 1000-grain weight and highly significant of grain yield and test weight at investigated barley were found in relation with the cultivar. Furthermore, 1000-grain weight was significantly affected by the year x cultivar interaction

($p<0.05$). The interaction of grain yield and year x cultivar very significant differences at investigated barley cultivars ($p<0.01$).

Achieved statistically significantly higher yields in 2006-2007 were, primarily, the result of heavy rainfalls and their good distribution as well as favorable air temperatures during the vegetation period (Table 1). Đekić et al. (2014) in his research states that the air temperatures and the rainfall amount and distribution during the barley growing season have the greatest impact on high yields and grain quality.

Conclusion

Based on the gain results during two-year investigation on four Kragujevac's winter barley cultivars, it can be concluded that the highest yield achieved the cultivar Jagodinac (6.647 t/ha). Maksa and Grand cultivars have achieved satisfactory results, while the poorest results were achieved by the cultivar Rekord. During 2006-2007, statistically significantly higher grain yield per area unit as well as 1000 grain weight was achieved, compared with 2005-2006. Significant differences in 1000 grain weight at investigated barley cultivars were found relative to the cultivar and very significant differences at grain yield relative to environmental factors. Very highly significant influence of the cultivar on 1000 grain weight was established at investigated winter barley cultivars by variance analysis, while genotype influence on grain yields and test weight was highly statistically significant.

Grain quality is a qualitative characteristic affected by genetic and environmental factors, as well as their interactions, and therefore the cultivar in individual years can acts as a beer or forage cultivar, what can be test determined and that way the grain can be direct for a particular purpose.

Abstract

The study was carried out in a stationary field trial involving fertilization over a two years period from 2008/09 to 2009/10. Trials were first set up in the experimental fields of the Small Grains Research Centre in Kragujevac in 1970. The wheat cultivar used in the experiment was Vizija, the dominant cultivar in the production region of Serbia. Studies of fertilization effects were conducted in a stationary field trial on a degrading vertisol soil with low pH. Eight variants of mineral nutrition (control, NK_1, NP_1, NP_2, NP_3, NP_1K_1, and NP_2K_1) and untreated control (without nutrition) were tested in the experiment. The highest grain yields under mineral nutrition involving a combination of three mineral elements NP_1K_1 (4.827 t/ha) and two mineral elements NP_3 treatment (4.564 t/ha). Over the two-year period, all investigated treatments of wheat achieved the highest average test weight in the NP_2 (76.545 kg/hl).

Based on the analysis of variance, it can be concluded that two are highly significant differences in grain yield regard the year of investigation ($F_{exp}=12.033^{**}$) and significant differences at 1000-grain weight ($F_{exp}=8.216^{*}$) and highly significant differences in test weight ($F_{exp}=121.874^{**}$). Highly significant differences in grain yield at investigated wheat cultivar were found relative to the fertilization. In the dual interaction between the year and fertilization, significant effects were highly significant on grain yield and 1000-grain weight.

Grain yield were significantly positively correlated with 1000-grain weight only in the 2009/10 ($r=0.45^{*}$). Test weight in 2008/09 was positively correlated with 1000-grain weight ($r=0.47^{*}$).

Key words: *fertilization, yield, quality, wheat*

Introduction

New perspective wheat lines and varieties has more and better filled grain, higher yield, grain mass and farinaceous content, while proteins and lysine was smaller compared with older varieties (Đekić et al., 2014, 2015). Several factors are decisive in increasing wheat yields: the cultivar, cultural practices, agroecological conditions, local climatic and soil characteristics, mineral nutrition and adequate protection from plant diseases, pests and weeds. Wheat productivity and grain quality in Central Serbia are governed by a range of factors, notably climate, soil, genetics and crop nutrition. Soil acidity in wheat fields in Central Serbia has become a severe problem that leads to a significant decline in grain yield and quality of wheat (Đekić et al., 2013, Jelić et al., 2012). Mineral fertilizers play a vital role towards improving crop yields but one of the main constraints in achieving proven crop potential is imbalanced use of nutrients, particularly low use of P as compared to N. The optimum rate of P application is important in improving yields of most crops (Jelić et al., 2013, 2014). In Serbia, farmers are using only nitrogen fertilizers for fodder crops while the use of P fertilizer is negligible. These crops are often grown on marginal lands. Hence, the production is low and quality is poor. The absence of record yields indicates that an answer could be sought in soil,

the main substrate for field crop production. Additionally, the major previous crops of small grains also suffer from negative nutrient balance. The use of incomplete production technology in previous decades had definitely affected the potential and actual soil fertility.
The objective of this study was to evaluate the effect of different fertilization systems on the grain yield and quality of wheat grown on a vertisol soil. The study was also aimed at optimizing fertilization for maximum profitability in the future wheat production of Central Serbia.

Materials and methods

Experimental design and statistical analysis

The study was carried out in a stationary field trial involving fertilization over a two years period from 2008/09 to 2009/10. Trials were first set up in the experimental fields of the Small Grains Research Centre in Kragujevac in 1970. Plot size was 50 m^2. The wheat cultivar used in the experiment was Vizija, the dominant cultivar in the production region of Serbia. This investigation included an untreated control and six variants of fertilization: NK_1 (80 kg/ha N, 60 kg/ha K_2O), NP_1 (80 kg/ha N, 60 kg/ha P_2O_5), NP_2 (80 kg/ha N, 80 kg/ha P_2O_5), NP_3 (80 kg/ha N, 100 kg/ha P_2O_5), NP_1K_1 (80 kg/ha N, 60 kg/ha P_2O_5, 60 kg/ha K_2O) and NP_2K_1 (80 kg/ha N, 80 kg/ha P_2O_5, 60 kg/ha K_2O). A non-fertilized variant served as a control. The trial was set up in a randomized block design with five replications. Fertilization was regular and followed a long-time scheme. Total amounts of phosphorus and potassium fertilizers and half the nitrogen rate are regularly applied during pre-sowing cultivation of soil.
On the basis of achieved research results the usual variational statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Agroecologial and soil conditions

This study was conducted over a three-year period in the Šumadija region, Central Serbia, on a Vertisol soil, at Kragujevac location, 173-220 m a. s. l. (44° 22′ N, 20° 56′ E), in a temperate continental climate having an average annual temperature of 11.5°C typical of Šumadija districts in Serbia and a rainfall amount of about 550 mm. Kragujevac area is characterized by a moderate continental climate, which general feature is uneven distribution of rainfall by month.
The data in Table 1 for the investigated period (2008-2010) clearly indicate that the years in which the researches were conducted differed from the typical multi-year average of Kragujevac region regard the meteorological conditions.

Table 1. *Mean monthly air temperature and precipitation (Kragujevac)*

Year	Months										Aver.
	X	XI	XII	I	II	III	IV	V	VI	VII	
Mean monthly air temperature (°C)											
2008-09	13.1	8.5	4.4	2.3	2.0	6.8	13.4	17.8	20.2	22.5	11.1
2009-10	11.7	8.8	2.6	0.9	3.2	7.2	12.1	16.5	20.2	23.1	10.63
Average	11.8	5.6	1.9	0.6	2.0	6.2	11.2	16.2	19.4	21.3	9.62
The amount of rainfall (mm)											
2008-09	31.3	30.6	29.7	57.7	76.9	40.3	16.8	46.0	137.8	25.2	492.3
2009-10	102.6	77.5	194.2	57.0	150.5	43.3	142.2	116.7	196.7	14.8	1095.5
Average	47.5	50.0	49.5	36.8	33.9	43.5	51.5	64.8	79.3	62.5	479.3

The average air temperature in 2008/09 was higher by 1.48°C and 2009/10 was higher by 1.01°C. The sum of rainfall precipitation in 2008/09 was higher by 13.0 mm, where the sum of rainfall in 2009/10 was 616.2 mm higher than the average of many years and with a very uneven

distribution of precipitation per months. Spring months April, May and June in 2009/10 were surplus of precipitation, what affected unfavorable on the crops. During the April in 2009/10 it was 142.2 mm of rainfall, what was 90.7 mm more compared with the perennial average. During the month of June in 2009/10 it was 196.7 mm of rainfall, what was 117.4 mm more compared with the perennial average. Regard the high importance of sufficient rainfall amounts during the spring months, particularly May for small grains production, the distribution and amount of rainfall over the growing season 2008/09 were considerably more favorable, what resulted with increment of yields during that year (Table 1).

The trial was set up on a vertisol soil in a process of degradation, with heavy texture and very coarse and unstable structure. The humus content in the surface layer of soil was low (2.22%). Soil pH indicates high acidity (pH in H_2O 5.19; pH in KCl 4.27), nitrogen content in soil is medium (0.11-0.15%), while the content of available phosphorus ranges from very low (1.7-2.9 mg/100 g soil) in the N and NK trial variants to very high (26.9 mg/100 g soil P_2O_5) in the NPK variants of fertilization. Available potassium contents are high, ranging from 19.5 to 21.0 mg/100 g soil K_2O.

Results and discussion

Results clearly show that yield components were significantly affected by fertilization (Table 2), the lowest values for grain yield and yield components were obtained in the untreated control.

Grain yield were the highest in the combined treatment with lime, manure and mineral NP_1K_1 fertilizer (4.827 t/ha). The grain yield of wheat significantly varied across years, from 2.341 t/ha to 5.623 t/ha in 2008/09, from 1.412 t/ha to 4.030 t/ha in 2009/10. During the first year of

investigations, the highest average value of 1000-grain weight achieved the NP_1 and NP_2-treatments (41.860 g and 41.280 g). During the second year of investigations (2009/10), the highest average value of 1000 grain weight achieved the NK_1 and NP_3 treatments (39.720 g and 39.660 g). A number of authors (Đekić et al. 2014; Jelić et al. 2013) underline that 1000-grain weight is a cultivar-specific trait, with considerably higher variations being observed among genotypes than among treatments or environmental factors. As illustrated in Table 2 during the first year achieved the highest test weight at NP_1-treatment (79.45 kg/hl), while the lowest test weight was the control treatment (76.38 kg/hl). During the second year of investigations, the highest test weight at NP_1K_1-treatment (74.65 kg/hl), followed by NP_2 (74.053 kg/hl).
Differences between grains yield of the untreated control and variants with fertilization were statistically highly significant. Fertilization with nitrogen alone resulted in a statistically highly significant increasing in grains yield, compared with the untreated control, but further increasing, when nitrogen was applied in combination with P and K fertilizers, did not result in statistically high significance. The study showed that among investigated fertilization variants the highest grain yields were achieved in variant with 80 kg/ha nitrogen rate, phosphorus rate of 60 kg/ha P_2O_5 and potassium rate of 60 kg/ha K_2O. Usage of fertilizers and certain amendments on extremely acid soils in certain years, particularly those less favorable for production, almost certainly had different effects on grain filling, resulting in diverse relationships between productive and qualitative traits. Presented results confirm the opinion of many authors that the traits analyzed are genetically determined, but strongly modified by the nutrient status and weather conditions (Đekić et al., 2014; Jelić et al., 2013).

Table 3. *Analysis of variance of the tested parameters (ANOVA)*

Effect of year on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F(1. 68)	p-level

1000-grain weight (g)	12.97490	0.511679	25.357**	0.000000
Test weight (kg hl^{-1})	4.23732	3.578286	1.184	0.328033

nsnon significant; *significant at 0.05; **significan at 0.01.

Based on the analysis of variance, it can be concluded that two are highly significant differences in grain yield regard the year of investigation (F_{exp}=12.033**) and significant differences at 1000-grain weight (F_{exp}=8.216*) and highly significant differences in test weight (F_{exp}=121.874**).
Highly significant differences in grain yield at investigated wheat cultivar were found relative to the fertilization (Table 3). In the dual interaction between the year and fertilization, significant effects were highly significant on grain yield and 1000-grain weight.

Table 4. *Correlation coefficients for the traits analyzed across treatments*

Correlations between the traits analyzed in the unfertilized control			
	Grain yield (t ha^{-1})	1000-grain weight (g)	Test weight (kg hl^{-1})
Grain yield (t ha^{-1})	1.00	0.69*	0.75*
1000-grain weight (g)		1.00	0.94**
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the NK_1			
Grain yield (t ha^{-1})	1.00	-0.19^{ns}	0.21^{ns}
1000-grain weight (g)		1.00	-0.36^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the NP_1			
Grain yield (t ha^{-1})	1.00	0.37^{ns}	0.29^{ns}
1000-grain weight (g)		1.00	0.79*
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the NP_2			
Grain yield (t ha^{-1})	1.00	0.52^{ns}	0.50^{ns}
1000-grain weight (g)		1.00	0.95**
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the NP_3			
Grain yield (t ha^{-1})	1.00	-0.04^{ns}	0.83*
1000-grain weight (g)		1.00	-0.22^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the NP_1K_1			
Grain yield (tha^{-1})	1.00	0.23^{ns}	0.67*
1000-grain weight (g)		1.00	0.25^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the NP_2K_1			
Grain yield (t ha^{-1})	1.00	-0.79*	0.79*
1000-grain weight (g)		1.00	-0.67*
Test weight (kg hl^{-1})			1.00

Positive correlations were observed (Table 4) between grain yield and test weight in all treatments. Pozitive and strong correlations were also found between grain yield and 1000-grain weight in the control treatment (r=0.69*) and negative and strong correlations in the NP_2K_1-treatment (r=-0.79*). Negative and strong correlations were also found between test weight and 1000-grain weight in the NP_2K_1-treatment (r=-0.67*). The present results confirm the opinion of many authors that the traits analyzed and their correlations are genetically determined but are strongly modified by the nutrient status of the environment and weather conditions (Jelić et al., 2013; Đekić et al., 2014).

Table 5. *Correlations between the traits analyzed during 2008-2010*

	Correlations in 2008/09			Correlations in 2009/10		
Traits	Grain yield, t/ha	1000-grain weight, g	Test weight, kg/hl	Grain yield, t/ha	1000-grain weight, g	Test weight, kg/hl
Grain yield (t ha^{-1})	1.00	0.28^{ns}	-0.03^{ns}	1.00	0.45*	0.27^{ns}
1000-grain weight (g)		1.00	0.47*		1.00	-0.07^{ns}
Test weight (kg hl^{-1})			1.00			1.00

Testing the correlation coefficients between grain yield and 1000-grain weight of wheat (Table 5) was found positive and medium-dependent statistically average correlation between test weight and 1000-grain weight in 2008/09. However, 1000-grain weight were significantly positively correlated with grain yield only in the second year ($r=0.45^{*}$). Test weight in 2008/09 was negatively correlated and 2009/10 was positively correlated with grain yield. The results suggest that grain yield and quality formation is affected by both genetic and environmental factors (Jelić et al., 2013).

Conclusion

Over the two-year period, all investigated treatments of wheat achieved the highest average grain yield in the NP_1K_1 variant of fertilization with the higher rate of phosphorus (4.827 t/ha). Considering the average yields value and test weight in two-year period, it was evidently that the yields and test weight were highly statistically significantly different and 1000 grain weight were significantly different between the year. Effect of fertilization on the grain yield were highly statistically significantly. Significantly positively correlated with yield and 1000 grain weight both in 2009/10 (0.45^{*}, respectively), and positively correlated with 1000-grain weight and test weight both in 2008/09 (0.47^{*}, respectively). Significant positive correlations were observed between 1000 grain weight and test weight in control, NP_1 and NP_2 treatments, and negatively correlations were observed between 1000 grain weight and test weight in NP_2K_1.

Abstract

Trends for increased biomass and grain yield production with costs lowering, has consequence in products low in mineral nutrients. Minerals deficiencies in nutrition, particularly of iron, magnesium, zinc and selenium are present worldwide. To combat such a situation, increase in mineral nutrients in food is necessary. This could be provided by fortification which includes different cropping practices and genetic engineering. Almost half of soils are deficient in mineral nutrients. Cropping practices which include increase in soil fertility, application of foliar fertilizers etc. could be measures for increasing plant’s ability to utilize mineral elements. Methods of conventional breeding and genetic engineering could increase mineral nutrients concentration in edible parts of plants. Fortification also includes lowering of antinutrients (phytate, phenolics, etc.) that inhibit nutrient bio-availability, as well as increasing of enhancing substances - promoters (ascorbic acid, β-carotene etc.) that promote nutrient bio-availability. Increase of mineral nutrients concentration and their availability from produced crops are complex traits which demand new approach in crop production.

Key words: *crop improvement, mineral elements, bio-availability, antinutrients, promoters*

Introduction

Nutrients, as a basis for wellbeing came from agricultural production. If agricultural systems is not capable to product enough food diversity and quantity to satisfy all the nutrients essential to human life, people will suffer, mortality and morbidity rates will increase, working productivity will be reduced, societies will deteriorate (Welch, 2002). In recent time, many food systems, irrespective that they belong to developed or developing countries are incapable to meet the nutritional needs. Nutritional deficiencies afflict over three billion people globally, causing chronic diseases, such cancer, cardio-vascular diseases, stroke, diabetes, osteoporosis etc. (Graham et al., 2007).

Agricultural production depends mainly on variation in environmental factors. In combination with low soil fertility, soil degradation, inadequate use of fertilizer inputs climatic factors could be the main reason for food insecurity, (St.Clair and Lynch, 2010). One of the most important factors that induce elemental imbalance in plants is raising CO_2 level in atmosphere. Fernando et al. (2012) obtained that elevated atmospheric CO_2 reduced proteins and mineral elements concentrations in wheat grain by 12.7%.

The accumulation of mineral elements in plant tissues is limited by their supply and availability from soil, unless foliar fertilizer was applied (White and Broadley, 2009). Adequate mineral nutrition is crucial when crops are growing on infertile soils. Physical characteristics of some soil, like concretion, poor drainage, shallowness, poor water retention, as well as chemical characteristics, such as acidity, alkalinity, salinity, ion toxicity and sub-optimal availability of mineral nutrients, could be stressful to plants. Most of the soils worldwide are characterized by low availability of mineral nutrients and/or ion toxicities. This

includes the combination of low P, low Ca, Al toxicity, and Mn (Lynch and St.Clair, 2004). Imbalance between ions is present in areas with intensive agricultural production, where high yielding potential of grown crops, together with high inputs of N, P, K fertilizers devastate soils for other mineral nutrients. Also, in areas with poor fertilization level, even good soil fertility was decreased. The aim of this study is emphasize importance of biofortification in improvement of global health.

Importance of mineral nutrients for human health

Nutrition is source of all substances necessary for human organism. Nutritional deficiencies, which mainly include Fe, Zn, I, Se, vitamin A, affect almost 3 billion people worldwide and are responsible for almost two-thirds of the childhood deaths worldwide (Graham et al., 2007).

Fe deficiency, recognized as anemia, affects about 30% of the world's population. Poor Fe availability from foods, is the main factor that induce anemia, while the other factors, such deficiencies in Zn, I, Se, vitamin A and its pro-vitamin β-carotene, folate, vitamin B12, certain gut bacteria, and pathogens in human organism could contribute to anemia, too (Graham et al., 2007). Zn deficiency has been connected to abnormal blood and muscle mass losses, problems associated with other physiological processes due to its high physiological requirements for growth, puberty, pregnancy and lactation (Hunt2003). This means that Zn deficiency is ultimate "hidden hunger", affecting about 2.6-3 billion people (Graham et al., 2007). Mn is essential for humans. It has important role in antioxidant system for metabolism, bone development and wound healing.

Ca plays an important role in skeleton structure and its health, and it is also important for cardio-vascular system, kidneys, regulation of energy metabolism, (inhibiting diet-induced obesity, promoting lipolysis, lipid oxidation, and thermogenesis) (Cappuccio et al., 2000; Zemel, 2004). Mg have many important functions in cellular metabolism and homeostasis, including transport of K and Ca ions, modulation of signal transduction, energy metabolism and cell proliferation (Saris et al., 2000). Low Mg status has been associated with a chronic inflammatory stress component, widely connected with obesity, alcoholism, atherosclerosis, eclampsia, hypertension, osteoporosis, diabetes mellitus, cardiac diseases, asthma, and cancer (Saris et al., 2000; Nielsen, 2010). Se has structural and regulatory role as constituent of whole range of selenoproteins, it plays an important role as an antioxidant and catalyst for the production of active thyroid hormone (iodothyronine 5'-deiodinases) (Rayman, 2000). The other important functions are connected to the proper functioning of the immune system, regulation of the inflammatory mediators in asthma. I deficiency causes mental defects, goiter, reproductive damage, childhood mortality, and hypo- and hyperthyroidism (Vitti et al., 2003). To combat I deficiency, universal salt iodisation is introduced as mandatory measure in nearly all countries worldwide and two-thirds of the world's population is covered by iodised salt. Still one-third of households lack access to adequately iodised salt (Andersson et al., 2010).

Mineral nutrients from various foods are partly available owing to the presence of anttinutrients, like phytic acid, phenolic compounds, some types of cellulose etc. that inhibit absorption. Other substances, promoters, increase absorption of nutrients, diminishing negative effects of antiunutrients. From this point Graham et al. (2007) statement "You are not what you eat, you are what you eat and do not excrete" is referred to bioavailability.

Biofortification

Biofortification is sustainable strategy to combat micronutrient malnutrition. It combines different techniques, like plant breeding and cropping measures. Breeding is using to improve genotypes with enhanced efficiency for absorption and accumulation of targeted nutrients.

Agronomic fortification includes mainly usage of soil and foliar fertilizers (with increased concentration of desired nutrients) and techniques that enhance absorption of mineral nutrients.

Modern crop production has to be based on genotypes able to achieve high yields, with lesser inputs of water, fertilizers, agro-chemicals etc. They also have to have improved nutritional quality, to meet nutritional requirements of humans and animals. The useful breeding techniques for fortification are conventional breeding, marker assisted selection (MAS), which could also be combined with transgenic approach. Conventional breeding is possible only if high variation among genotypes is present in gene pools that control desired trait and if it is established in nutrient efficiency in the field Rose et al. (2013). Dragičević et al. (2013) and Gupta et al. (2015) pointed that maize is characterized as a species with high variability in β-carotene, Fe, Mn and Zn and so, some antinutrients, offering distinct opportunity to deliver bioavailable minerals through diet. According to chemical composition, three distinct strategies are being distinguished: I - to increase mobility of mineral nutrients together with grain binding capacity; II - to decrease inhibitors of absorption; III - to increase concentration of substances that directly promotes absorption or indirectly by stimulation of gut's microbiome (Clemens, 2014). Up today majority of efforts was given to the firs group.

Introduction of genetically modified plants gave opportunity to overcome problem of boundaries in natural variation in accumulation and bioavailability of mineral elements. Overexpression of uptake and storage proteins could increase Fe and Zn concentration to a limited extent, so introduction of substances that enhances mineral element absorption in gut even in the presence of naturally occurring inhibitors could provide satisfactory results (Lonnerdal, 2003). That is why strategies for increase in concentration of important nutrients, like β-carotene, vitamin C, or folate are important, too. Genome-wide association studies were used to identify variation for genes controlling enhancing substances, like β-carotene (Suwarno et al., 2015), resulting in several fold higher β-carotene level in modified plants (such "golden rice"). Biofortification of plant folate resulted in 25-fold more folate accumulation in tomato fruits (Garza et al., 2007). Interesting example is simultaneous modificatrion of three separate metabolic pathways in maize, resulting in kernels that contained 169-fold higher amount of β-carotene, 6-fold higher amount of ascorbate, and two-fold higher amount of folate (Naqvi et al., 2009).

Even if crops efficiency is enhanced, the nutrient absorption from soil that is low in mineral nutrients is under question. Crops, like humans also require balanced nutrition for optimal growth and development. The application of fertilizers, as fortifying measure could improve nutritional quality of crops, as well as to increase yield. For instance, Zn-enriched NPK fertilizers could full support on-going breeding programs with genotypes with increased Zn efficiency (Cakmak, 2008). Fertilizers that contain macro-elements (N, P, K, S) could affect absorption and accumulation of microelements. For instance, application of N fertilizers in rice increased transportation ability of microelements from root to shoot (Hao et al., 2007). Due to the variations in plant requirements during vegetation, variations in environmental factors, and possible runoff, the combination of soil and foliar fertilizers could give the best results in Zn enrichments (Cakmak, 2008). Prolonged effect of these measures is obtained in higher vigor of enriched grains, denser stands and higher stress tolerance on potentially Zn-deficient soils.

Application of foliar fertilizers is the most efficient way for utilization of deficient mineral nutrients, since soil factors which restrain availability of some mineral nutrients are diminished. Moreover foliar fertilizers that contain different bio-active compounds, like secondary metabolites and phytohormones could enhance Fe accumulation in soybean grain, also increasing potential availability of Fe, Mn and Zn to humans and animals (Dragičević et al., 2015a). Some of the useful methods for enrichment of crops with Se is use of plants

grown on Se rich soils (part of phytiremediation) as a green manure or supplementary source (Wu et al., 2015). Sustainable agricultural technologies are based on natural potentials to improve agricultural products. Very important place was given to the application of biofertilizers, like arbuscular mycorrhizal fungi which facilitate absorption of Cu, Fe and (to a limited extent) Mn. Also, phytosiderophores from maize root could improve the Fe nutrition of intercropped peanut and soybean (Xiong et al., 2013, Dragicevic et al., 2015b), with increased potential bioavailability of Mg, Fe and Zn from grain of maize and soybean, due to the elevation of β-carotene, together with reduce in concentration of anti-nutrients in grain.

Agronomic biofortification is required for optimizing and ensuring the success of genetic biofortification of cereal grains (Cakmak, 2008), while the efficiency of all applied cropping measures in increasing concentration of mineral nutrients depends on many factors, like soil type, crop, cultivar, rotation, environmental and other factors, resulting in a specific set of measures for individual regions (Rengel et al., 1999). Besides, usage of fortified plants in nutrition lower the risk of overdosing. Just increase in concentration of mineral nutrients in edible parts of plants doesn't mean that they will reach the goal, to enable health benefit through nutrition. Different techniques, like conventional breeding, MAS and genetic modifications, are using to increase bioavailability of mineral nutrients due to the decrease of antinutrients, mainly phytic acid concentration in grain. The molar ratios between mineral nutrients with P are useful traits in biofortification research (Šimić et al., 2012). The mutations that block PA synthesis, contributes to the increased P bioavailability, due to increased concentration of inorganic P (Raboy, 2013). Owing to negative aspects in PA decrease in grains, such reduced germination, emergence, tolerance to pathogens and various diseases, and yield, different processing methods could be useful in decrease of PA, like cooking, germination, fermentation, soaking, autolysis (Urbano et al., 2000). When anti-carcinogenic properties of PA are also taken into account, strategy for increasing promoter concentration (such vitamin C, β-carotene and nicotianamine), could express the promising results for increased bioavailability. For instance, introduction of nicotianamine synthase gene (OsNAS1) into rice significantly increased nicotianamine concentrations in both unpolished and polished grain, increasing twice Fe bioavailability (Zheng et al., 2010).

Conclusion

Raising population, increased CO_2 concentration in atmosphere, together with meteorological extremes, soil devastation, as well as crops with increased yielding potential contributes to globally present malnutrition. To combat such situation, biofortification, as innovative as sustainable strategy arose. Breeding and genetic engineering produced new genotypes, with improved efficiency in absorption and accumulation of mineral elements in edible parts of plants, even from the soils poor in nutrients. Agronomic biofortification is focused on environment, i.e. application of measures that enhance absorption of mineral elements. Special attention was given to fertilization through soil or plant foliage, assuring fast metabolisation of targeted mineral nutrients. Combination of agronomic fortification and breeding offers reliable results in biofortification. It also includes breeding or modification of genotypes with decreased antinutrients concentration, as well as increased concentration of promoters, enabling better availability of mineral nutrients to humans and animals, as a final goal. The holistic approach that includes application of the results from different scientific areas could be fruitful as more effective and sustainable biofortification solutions and improving of human health.

Abstract

Six wheat varieties where tested on the effect of 2,1 kg/ha bentazone in herbicide at field trial. Stem growth two weeks after treatment at heading and flowering was -5- 9% due to its accelerated degradation correlated to hydrolytic stability of race specific leaf rust resistance genes (Lr). Of variety Pobeda was -2, increasing to -7% in June 2015th. At additional Lr near isogenic lines (NILs) different by nonspecific Lr genes present also in the tested varieties grown in greenhouse at 20^{o}C during December, assumed plant parts lengths reduction estimated ten days from first leaves treatment was -17-20% similar to Pobeda of -15%. Than, of specific Lr genes about halved influence could be related to increased amount of Mg in seed solving consequences of degraded herbicide in chloroplast membrane where relisted SO_2 transfer in acids that reduced chlorophyll. 23 – 28th May, temperature below 15^{o}C and heavy rains facilitated *Puccinia striiformis* and facultative parasites infections. *Septoria tritici* growth at middle leaves was reduced for 10% causing 10% of yellow rust increase at susceptible varieties equal by 5% *Pyrenophora tritici repentis* main *Puccinia triticina* antagonist which toxin such effect in June was not disturbed. Reaction types to *Puccinia triticina* after treatment were increasing, except stable maximal one at Pobeda. Scab of 2% was generally reduced to about 1%. Shortened currency period of approximately two months by Lr genes 1, 3a, 19, 24 and 29 facilitated multiple pests protection regional suggested after continual moisture at flowering when over frequented all of weeds appeared.

Key words: wheat protection, bentazone, Lr genes

Introduction

The attempts to solve problem of negative consequences of herbicides to wheat were trough genes mutations. Of bentazone adequate one was achieved by Gamma ray irradiation while mutation was recognized throw ten times increased dose and herbicide concentration in the middle parts of leaves instead of all round effect (Kim et al., 2007). By same strategy founded was tolerant gene to glyphosate (Gordon et al., 2004) while of tolerant soya analysis confirmed linkage by phosphate group to novel gene (Funke et al., 2006). Such, problem of consequential former residua degradation was not solved. Increased rust resistance of wheat and soya bean genotypes declared as to glyphosate resistant was recognized (Anderson et al. 2006, Feng et al. 2005). Initiated were investigations focusing accelerated enzymatic degradation of pesticides by structure similar to of *Puccinia triticina* cell wall (Harder and Chong, 1984). Recognized were accelerated degradations of dithiocarbamate, phtalamide, neonicotinoides and glyphosate at seedlings by decreased growth in the presence of same of specific Lr (leaf rust resistance genes) in near isogenic lines (NILs) or wheat varieties as well as confirmed simultaneous influence of products on *Puccinia triticina* reaction type. Lr genes products were founded to be different by hydrolytic stability, cleaved linkage strength and approach ability to middle weighted elements sulphur, phosphorus and chlorine (Jerkovic and Prijić, 2012; Jerković et al., 2014, 2015).

The hard continental climate characterized the highest amplitude between winter and summer temperatures amplitude more than 50^{O}C during wheat vegetation. When combined pesticides were applied twice in spring yellowing of leaves of the varieties except Pobeda was linked to

interactions between specific Lr genes and pesticides and simultaneous accelerated degraded gluten in leaves (Jerkovic et al., 2014a). In the same paper assigned was problem of defining the stable acidic elements amount applicable trough pesticides in focused climate with grain filling period about forty days. Simultaneous of glyphosate influence on *Septoria tritici* facultative parasites in field was recognized as well as no significant influence to *Pyrenophora tritici repentis (Ptr)* growth confirming results of Sharma et al. (1989). By forecasting model for the first time involving of the facultative and obligate parasites antagonism recognized was time for economical protection at the beginning of June throw reduction of *Puccinia triticina* at susceptible varieties when Ptr intensity at middle leaves was bellow 10% (Jerković and Jevtić, 2012; Jerković et al., 2013). Because of short grain filing period and lower yields once protection by pesticides from more pests become only rentable solution also. The problem of weeds and *Septoria tritici* was not generally solved with glyphosate because of Lr genes specificity according to activation time in drought conditions and possible consequences as were on weeds. Bentazon was found to be contact herbicide acting as a photosynthetic electron transfer inhibitor. Its selectivity was previous related to the ability of the crop plants to quickly metabolize bentazon to 6-OH- and 8-OH-bentazon and conjugate it with sugar (Banokowska, 1999). Fast linkage to membrane of chloroplast reducing effect instead of enzyme inhibiting as was by glyphosate, recognized by Bethenfalvay et al., (1979). Uptake and accumulation of bentazones was investigated by Sterling et al. (1990) while transformation to lipids was not recognized in soybean and Abutilon tissue cultured cell suspension. Photo catalyst based on Zn was recognized by Borhade et al. (2014). Similar could be explained detoxification in rice (Yingzhi et al., 2015) generally founded to be crop damaging, immediately after treatment. Rice non host resistance to rusts (Aylife et al., 2011) was previous related to collase fast consequence, hydrogen peroxide relisted before haustorium formation. Early at spring application suggested Bentazone manufacturers focusing under allowed original residua amount in wheat seed and effect on branching weeds. By its structure it was expected that race specific Lr genes from most of clusters could accelerate relist bentazone sulfur linkages. Hypothetic were different interactions of nonspecific and specific Lr genes in regional varieties with bentazone and parasites in field.

Aimed was to recognize not so risky solution for occasional economical treatment in hard continental climate, focusing all weeds reduction after appearance, as well as Scab and *Septoria tritici* without disturbed *Pyrenophora tritici repentis* antagonism to leaf rust cause.

Material and method

Six wheat varieties were selected according to different combination of specific and nonspecific Lr genes (Jerkovic et al., 2013). These varieties and four Lr NILs with only nonspecific Lr genes were grown in the glasshouse at average air temperature around 20^{o}C at day/night regime 10/14 h. 50 seeds of each genotype was simultaneous sown in pots (5x5x7cm). Daily watering of the soil was stopped two days before 0,21 mg/m2 of pure bentazone in herbicide in 0,1 l of water suspended was applied six days after germinating. NILs were halved by cover before the treatment. For further calculations criterion was that stems of NIL sample could to be different in the interval of 5 mm. At least five plants from twenty viable in each of the replications had to be in representative sample for calculation of average part lengths of the NILs. Of treated and control NIL growth potential was equalized across formula: (average first and second leaf lengths sum of treated or control NIL with lower average stem length) x average higher stem length: average lower stem length + average higher stem length while growth difference presented in percents (average up ground length of treated plant parts: average up ground length of treated plant parts x 100).

The field trial was postulated according to method of Jerkovic and Jevtić (1997). Such, the control and treated varieties again by 2,1 kg –ha bentazone at 30th April , 15th May. and 3rd June 2015th were sown parallel at six m^2, 29.10.2014th while distanced two. The estimation of *Septoria tritici, Purenophora tritici repentis intensity* presented in percents of covered area at middle leaves was performed at 17th May while 8th June at last two. Simultaneous estimated was also reaction type (Stakman et al., 1962) to *Puccinia triticina* for the difference of *Puccinia striiformis* when was only intensity at flag leaf. The Scab intensity was presented trough percent of necrotic middle of the spikes while parasite proved by development in permanent humid conditions kept in Petri dishes at air temperature around 20^{O}C. At 3th June were measured the distance of spike from second internodia below and stem length while their ratio was SAGR.

Results and discussion

At seedling stage of Lr near isogenic lines (NILs) with Lr 34, Lr 13 present also in the tested varieties parts lengths reduction by bentazone was -17-20% similar to Pobeda one of -15%. Specific Lr genes in other varieties caused reduction 3-7%. At defined seedling stage nitrogene was not uptaken from the soil due to reserves in seed (Vuurde and Tonneyck, 1978). The vigour by bentazone was not recognized as when thiametoxam was applied because of relative lover amount of fast viable nitrogene from pesticide (Jerkovic et al., 2015). The bentazone similar dosed and applied in field did not caused spike whitening as glyphosate (Jerkovic et al., 2014a). The previous recognized lower influence on growth than of glyphosate in the presence of specific Lr genes could be related to additional Na in the particular applied herbicide recognizable by brown color according to EPA, that decreased Mg salted amount. In Table 1 presented was treatment results when recognized were highest differences in growth. Exceptional opposite was recognized at variety Pobeda related to no presence of specific Lr genes confirmed by unique SAGR also. Generally stem reductions were correlated with these at seedling stage while focusing nonspecific Lr genes in near isogenic lines trough Pobeda, differences were not so huge and related to assumed prolonged daily light and intensity during the May reducing the effect of herbicide. The most of the varieties expressed SAGR values bellow of Pobeda one were related to presence of sucrose (Lr 13) and SUTs (Lr 34) and specific Lr genes (Jerkovic et al., 2013a), however excluding sugar as tolerance cause Amylase was recognized as product of Lr 22b found to be in Rapsodia accompanied with sucrose trough relative highest SAGR up to 0,68. Generally, parameter was correlated with previous years but lower for approximate 0,05 than maximal one because of relative lower temperatures during the May. By its declining the infection efficiency of obligate parasites was relative increased. Of both facultative leaves affecting ones growth was increased but fructification absent by treatment except stable from all leaves of Rapsodia. The intensity at upper leaves of controls was declining from maximal of 20% correlated to SAGR as was recognized previous by Jerkovic and Jevtić (2012). Focusing *Puccinia triticina*, of nonspecific Lr genes enzymes removed or degraded sugar simultaneous eliminated it as a cause of whitening about infection sites when bentazone based herbicide was applied. Whitening without pustules was recognized at most of the treated varieties at 17th May except on Pobeda with stable maximal reaction type. Moderately resistant reaction type was explained by effect on bentazone and overcome resistance of Lr 1 in Simonida and Rapsodia. The all of reaction types on flag leaves were maximized at June confirming no further presence of herbicide residua with sulfur. Across decreased infection severity to leaf rust opposite than was of yellow one variety Enigma had to have Lr 19 beside previous detected Lr 29 trough interactions with pesticides. It was not disturbed spreading on upper leaves of facultative parasites from Rapsodia with reproductive organs formed before treatment related to accelerated growth of further plant parts defined by increased SAGR. The

growth at lower leaves of *Septoria tritici* was stopped by herbicide. These parasite toxins also influenced yellow rust at flag leaves which development was facilitated by unusual period of stable temperatures 10-15^{0}C from 23-28th May. Its reduction was for 10% due to 10 % increased growth of *Septoria tritici* at controls focusing varieties without Lr 3a as was in NS 40S and Lr 24 in Ilina. Scab intensity was halved by both treatments most likely by not complete entrance of herbicide concluded trough same effect on Pobeda and varieties containing Lr 1 permanent active during critical time for the infection.

Table 1. The disease causes intensity changes by bentazone and growth reductions at adult and seedling stages

Legend: K= control plants, T= treated plants

Main antagonist of leaf rust *Pyrenophora tritici repentis* (Jerkovic et al., 2005) was present mostly about 5% at middle leaves. In June its spreading on upper leaves was recognized in traces about Rapsodia surrounded varieties while development was not influential on leaf rust cause because of no time for enough toxins production from lessons appeared in lower density than were below. Each of toxins from two facultative parasites influence to reduction of yellow rust cause was still not precise defined but seemed to be as to leaf rust one (Jerković, 2008).

Conclusion

Of bentazone residua with sulfur were degraded after later than proposed treatment facilitated by some of different clustered specific Lr genes products concluded across no effect on leaf rust cause in June and increased growth two weeks after treatment. There was no complete equalizing about half of grain filling period. The advantage from treatment at wheat flowering was recognized trough reduction of later appeared weeds, than predictable Scab by temperatures and humidity and *Septoria tritici.* The treatment against last mentioned parasite in reproductive phase had no sense while antagonism between *Pyrenophora tritici repentis* and leaf rust cause was not disturbed. The effects of treatment on obligate parasites reduction had to be slight increased in production at varieties with effective specific Lr genes because of induced complete resistance in May and not so nearby infection source.

The residua of bentazone when sulfur was relisted were recognized to be degraded in underground water by micro organisms. However, the residua facing directly soil surface had to be reduced by later treatments as well as micro organism’s development supported by cultural plants parts and weeds after their incorporation.

Abstract

This paper illustrates the variation of the number of bunches in the cultivar White Tamjanika. The investigation has been carried out at a productive vineyard in private property, at the location Svracak, during the period 2008-2010. The vineyard was planted in 2002, with planting distance 2.8 x 0.9 m. Three pruning variants with short and long spurs and three variants of mixed pruning with canes eight and ten buds long were applied. Ecological conditions were favorable for growth and development of vine cultivar White Tamjanika. The study was aimed to variation of the number of bunches of this cultivar, as well as possibility for its spreading in the vine district of Zupa. The following parameters were observed: bunches per bud, bunches per developed canes, bunches per productive canes and bunches per vine. Results of the study confirm a possibility of successful growing of White Tamjanika cultivar in the conditions of Zupa Vine District.

Key words: *cultivar, bunches, ecological conditions.*

Introduction

The Muscats are a large, wide-spread family of grapevines, having in common besides the name the typical Muscat flavour. A huge number of synonyms and homonyms makes it difficult to identify them (Crespan and Milani, 2001). Bešlić et al. (2012) researched genetic profile of 12 varieties through a genotyping approach that included the „core set" of 9 SSR markers chosen by the international grape comunity for genetic identification and further 13 common microsatellites to strengthen relationship analysis. Consistent matching with SSR markers of grapevines cultivated in neighbouring countries or maintained in European germplasm collections was found for most of the molecular profiles, suggesting possible synonyms. These included three Muscat-type cultivars which showed identical SSR profiles with true-to-type "Moscato Giallo", "Moscato Rosa" and "Muscat fleur d'Oranger" varieties. When compared with germplasm representing the classical eco-geographic grouping of grape varieties, Serbian cultivars were divided into two distinct clusters. The Muscat-type cultivars were included within the Convar orientalis subconvar caspica.

This paper has been aimed to establish the most important agrobiological traitis of White Tamjanika cultivar. Environmental conditions significantly influence the biological characteristics of the vine, as stated by many authors: Buric et al. (1985), Todic et al. (2000), Rapcha (2001), Cirkovic et al. (2013). Environmental conditions of Zupa vine district enable a normal annual development cycle of vine, as well as good ripening of the studied cultivar grapes and shoots.

The applied pruning systems and fertile bud loads per vine expressed a significant effect on variation of the number of bunches per bud, bunches per developed cane, bunches per productive cane and bunches per vine.

Based on the analysis of the obtained results one can conclude that the applied pruning systems expressed a significant effect on number of bunches of the vine cultivar White Tamjanika in the conditions of Zupa vine distrct.

Material and Methods

The investigation has been carried out during the period 2008-2010 at a productive vineyard in private property, at the location Svracak. This vinyard is located in Župa vine district, characterized by moderately parish climate with average annual air temperature of 11.0^{o}C and average vegetational air temperature of 16.8^{o}C. The absolute minimum of air temperature during the study was -14.0^{o}C. The absolute maximum of air temperature during the study was 36.5^{o}C. The sum of active temperature was slightly higher than the multiannual average (3528^{o}C) and varaied from 3543^{o}C (2010) to 3673^{o}C (2009). The average annual precipitation amount in the observed period varied from 619.5 mm (2008) to 738.3 mm (2009), and from 380.6 mm (2008) to 491.4 mm (2010) of which fell during vegetation. Agroecological conditions in the observed period were very good for the cultivar White Tamjanika.

The vineyard was established in 2002 and it is in the period of growing yield. The planting distance of 2.8 x 0.9 m (3968 vines per ha). Bud load per vine was varied from 18 to 36 buds in six variants. Three pruning variants with short and long spurs and three variants of mixed pruning with canes eight and ten buds long were applied(tab 1.). The trial was set in random complete block design with four replications, and the data were processed by analysis of variance.

Table 1. Review variants and number of buds per vine

No	Variants	Pruning system	Number of buds per vine
1	I	(6 X 3)	18
2	II	(4 X 4 + 4 X 2)	24
3	III	(4 X 5 + 3 X 2)	26
4	IV	(2 x 10 + 3 X 2)	26
5	V	(3 X 8 + 3 X 2)	30
6	VI	(3 X 10 + 3 X 2)	36

Results and Discussion

The number of bunches per vine is the ratio real fertility, and shows the average number of bunches obtained from pruning abandoned buds. The highest number of bunches per bud (tab. 2) was observed in the five and six variants with the highest load (1.26), and the lowest in the second variants with the lowest load (1.12). The fertile bud loads per vine expressed a significant effect on the number of bunches per bud. By leaving a larger number of buds per vine the number of bunches per bud developed decreases in the first and second variants.

The number of bunches per developed cane the capacity index (tab. 3). The values of this indicator varied significantly depending on weather conditions of the investigated year. The short pruning had a positive effect on the number of bunches per developed cane, indicating that the buds at the base of shoots vary birth. To access such data came Garić (1997). The highest number of bunches per developed cane was in 2009 (1.42), very significantly higher than in 2010 (1.36), which recorded the lowest number of bunches per developed cane. Between 2008 and 2009. capacity index did not vary significantly. The number of bunches per productive cane the fertilitiy (tab.4). The highest number of bunches per productive cane was observed in the sixth variants (1.72), and the lowest second variants (1.40). The number of bunches per productive cane is quite a variable feature, which is very dependent on the agroecological conditions (Nakalamic, 1987).

The obtained results show that the dependence the number bunches per vine on the fertile bud loads per vine assessed based on the data shown in table 5. The number buds per vine a positive effect on the number bunches per developed cane. By leaving a larger number of buds per vine during pruning 18 buds (variants I) to 36 buds (variants VI) the number of bunches per vine increased from 22.37 to 45.47.

Table 5. The number of bunches per vine

Conclusion

Based on the results of the three-year-long research, the following conclusions can be made: White Tamjanika showed positive agrobiological properties in the conditions of Zupa vine district. The climatic characteristics of the investigation year were very good for this cultivar. The highest number of bunches per bud was observed in the fifth and sixth variants with the highest load (1.26), and the lowest in the second variants with the lowest load (1.12). The highest number of bunches per developed cane was in 2009 (1.42), very significantly higher than in 2010 (1.36), which recorded the lowest number of bunches per developed cane. The number of bunches per productive cane is quite a variable feature, which is very dependent on the agroecological conditions, and varied from 1.40 (second variants) to 1.72 (sixth variants). With the increase in the fertile bud loads per vine increased the number of bunches per vine.

STORAGE PROTEIN VARIATION IN CENTRAL EUROPEAN WHEAT VARIETIES

Edita GREGOVÁ*, Svetlana ŠLIKOVÁ, Rastislav BUŠO

National Agriculture and Food Centre, Research Institute of Plant Production, Bratislavská cesta 122, 921 68 Piešťany, Slovak Republic

Abstract

Genomes of wheat varieties provide an available and highly efficient polymorphic system of genetic markers. Suitable protein markers in wheat are endosperm storage proteins – gliadins and glutenins. The HMW glutenin subunits were separated by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE), and gliadins by acid polyacrylamide gel electrophoresis. The objective of this study was to determine the composition of high molecular weight glutenin subunits and gliadin block of 94 European varieties of hexaploid wheat (*Triticum aestivum* L.) The allelic block *Gli-1B3*, the marker of rye translocation *1RS/1BL* as well as the marker of poor bread-making quality was detected in 27 genotypes. Sixteen high molecular weight (HMW) - glutenin subunits (GS) were found, three belonged to *Glu-1A*, nine to *Glu-1B* and four to *Glu-1D* locus. The most frequent (32, 9%) HMW-GS at the *Glu-1A*, *Glu-1B* and *Glu-1D* complex loci were 0, 7+9, and 5+10 respectively. Bread quality (class) in the examined accession varied from minimum value 4 to maximum value 10.

Keywords: *Triticum aestivum* L., glutenin, gliadin, SDS-PAGE, A-PAGE

Introduction

The quality of wheat flour for bread making depends on the viscoelastic properties of the dough, which are influenced by the quantity and quality of the gluten-forming storage proteins of the endosperm. These proteins consist of two classes, monomeric gliadins and polymeric glutenins, a classification based on the disulfide-bonding behavior of the individual proteins. The gliadins are monomeric proteins that either lack cysteine residues (omega gliadins) or have only intra-chain disulfide bonds. Glutenin subunits bind to each other forming polymers linked by disulphide bonds. After the reduction of disulfide bonds, glutenin subunits can be divided in two main groups: high molecular weight glutenin subunits (HMW-GS) and low molecular weight glutenin subunits (LMW-GS), based on relatives mobilities in SDS-polyacrylamide gel electrophoresis (SDS-PAGE). The qualitative composition of the HMW and LMW glutenin subunits of a variety is a genetically determined characteristic, and they are not affected by variation in environmental conditions. The HMW glutenin subunits (HMW-GS) are encoded by *Glu-1A, Glu-1B,* and *Glu-1D on* the long arm of chromosomes 1A, 1B and 1D respectively. The LMW glutenin subunits (LMW-GS) are encoded by *Glu-3A, Glu-3B,* and *Glu-3D on* the short arm of these chromosomes. The HMW-GS can be classified according to their electrophoretic mobility, their structure and composition. Molecular analyses have shown that each *Glu-1* locus contains two genes, one encoding a higher molecular weight x-type subunit, the other a lower molecular weight y-type subunit. The absence of subunits in some cases has been proved to be due to gene silencing. Most of bread wheat cultivars possess from three to five active HMW-Gs (Payne at al., 1979). Usually, the *Glu-1D* locus encodes both types, the *Glu-1B* locus encoded both types (x-type and y-type) or one x-type subunit, and the *Glu-1A* locus can have one or none active subunits. Unfortunately, it is not a simple matter to develop wheat lines that consistently express high levels of glutenin. Glutenin proteins are encoded by six genes and the total glutenin content of the grain

is proportional to the expression of these genes. However, specific gene silencing often results in one or more of these genes not being expressed, with the result that varieties may not reach optimal glutenin content. Seed storage proteins are considered to be usable markers for the studies of wheat genetic resources (Bradová et al., 2005; Gálová et al., 2002; Gregová et al., 2007; Šramková et al., 2010). From them, glutenins are in addition associated with the technological quality of wheat flour and the specific gliadin alleles are associated with plant earliness and cold resistance (Metakovsky & Branlard, 1998). Payne et al. discovered a correlation between the presence of certain HMW-GS and gluten strength, measured by the SDS-sedimentation volume test. On this basis, they designed a numeric scale to evaluate bread-making quality as a function of the described subunits *Glu -1 quality score* (Payne et al., 1983). Assuming the effect of the alleles to be additive, the bread making quality was predicted by adding the scores of the alleles present in the particular line. It was established that the allelic variation at the *Glu-1D* locus have a greater influence on bread-making quality than the variation at the other *Glu-1* loci (Payne at al., 1984). During the last few years an increasing interest of wheat breeders for genetically adapted and diverse raw material can be detected, mainly influenced by the need for quality traits, specific adaptability, and yield stability of wheat. The objective of this work was detect genetic backround for bread-making quality based on variations of HMW-GS in *Triticum aestivum* L. genetic resources originated from the Europe.

Material and methods

We analyzed seed storage proteins, which were extracted from 94 genotypes of hexaploid wheat (*Triticum aestivum* L.) grain originating from seven different geographical areas (Slovakia, Austria, Hungary, Germany, Poland, Sweden and Czech Republic) of Europe in 2014. All samples were obtained from the collection of genetic wheat resources of the Gene Bank of Slovak Republic in Piešťany. Seed storage proteins were isolated from the endosperm of intact, dry and mature single seeds. Glutenins were extracted by a standard referee method ISTA and were performed by discontinuous PAGE based on ISTA methodology (Wrigley, 1992) using the electrophoretic unit Protean II (BioRad). Standard ISTA reference method (A-PAGE) was used to extract alcohol-soluble proteins-gliadins (Draper, 1987). Protein fractions were stained by Coomassie Brilliant Blue R – 250. The separate gluten subunits were identified by the nomenclature of Payne and Lawrence (1983). Bread-making quality of the grain is expressed as a score (*Glu-score, Rye-score*) deriving from the presence or absence of specific HMW-GS and gliadins.

Results and discussion

Wheat accessions originating from Slovakia (44), Austria (3), Germany (13), Poland (6), Czech Republic (10), Hungary (15) and Sweden (3) were evaluated for high molecular weight glutenin subunits using SDS – PAGE. Each cultivar from four and five HMW subunits, where *Glu-1A* encoded one or no subunits, *Glu-1B* encoded one or two subunits, and *Glu-1D* encoded two subunits, depending on allele.

Three alleles were identified at *Glu-1A* locus subunits 1, 2* and null allele (Figure 1 and Figure 4), five alleles encoding subunits 7+8, 7+9, 17+18, 20 and 6+8 (Figure 2 and Figure 5) at *Glu-1B* locus and two alleles at *Glu-1D* locus encoding 2+12 and 5+10, respectively. (Figure 3 and Figure 6).

The alleles were found at widely differing frequencies in wheat genotypes analyzed. The most frequent allele was at *Glu-1A* null allele (64,9%), at the *Glu-1B* encoding 7+9 (50%) and at *Glu-1D* encoding 5+10 (73,4%), respectively.

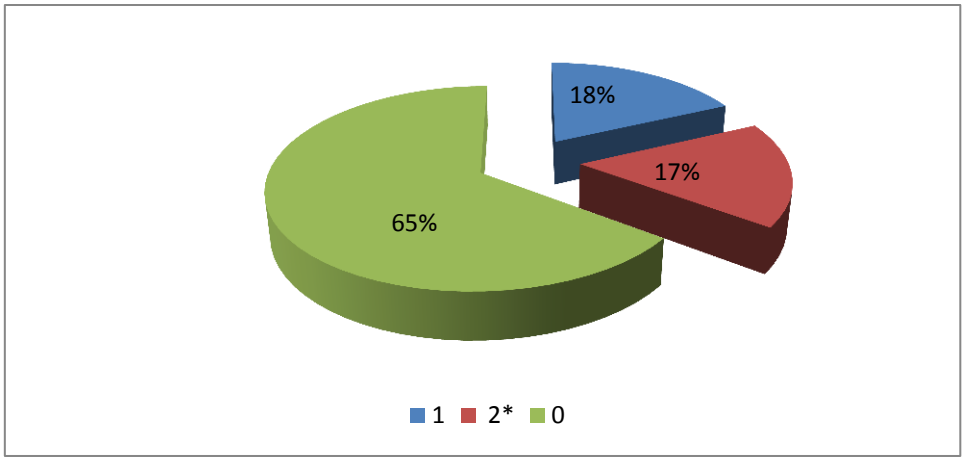

Figure 1 Allelic frequency at *Glu – 1A* locus

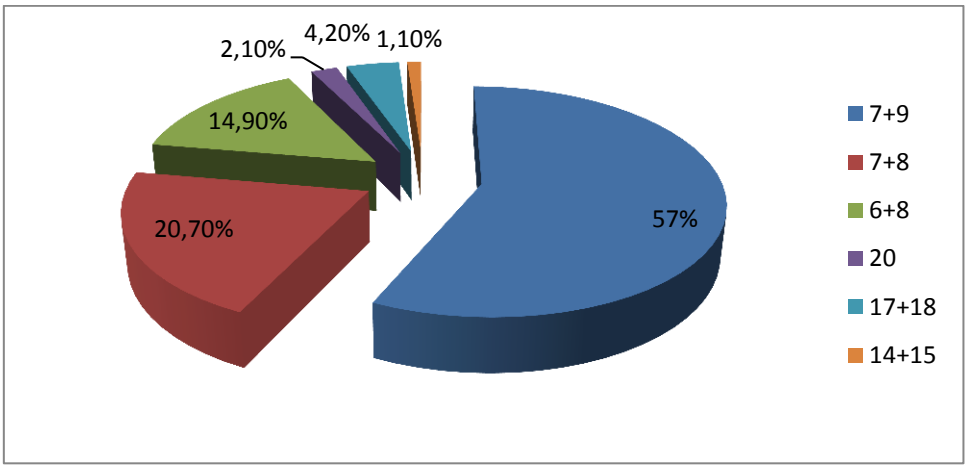

Figure 2 Allelic frequency at *Glu – 1B* locus

At the *Glu-1A* locus, subunit 1 and subunit 2* were found to be expressed in 17 and 16 cultivars, respectively, and the null subunit was present in 61 cultivars. Most cultivars (64,9%) had the null subunit, which has no relevance to superior bread making quality. Distribution of the HMW glutenin subunits revealed that advanced lines having subunit 1 or 2* encoded by *Glu-1A* locus possess better bread-making quality attributes because of the linear relationship of these fragments with higher extensibility and better dough strength.

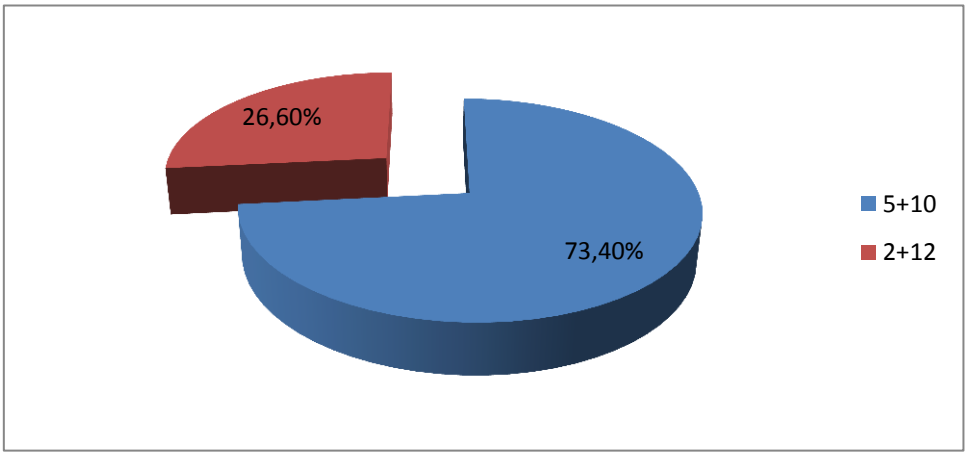

Figure 3 Allelic frequency at *Glu – 1D* locus

Six different compositions 7+9, 7+8, 6+8, 17+18, 20, 14+15 were found at the *Glu-1B* locus with subunits 7+9 predominant (54 cultivars) which according to Payne (1987) contributes to good bread-making quality. Relatively rare allele *Glu-1B* 17+18 and *Glu-1B* 14+15 associated with good bread making quality was found. In Slovakian genotype Veldava very rare subunit 20 was identified and appeared with low bread making quality. Subunits that were studied most are those encoded by the *Glu-1D* locus. Payne et al. (1979) were the first to discover that subunits 5+10 at the *Glu-1D* locus occurred in wheats with high bread-making quality and subunits 2+12 in wheats with low bread making quality. This discovery was subsequently confirmed by several authors (Gálová et al., 1998; Békés, 2011). Most of the cultivars were found to express subunits 5+10 (69 cultivars) at the locus *Glu-1D*.

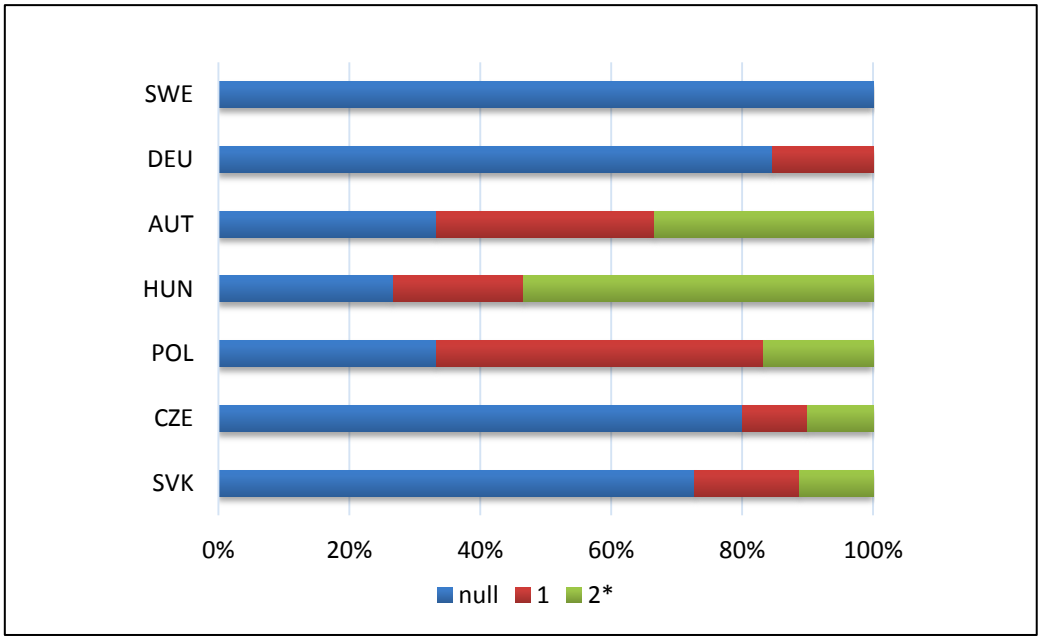

Figure 4 Allelic frequency at *Glu – 1A* locus according to the country of origin

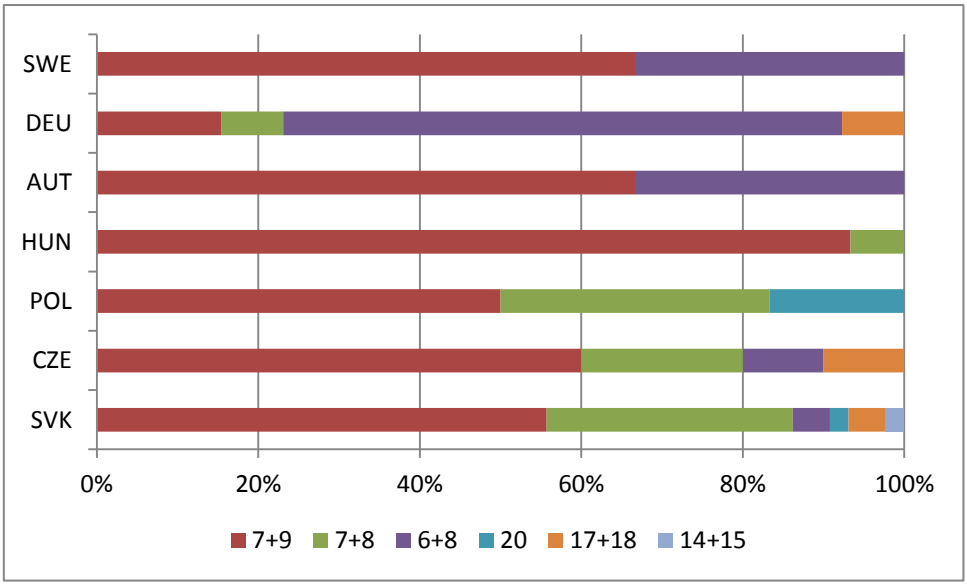

Figure 5 Allelic frequency at *Glu – 1B* locus according to the country of origin

The presence of *Gli-1B3* secalin allelic block (bread-making quality inhibitor) is a consequence of translation of rye chromosome segment into wheat genome (*1RS/1BL*). The allelic block *Gli-1B3*, the marker of rye translocation *1RS/1BL* as well as the marker of poor bread-making quality was detected in 27 genotypes. In order to predict the bread making quality of wheat genotypes, *Glu-score* was calculated for the wheat genotypes on the basis of high molecular weight glutenin subunits detected. Our data showed that the *Glu – score* in wheat genotypes varied within an interval from 4 to 10. One Polish cultivar Simbol and five Slovak genotypes (Axis, Klaudia, Viola, IS Escoria and IS Gordius) reached the highest value of *Glu–score* (10).

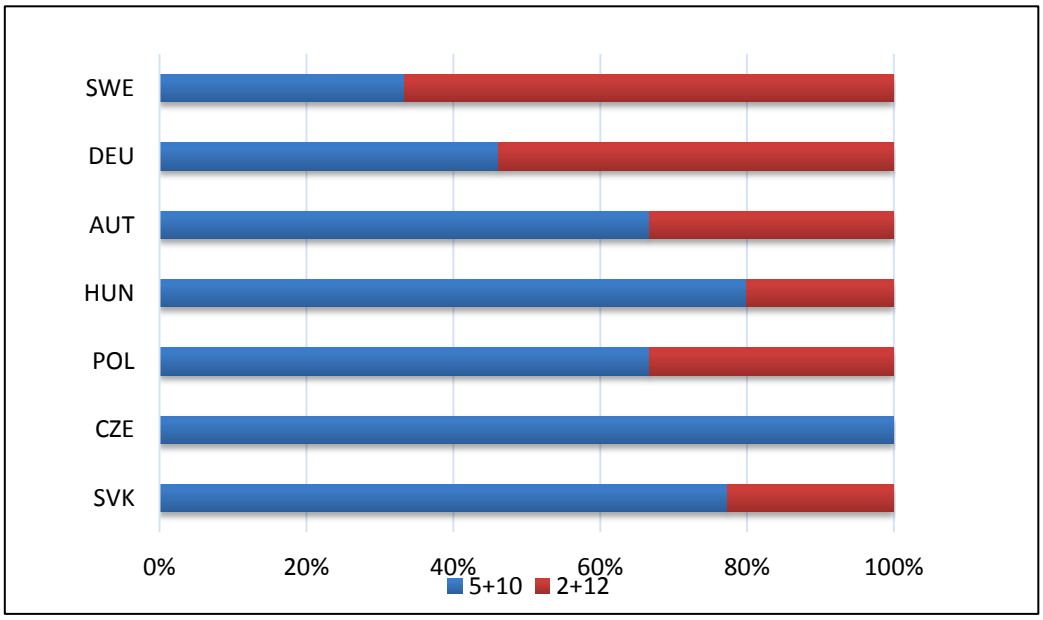

Figure 6 Allelic frequency at *Glu-1D* locus according to the country of origin

One Slovak cultivar (Veldava), one Swedish cultivar (Meridiem) and four German cultivars (Previa, Previna, Windsor and Korsika) reached the lowest value of *Glu- score* (4). Overall, Slovak, Hungarian, Czech and Polish wheat collections had a good technological quality.

Conclusion

The composition of both HMW glutenin subunits and gliadins contributed to the variation in gluten quality. Results reported herein indicate that in the case of wheat varieties the *Glu-score* can be used to predict bread making quality. Accordingly, the score can be used to screen breeding populations for bread making quality.

DETERMINATION OF VEGETATIVE AND GENERATIVE CHARACTERISTYICS OF DIFFERENT COTTON VARIETIES UNDER DROUGHT STRESS

Esengül DEMİREL*, Berkant ÖDEMİŞ

University of Mustafa Kemal, Faculty of Agriculture, Department of Biosystem Engineering-Hatay, Turkey
*Corresponding author: esenguldemirel28@hotmail.com

Abstract

The research was carried out to determine the effect of different irrigation water requirements of different irrigation levels (mm), on the evapotranspirasyon seed yield (kg da^{-1}) with vegetative and generative properties of two cotton types (drought tolerant, BA 525) and (drought susceptible, Lydia),in the Eastern Mediterranean region (Turkey). Drought or water deficit stress elicits many different phenological responses in plants. The study of vegetative features included the wet and dry weight of plant (gr), leaf area (cm^2), number of leaves (number plant^{-1}), number of fruit branches (number plant^{-1}), number of bud formation (number plant^{-1}) and number of node (number plant^{-1}). This result indicates that water stress in plants limit the phenological development significantly and The average of all measurements made after flowering has been observed to decrease. According to this research the average value of the weakening due to stress and aging undermines vegetative features significant effect on yield.

Keyword: *Cotton, Irrigation Level, Drought, Drought tolerance, Growth Periods*

Introductıon

Drought (water stress) is one the major abiotic stress factors that affect all organisms lives including human in terms of health and food. Plant responses to drought are complex, and different mechanisms are adopted by plants when they encounter drought (Jones, 2004). These mechanisms can include: (1) drought escape by rapid development, which allows plants to finish their cycle before severe water stress; (2) drought avoidance by, for instance, increasing water uptake and reducing transpiration rate by the reduction of stomatal conductance and leaf area; (3) drought tolerance by maintaining tissue turgor during water stress via osmotic adjustment, which allows plants to maintain growth under water stress; and (4) resisting severe stress through survival mechanisms (Izanloo et al., 2008).The plants crops are imperative to improve the drought tolerance of crops under the changing circumstances.

Water stress has been identified as a factor that negatively affects the ratio of reproductive to vegetative growth, seed yield and its components (Iannucci and Martinello, 1998). When water stress is reduced from -1.0 to -2.0 MPa, cells become smaller and leaves develop less, resulting in a reduced area for photosynthesis. At these water potentials, ion transport is slowed and may also lead to a decrease in yield (Medrano et al., 2002). Achten et al. (2010) observed that drought treatment significantly influenced growth, biomass allocation, allometry and leaf area.

The objective of this study is to investigate the effect of water stress on growth,vegetative and generative characteristyics of two cotton cultivars grown in the Antakya of Turkey. A number of growth parameters were determined under water deficit stress, including plant height, leaf area, dry matter, number of leaves, number of fruit branches, number of node and total plant dry weight.

Materıal and method

In this study four recently improved varieties of ProGen Seed firm of Turkey, namely as BA525 (drought tolerant), and LYDIA (drought sensitive) were evaluated in a split plot design; 4 different irrigation levels, 3 replications and each replication consists of 15 meters. Each irrigation level is planned 4 ordinary, and intra-row spacing is 0,70 m, row spacing is 15 cm. The first irrigation is made when consumed 50% of the suitable capacity the subsequent irrigations are also completion of the missing moisture (about 6 days intervals). Irrigation issues are waterless (waterless, I_0), full irrigation issue (I_{100}- the missing moisture is brought to field capacity), 66% and 33% of full irrigation. 120 cm layer is discussed for determination of moisture content. In the irrigation, the area of land to be soaked was acknowledgment 35% because of the drip irrigation is used and long annual average rainfall in the region is more than 72 mm (Yıldırım, 2008).

Plant samples were taken to determine the effects of drought on cotton vegetative features 3rd period (first flowering, mid flowering and boll formation). Plant samples were taken in each iteration from 50cm. Properties studied in plants are **Plant Hight (cm):** Plants is measured as the growth cone cm distance from the top of the cotyledon leaves. After than the average of these values is taken. **The Number of Fruit Branch (number/plant**): Primary fruit branches were counted formed on the main stem of the plant and average of these values is taken. **Leaf Area (cm^2/plant):** All the leaves of plants were taken from the stem and plant area were measured with a LICOR Laser Area Meter. After than the average of these values is taken. **Seed Cotton Yield (kg da^{-1}):** Whether harvesting crops from each repetition, weighed 0.01 sensitive scales and averaged.Plant from vegetative features are number of leaves, number of bud, and number of node was counted on the example of plants and averaged. **The Number of Bud Formation (number/plant):** Primary bud formations were counted formed on the main stem of the plant and average of these values is taken.**The Number of Leaves (number/plant**): All the leaves of plants were taken from the stem and average of these values is taken. **The Wet and Dry Weight of Plant (gr):** samples taken from the field for biomass plants were weighed immediately by precision scales after than the average of these values is taken. After standing leaf area measured plants for 48 hours in 70^0C, dry weight was measured the average of these values is taken.

Result and dıscussıon

Irrigation Water and Evaporation: Both cotton varieties in the test were irrigated 8 times. Same amount of water was given to the kind of cottons during the irrigation period, respectively compared to I_{33}, I_{66}, I_{100} subjects; 433 mm, 852 mm, 1287 mm irrigation water was given to plants. Evaporation was determined respectively compared to I_{33}, I_{66}, I_{100} subjects in Lydia are 195.5, 532.4, 942 mm; in BA525 are 206.9, 532.4, 945.0 mm. Evapotranspiration occurred at very low levels (53mm) in I_0 subject because of that it was not rain.

Yield: Drought resistant (BA525) and drought-sensitive (Lydia) the difference between the yields of the cultivars were significant at $p < 0.001$ level (Table 1). When the type of average value calculated BA525 type 490 767 kg / da, Lydia type 377 150 kg / da was produced. 23,15% is calculated as the difference in yield between varieties. When type of efficiencies realized in different irrigation levels were assessed, at I_0 average 187.80 kg / da, at I_{33} 391.08 kg / da, at I_{66} 541 567 kg / da, at I_{100} 615 383 kg / da yield was obtained. Average yields took place in a different group at each level of irrigation.

Table 1. Analysis of variance results for the yields

Variance Source	Sd	Sum of Squares	F
Variety	1	77452.482	45.359***
Irrigation Level (Sd)	3	641560.648	125.239***
Variety * Sd	3	15638.628	3.053od
Error	23	761972.738	

The response to both types of irrigation levels have varied considerably. For the BA525 on I_0 varieties 239.9 kg / da., on I_{33} 415.17 kg / da., on I_{66} 596.9 kg / da. and on I_{100} 711.0 kg /da; In Lydia varieties at I_0 135.7 kg / da., at I_{33} 367.0 kg / da., at I_{66} 486.2 kg / da. at I_{100} 519.7 kg /da are also measured. On the difference between watering levels of type has been calculated as at I_0 43%, at I_{33} 11.6%, at I_{66} 18.5%, at I_{100} 27%. As we have seen, the biggest difference in yield occurred thirsty housing. This suggests that an extremely powerful mechanism of drought resistance varieties of BA525. Author (2009), the yield decrease in soil water deficit degree stated that stress sensitivity of plants and effective atmospheric conditions.

Vegetative and Generative Results: Variance analysis of the number of leaves, average of leaf area, plant height, the number of fruit branches, number of the bud formation, number of nodeand and wet and dry weight of plant forming the material value of the range results and the groups are formed according to DUNCAN test are given in Table 2,3,4,5.

The number of leaves, average of leaf area, plant height, the number of fruit branches, number of the bud formation, number of nodeand in the resistant varieties (BA525) were found higher than in susceptible varieties (LYDIA) in all of the irrigation levels (Figure 1). In this research, average leaves area of plants are measured I_0=564.056, I_{33}=865.056, I_{66}=1701.44, I_{100}=10576.278 cm^2. Average leaf areas were showed diversity between varieties ($p<0.05$). The average leaf area was found insignificant for variety and variety*irrigation levels interaction. Increased levels of irrigation increased leaf area. Birda et all. (1998) reported that number of leaves per plant, increases the leaf area index.

The plant height was varied depending on the variaties ($p>0.05$), irrigation levels ($p<0.01$), and variaties*irrigation levels of interactions ($p>0.05$). Plant height, number of leaves and leaf area occurred about quietest waterless (I_0). Irrigation level increased plant height, leaf number and leaf area was also increased (Figure 1). Asraf and Iram (2005) reported that, limiting the development of plant water stress one of the most important factors. Sankar et al. (2008) in a study conducted in five different varieties of okra found that drought stress causes leaf area and net assimilation rate decreased compared to control plants.

When the average number of fruit branches examined in terms of the cultivars, the number of the average fruit branches of BA525 is number of 6,472 and at the LYDIA is also 5,639. The number of fruit branches have varied according to the level of irrigation ($p<0.01$), varieties ($p>0.05$) and variety*irrigation level of interactions was found insignificant (Table 4).The maximum number of fruit branches were observed in BA525 (7,889). In both kinds of fruits branches also increased by increased irrigation levels. Mert (2005) showed that different reactions of genotypes in the growth period in order to determine the impact of irrigation on different genotypes study which was conducted in Hatay conditions. The number of fruits branches, plant height, number of cocoons in all varieties of decrease at the application of irrigation is not done.

Plant wet weight (stem+leaves) varied depending on the varieties ($p>0.05$), irrigation levels ($p<0.01$), and varieties*irrigation levels of interactions was found insignificant. Plant wet weight was realized with the lowest dry matter (I_0) and average of the wet weight of the I_0 is 444,167 gr. Irrigation levels increases plant wet weight increased. Plant wet weight of the two varieties of waterless condition occurred at about the same level (BA525 444,111gr and LYDIA 444,222gr). Irrigation levels has created two different groups in terms of wet weight

of plants. I_{33}, I_{66}, I_{100} were included in the same group. Drought stress occurred as a result of cell dehydration, plasma membrane resulting sag and released hydrolytic enzymes causes cytoplasm autolysis, eventuall The slowdown in growth and turgor reduction occurs (Kalefetoğlu and Ekmekçi 2005).

In our research, the dry weight (stem+leaves) of the plants are created differences between varieties but it was found insignificant and irrigation levels (*p>0.05).*In Duncan group, irrigation levels are divided into two groups. I_{100} and I_{66}, I_{33} and I_0 are in the same group. Average dry weight of the BA525 is measured that 128,417gr, in LYDIA 123,639gr also. maximum average of dry weight is calculated in BA525 variety. Tsuji et al. (2003) in study of sorghum, and Alexieva et al. (2001) in study of wheat, they are emphasized that drought stres results wet and dry weights of losses of plants.

Water stress has a major impact on the production of mainstem nodes and thus the number of fruiting branches and fruiting sites (Eric 2011). In this research the number of node and bud formation were increased by irrigation level increased (Figure 1). The number of nodes and bud formation showed differences between varieties but it was not important level (*p>0.05*) (Table 2,3). The average number of nodes in both varieties were found about the same (BA525=10.278 and LYDIA=10.028). The average number of bud formation disparity between varieties were calculated that I_0=3.0-2.4 (18,66%), I_{33}=3.78-3.44 (8,9%), I_{66}=5.0-4.22 (15,6%) and I_{100}=5.11-5.0 (2,15%). The average number of node and bud formation were affected *p<0.01* of level from the irrigation levels.

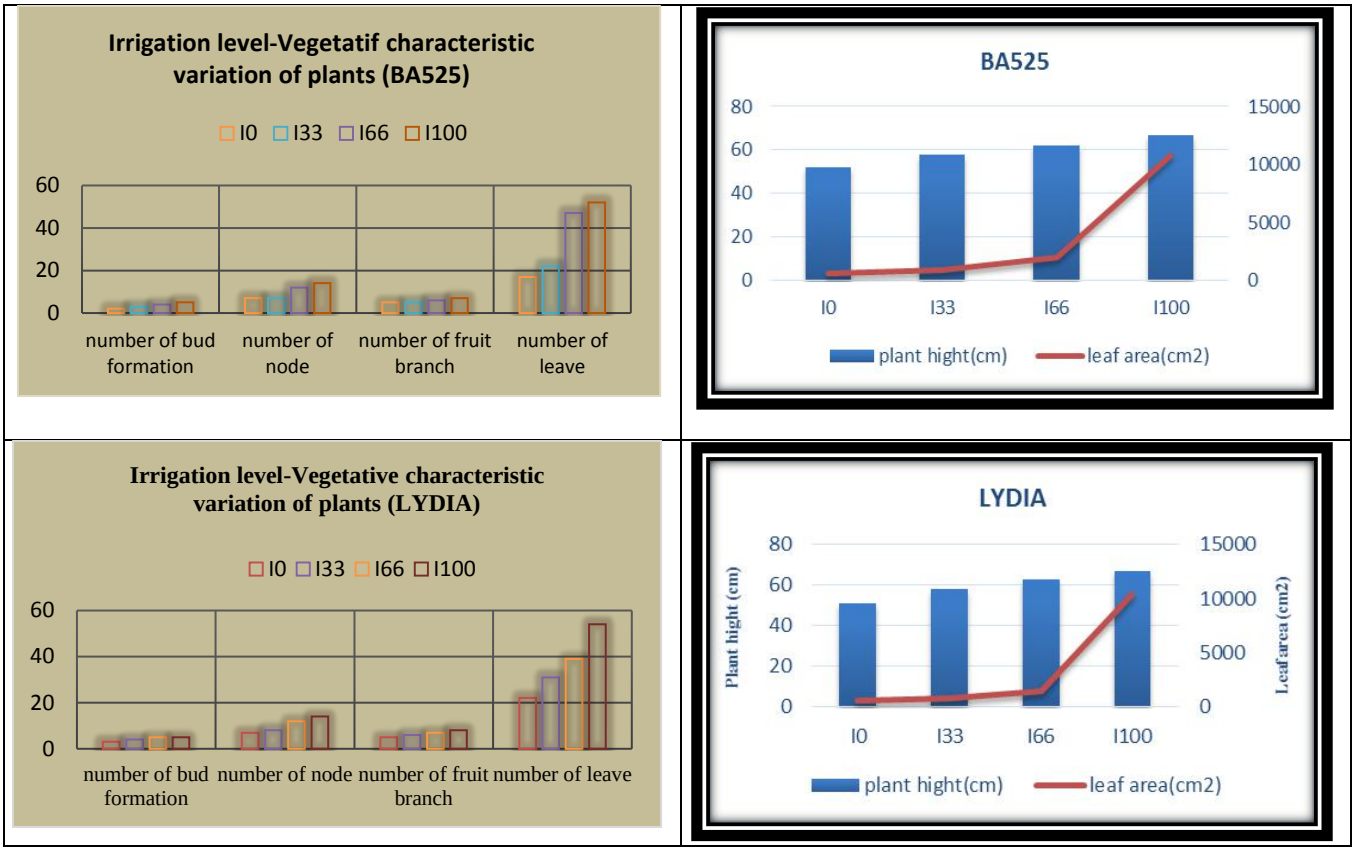

Figure 1. Change of the vegatitive measurement depending on the level of irrigation and varieties

Results

Water availability is potentially one of the most limiting factors to profitable cotton (*Gossipium hirsutum* L.) production.This study aimed to identify which parameter is more reliable in terms of vegetative and generative for determining the response to water stress of two distinct cotton varieties.

According to the analyzed characteristics, also it showed that in both variaties are significantly affected by the water stress. Average number of bud formation, node, leaves, plant height, plant wet weight and dry weight properties are unaffective significantly from variaties but they are affacted significantly from irrigation levels. Average number of fruit branch and leaf area are affected significantly from irrigation levels and variaties. To estimate the efficiency of determining the characteristics of the period examined developments (bud formation and flowering) constitute the yield of cotton is expected to be more effective. Because of that the average value of the weakening due to stress and aging undermines vegetative features significant effect on yield.

Abstract

This research was conducted at the Research farm of the Faculty of Agriculture, University of Süleyman Demirel (Isparta, Turkey) during a period of two years (2009-2011)to determine effects of different zinc application on yield and some agronomic characters of bread wheat (*Triticum aestivum* L.) and durum wheat (*Triticum durum* L.). The study was carried out on 4 wheat genotypes (bread wheat: Altay 200, Gün 91; durum wheat: Kızıltan 91, Kunduru 1149) on split-plot design in a Randomized Complete Block with 3 replications. The cultivars took place in the main plots whereas the zinc application doses (0, 9, 18, 27 and 36 kg ha^{-1} Zn) were in the sub-plots. Sowing was done by plot sowing machine providing 500 seeds per m^2. Phosphorus and nitrogenous fertilizers providing 40kg $ha^{-1}P_2O_5$ and 80kg $ha^{-1}N$ were appliedin the plots. According to the results including two years averages, zinc application had significant effect on properties examined and effect of wheat varieties had varying effects. Zinc application had positive effect on plant height, number of spike per square meter, biological yield, grain yield, harvest index, thousand kernel weights, crude protein content and zinc content in grain. The highest doses of zinc application negatively affected the examined agricultural properties and statistically, the mean values of studied trait decreased significantly.

Key words: Bread and durum wheat varieties, grain yield, yield components, quality

Introduction

The product group which has the maximum cultivation and production in the world is cereals. Cereals are widely used in animal feed and industry as well as human nutrition. Nearly 60% of the daily calorie intake is provided by wheat in less developed and developing countries (Çakmak et al., 2004). Also in these countries, where cereal-based food dominant in the diet, Zn deficiency is expanding rapidly with increasing number of micronutrient deficient people (Çakmak et al., 1996). Any increase in micronutrient concentrations in wheat seeds, has a significant impact on reducing micronutrient deficiencies.

Although the average yield in Turkey has increased to 300 kg/da in recent years, it is less than the yield obtained in developed countries. Therefore, it is necessary to improve the yield per unit area of wheat. In addition to other measures, this is only possible with the adequately balanced nutrition of plants. In our country's agricultural land, due to the use of fertilizer containing potassium, nitrogen and phosphorus for years, washing losses, and a little amount of green manure and farmyard manure usage. The balance of plant nutrients in our soil deteriorates and their benefits to the plants decrease. As a result, the area under cultivation in our country, the lack of micro-nutrients such as Fe, Mn, Cu and Zn (zinc) which are important in terms of plants has emerged. Due to different reasons, the plant grown in the agricultural lands, where plant nutrients are unbalanced, the deficiency of micro nutrients such as Fe, Mn, Cu and Zn occurs. There is zinc deficiency in about half of the agricultural land in Turkey (49.8%). In particular, this deficiency has been reported to be higher in Central Anatolia (Çakmak et al., 1996).

Conveniently zinc content in the soil of Isparta was determined Isparta 0.10 ppm (Özgüven and Katkat, 2002). On the other hand, 0.5 mg kg^{-1}andless ofthe zinc containing of soils is classified as weak soils (Lindsay and Norvell, 1978). Çakmak et al., (1996) have been reported to be 0.5mg $kg^{-1}$of Zn critical concentration limit in wheat fields of Central Anatolia. According to these data, it may be mentioned to be of zinc deficiency in the agricultural land of Isparta.

In this manuscript we presented that the effect of grain yield, yield components and quality of different Zn application has been studied in bread and durum wheat cultivars.

Materials and Methods

The field experiments were carried out at the Experimental Area of the Faculty of Agriculture, Süleyman Demirel University, Isparta (37° 45' N; 30° 33' E; and 1050 m), Turkey, in the 2009 and 2011 crop season under rainfed conditions. In the field experiment, two bread wheat cultivars (Gün-91 and Altay-2000) and two durum wheat cultivars (Kızıltan-91 and Kunduru-1149). The varieties are cultivated predominantly in this region by farmers. The experiment included five zinc application rates (0, 9, 18, 27 and 36 kg ha^{-1}Zn). The study was carried out on 4 wheat cultivars on split-plot design in a Randomized Complete Block with 3 replications. The varieties were placed in main plots whereas zinc application rates were placed in sub-plots. Sowing was done by plot sowing machine providing 500 seeds per m^2. The basal fertilizer applications were 40 kg ha^{-1} P_2O_5 and 80 kg ha^{-1} N as triple superphosphate and ammonium sulphate, respectively. Zinc sulphate was used as zinc fertilizer.

All of the phosphorus fertilizers were applied with sowing. Total nitrogen fertilization was applied in two equal doses, during sowing in autumn (October) and in early spring (March) when plants were at the tillering stage. Plot sizes were 9.6 m^2 (1.2 m x 8 m), with 6 rows and a row spacing of 20 cm.

Plant height was determined using 10 plants selected randomly in each plot. Thousand kernel weight was determined by weighing 100 grains three times, then multiplying their average by 10.Concentrations of Zn in grain were determined by atomic absorption spectrometry after ashing samples at 550°C and dissolving ash in 3.3% HC1 (Çakmak et al., 1996). The protein content of the samples was calculated by multiplying the Kjeldahl N by 6.25

All the above ground biomass washarvested at the maturity stage and dried in the sun (3days). The biomass was weighed for biological yield and spikes were separated from the vegetative organs. Biological yield and grain yield perhectare were calculated.

The soil of the research areas had a low water-holding capacity, was alkaline (pH 7.9-8.3) and Lime (25.5-30 % CaCO3), and contained a low amount of organic matter (1.15-1.34%). The P_2O_5, N and Zn contents were 192-197 mg/kg, 0.4-0.17 N % and 0.52-0.79 ppm, respectively. The long-term (1975-2007) total rainfall and average temperature of the location were 289.7 mm and 8.4°C, respectively.

The weather conditions during the two years were different. The long-term average temperature from September to June was 9.5 °C. Precipitation was 453.4 mm for the same period. The growing seasons (from October to June) in 2009-010 and 2010-11 had average temperatures of 10.7 and 9.8°C, total precipitation of 620.2and 459.3mm respectively. During the 2010-2011 growing season, there was quite a lot of rainfall during germination. In contrast, the 2009-2010 seasons were hotter during the seed filling stage.

Statistical analysis of the data obtained was carried out using MSTAT-c statistical package program. The calculated mean values were compared using Duncan’s multiple range Test.

Result and discussion

Plant Height

According to the averages of two years' results, compared to the control treatment, Zn application doses significantly increased plant height in the wheat genotypes (($p< 0.01$; Fig 1). However, the highest Zn application (36 kg ha^{-1}) reduced plant height. Because the response to Zn doses of wheat cultivars was different, cultivars x doses interaction was found significant. Even if Zn application in Kızıltan-91 cultivar had increased plant height, it would have been insignificant statistically (Fig. 1). As a result, plant height in all cultivars increased to a certain dose with Zn application and the highest doses reduced plant height (18 kg ha^{-1} and over these doses). Different results have been found in the studies on this subject. Whereas Bağcı (2000) showed that Zn application increased plant height in different cereals depending on the dose increase (0, 0.7 and 1.4 kg/da), Doğan et al., (2002) found Zn application insignificant in wheat.

On the other hand the toxic effect of Zn application was determined on plants. It was presented that higher Zn concentrations in the plant reduced cell division (Bobak, 1985), root height and chlorophyll amount (Bekiaroğlu and Karataglis, 2002) and made plant habitus small (Khurana and Chatterjee, 2001). In this study, it was thought that high Zn concentration in both bread and durum wheat cultivars reduced cell division, and had a negative effect on plant growth.

Number of Spike per M^2

According to the averages of two years' results, the effects of Zn doses and varieties were significant on the number of spike per m^2 ($p< 0.01$; Fig. 1). According to varieties on the number of spike per m^2 changed between 442.1 and 547.9numbers and the highest value in Kızıltan-91, the lowest one was in Altay-2000. Zn application (up to 18 kg ha^{-1}) increased number of spike per m^2. However, high Zn doses reduced number of spike per m^2. Because the reaction of wheat cultivars was different, Zn dose x cultivar interaction was found significant. Whereas the most number of spikes per m^2 in Gün-91 was 9 kg ha^{-1} Zn, it was 18 kg ha^{-1} Zn in [1]Altay-2000, Kızıltan-91 and Kunduru-1149 (Fig. 1). However, in these varieties, the differences between 9 kg $ha^{-1}$and 18 kg ha^{-1} Zn applications were insignificant. In the research Zn applications increased number of spike per m^2 in both bread and durum wheat cultivars. Similar finding was also reported by Bağcı (2000), Sönmez and Kıral (2002). Rengel and Graham (1995) showed that Zn fertilizer under Zn deficient conditions improved seedling vigor, resistance to pathogens and yield capacity of plants.

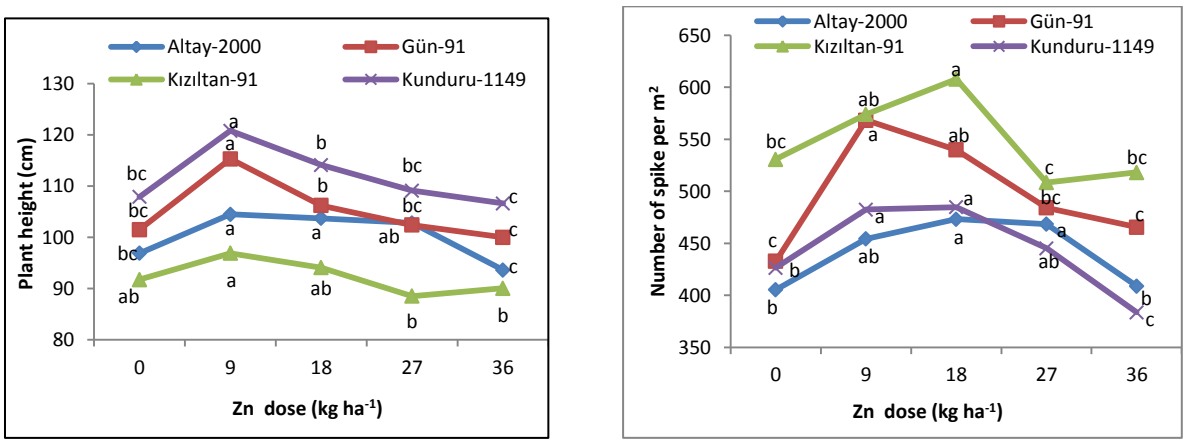

Figure 1.Effect of different zinc doses on plant height and number of spike per $m^2$of bread and durum wheat cultivars

Biological Yield

According to cultivars, two years mean biological yield changed between 10740 and 12516 kg ha^{-1} and this difference among cultivars was significant ($p<0.01$). While the highest biological yield was in Gün 91, the lowest biological yield was in Altay-2000. In general Zn application increased biological yield in cultivars and it was statically significant ($p<0.01$). Although according to control biological yield in Altay-2000 and Kızıltan-91 was 30% and it was 23% in Kunduru-1149, Zn applications were insignificant in Gün-91. For that reason cultivar x dose interaction was significant ($p<0.01$).

On the other hand, the highest concentrations of Zn applications reduced biological yield. In the research except for Gün-91, in the other cultivars Zn application increased biological yield up to 18 kg ha^{-1} (Fig. 2), but the values between 9 kg ha^{-1} and 18 kg ha^{-1} were statically in the same group.

Similar finding was also reported by Irmak (2002), and Özcan (2004) that the response of genotypes to Zn applications was different. Eker et al., (1999) showed that the response of genotypes to Zn deficiency could be different and the resistant varieties as to the sensitive ones could take more Zn from the soil. It was reported that Zn in plant tissues could also be used in different efficiencies (Torun et al., 1998). Otherwise high consentration has affected plant growth negatively (Khurana and Chatterjee, 2001; Bekiaroğlu and Karataglis, 2002).

Grain Yield

Variety, Zn applications and their interactions on grain yield in bread and durum wheat varieties were statistically found significant ($p< 0.01$).Different Zn applications in wheat cultivars had a positive effect on grain yield. According to two years mean the highest grain yield was in Gün 91 (3768 kg ha^{-1}), the lowest grain yield was in Kunduru-1149 (3229 kg ha^{-1}) (Fig. 2). The effect of Zn applications on varieties was different and while according to control (0 kg Zn ha^{-1}) the increase ratio in grain yield in Altay-2000 was 51.62%, this ratio in Gün-91 was 15.84%. But the increase rate in grain yield of durum wheat cultivars was similar to each other (Kızıltan-91, 38%; Kunduru-1149, 36%). Relativeincreases in grain yield of wheat by soil application of Zn in the Central Anatolia region varied between 5% and 554% with a mean of 43 %(Cakmak et al., 1996). Except for Altay-2000, in other varieties, grain yield obtained from Zn sulphate application between 9 kg $ha^{-1}$and 18 kg ha^{-1} was found insignificant. As to these results, sensitivity of varieties to Zn deficiency was different. The response of varieties to Zn deficiency could be related with the ability of taking Zn from the soil and using in different efficiency in plant tissues (Torun et al., 1998). On the other hand, it was reported that high Zn concentration reduced plant growth, seed number and seed weight (Khurana and Chatterjee, 2001). Thus in this study less grain yield in high concentration (36 kg ha^{-1}) showed the toxic effect of Zn.

In agreement with the previous reports (Yılmaz et al., 1997; Kalaycı et al., 1999), it was determined to be different response of zinc deficiency in wheat varieties. Zn efficiency for grain yield has been reported to range between57-92% (Kalaycı et al., 1999). Other than this,the increases in grain yield by Zn application were higher than those on biomass (Fig. 2). These results indicate that the importance of Zn nutrition for seed set is greater than for vegetative growth.

In this study, the grain yield of without applying Zn plants was significantly lower. Among the reasons, these are showed, less number of spike per m^2 and the weaker of the plant development (Fig. 1 and 2; Çakmak et al., 1989).Brown et al. (1993) reported that anther and pollen grain development in wheat plants having Zn-deficient were largely impaired, possibly as a result of reduced levels of indole acetic acid and proteins. In addition to, Sharma et al., (1979) reported that under Zn deficient conditions, there was increased abscisic acid concentration and inhibition of anther and pollen grain development in flowers.

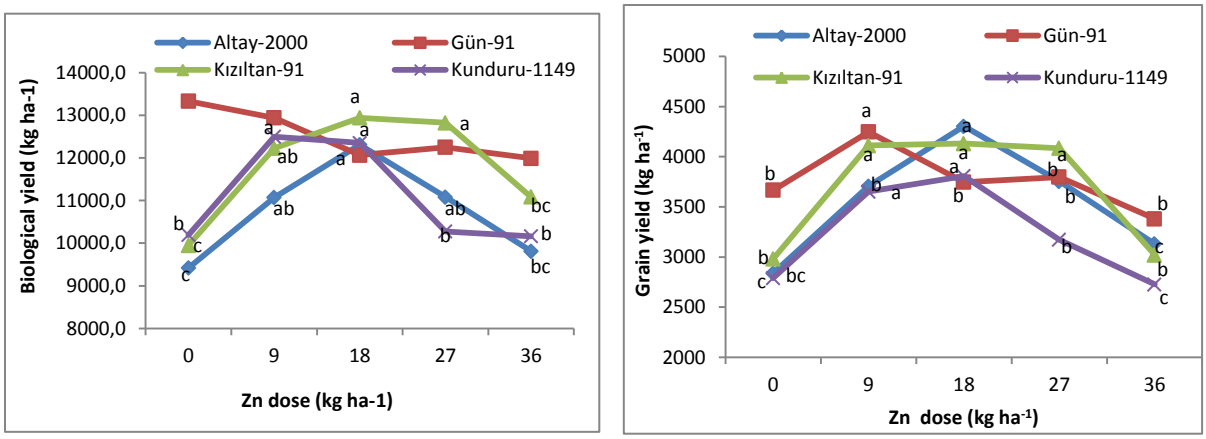

Figure 2.Effect of different zinc doses on biological yield and grain yield of bread and durum wheat cultivars

Harvest Index

According to the average of two-year results, Zn applications in wheat varieties on harvest index had a positive effect and it was statically found significant ($p<0.01$). In general, in all varieties the harvest index values between 9 and 27 kg ha^{-1}Zn application were statically in the same group. However the harvest index in the highest dose (36 kg ha^{-1}) reduced and this became significant (Fig. 3). In the research as two-year mean the highest harvest index was in Altay-2000 (32.25%), the lowest was in Kunduru-1149 (29.02%). The harvest index of Gün-91 (30.16%) and Kızıltan-91 (30.77%) was similar to each other. (Fig. 3). In this research, as in the other characteristics, the harvest index was affected from Zn application positively. But in the experiment the harvest index values had changes depending on the genotypes. Bağcı (2000) reported that, Zn application increased harvest index in cereals, it was 22.7-33.4% under dry conditions, 26.0-34.6% was under irrigations and the response of genotypes were different. On the other hand, it was reported that the effect of Zn application on harvest index in some researches was insignificant, and even it was less in some varieties (Doğan et al., 2002; Özcan, 2004).

Thousand Kernel Weight

According to the average of two-year results, Zn applications in wheat varieties on thousand kernel weight were statically insignificant. But the varieties and their interactions were statically significant ($p<0.01$). While thousand kernel weight in Zn doses was insignificant in Altay-2000 (38.13-40.14 g), Gün-91 (32.93-35.43 g) and Kızıltan-91 (47.06-50.43 g) it was statistically significant in Kunduru-1149. In general, thousand kernel weight of durum wheat was more than the one in bread wheat. Otherwise, thousand kernel weight was reduced in durum varieties by Zn application (Fig. 3). The reason of it was thought that there was a relationship with plant number in per area and grain numbers in spike. Because plant density increased depending on Zn application and it caused to reduce in grain size of spike. In agreement with the previous reports, Bağcı (2000) and Doğan et al., (2002) reported that thousand kernel weight increased by Zn application, and it was insignificant.

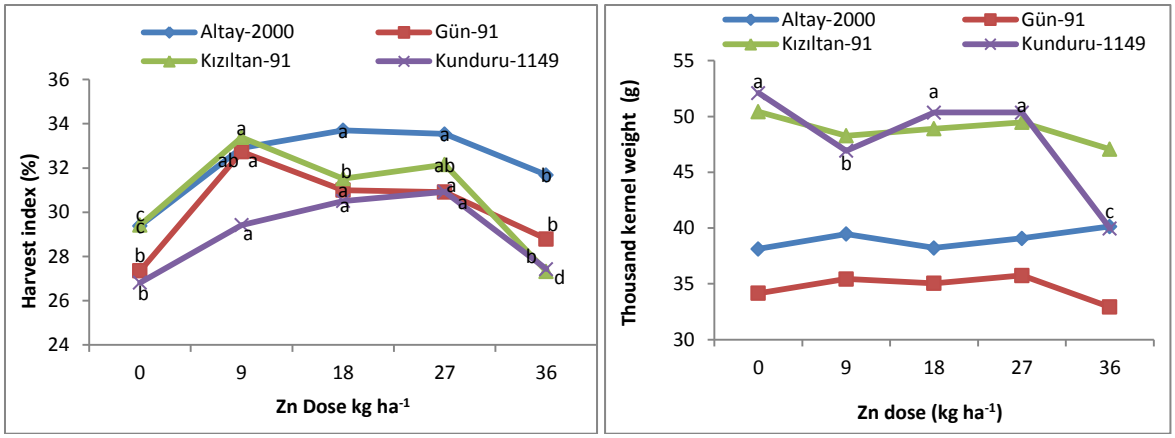

Figure 3.Effect of different zinc doses on harvest index and thousand kernel weight of bread and durum wheat cultivars

Crude Protein and Zinc (Zn) Contents in Grain

According to variance analysis, genotypes, Zn applications and their interactions on crude protein content and zinc content in grain were statistically found significant ($p< 0.01$).

The highest crude protein content obtained 27 kg Zn ha^{-1}(14.66%), the differences among other applications were significant. The lowest crude protein content (11.72%) was determined in plants not applied Zn, but the values between the highest Zn dose (36 kg ha^{-1}; 11.96%) and the lowest one were insignificant. Average crude protein content in grain in wheat varieties changed between 12.27% and13.51% and crude protein rate was found higher in durum cultivars. In the research, if response of wheat genotypes had been different by Zn application, it would have increased crude protein content (Fig.4). Generally, high dose Zn application in all varieties had an effect on crude protein content negatively. In the research mean Zn content obtained the most inKunduru-1149 (19.75 mg kg^{-1}). The Zn content was 15.02 mg kg^{-1}in Gün-91, 15.63 mg kg^{-1}in Kızıltan and 17.60 mg kg^{-1} in Altay-2000. Although response of genotypes was different by Zn applications, Zn content increased in all varieties. But the highest Zn dose reduced Zn content in grain (Fig. 4). Zn content in grain changed between 14.41 and 19.21 mg kg^{-1}depending on Zn application. The highest Zn content obtained from 9 kg ha^{-1} Zn application. The lowest one was from plants not applied Zn.

Protein content is an important criterion in determining of wheat quality. In several other studies a positive correlation between seed protein and seed Zn was found **(**Çakmak et al., 2004; Distelfeld et al., 2007). On the other hand Bağcı, (2000) reported that protein content in grain reduced by Zn applications and the negative effect under irrigation conditions was more than under dry conditions. In addition Irmak (2002) showed that the effect of Zn application on protein content was insignificant.

Several authors have reported the genotypic variation for Zn in cereals (Peterson et al., 1986; Yılmaz et al., 1997, Peleg, et al., 2008). In our study, the genetic variation for grain Zn content within bread and durum wheat varieties is observed. Furthermore, genotype x environment interaction is high and factors such as soil properties, water availability and fertilizer management have much greater effect on the micronutrient concentration than the genetic factors (Peterson et al., 1986; Çakmak et al., 2004).In our studies, average Zn content in grain by Zn applications varied from 14 to 19 mg kg^{-1}.

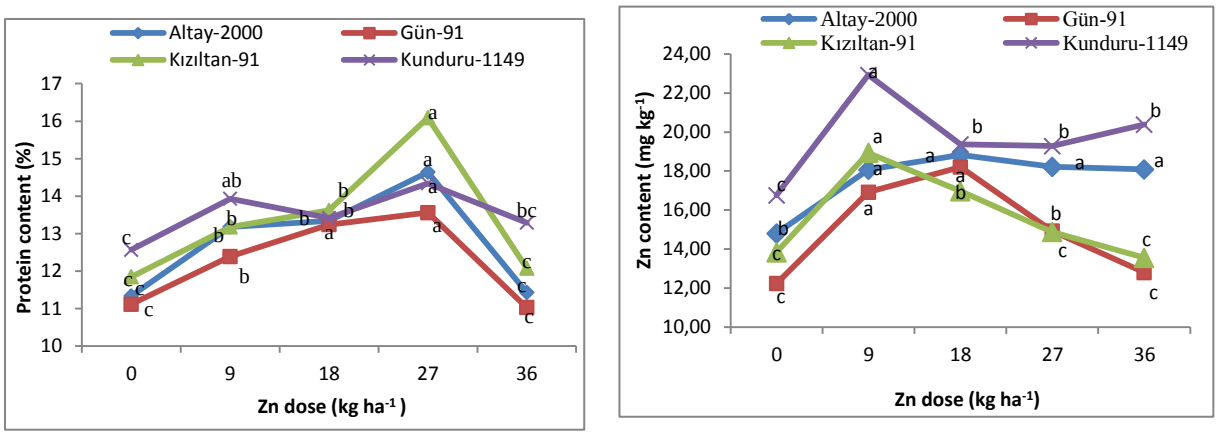

Figure 4. Effect of different zinc doses on crude protein and Zn contents of bread and durum wheat cultivars

Conclusion

According to two-year research results, Zn application in both durum and bread wheat increased grain yield and grain quality. For that reason, the application of fertilizers contented Zn could be suggested in Zn deficiency fields under Isparta conditions. For similar ecological conditions, Zn doses between 9 kg ha^{-1}and 18 kg ha^{-1}could be recommended depending on varieties.

ORNAMENTAL PEPPER BREEDING PROGRAM AS POTTED PLANT IN TURKEY

Kazım MAVİ

Mustafa Kemal University, Faculty of Agriculture, Horticulture Dept. 31034 Hatay, Turkey
*Corresponding author: kazimmavi@mku.edu.tr

Abstract

Turkey is a big producer for pepper production, but it hasn't got any ornamental pepper cultivar for pot and outdoor ornamental plants. This work describes the characterization of 32 pepper genotypes (*Capsicum* spp.) considering traits related to ornamental purposes, analyzes of the morphologic characterization. Qualitative and quantitative traits were used in the program. The experiment was carried out in unheated greenhouse. Fruit length and color were the most important traits to discriminate the genotypes. Desirable traits for ornamental use as small height, intermediate growth habit, three to five stages for fruit ripening maturation, early flowering and fruit set were identified in sixteen genotypes (MKU 35, MKU 43, MKU 44, MKU 68, MKU 73, MKU 74, MKU 76, MKU 79, MKU 82, MKU 83, MKU 84, MKU 85, MKU 87, MKU 97, MKU 101 and MKU 115). Other ten genotypes (MKU 18, MKU 19, MKU 30, MKU 71, MKU 72, MKU 86, MKU 92, MKU 96, MKU 104 and MKU 106) had also ornamental interest for garden growing because of the plant height, along with fruit color, size and shape. Genotypes MKU 19, MKU 35, MKU 43, MKU 83, MKU 86, MKU 92, and MKU 96 can be recommended for crosses seeking pepper ornamental breeding, based on genetic divergence and suitable agronomic traits. Also MKU 67, MKU 69 and MKU 71 can be used for sweet (non pungent) genetic material.

Keywords: *Capsicum species, selection, hybridization, morphological characterization*

Introduction

The pepper (*Capsicum spp*.) has been used for feed of human since 7000 BC and has been cultivated since 5000 BC in America (Bosland and Votova, 1999). Even though Capsicum did not originate in Turkey, where its greatest diversity can be found, it has been cultivated and consumed there for an estimated 300-400 years and thus it is reasonable to consider it a traditional local food (Mavi et al., 2013).

Within the genus Capsicum, several cultivars possess an aesthetic value for ornamental purposes in the garden and as indoor pot plants. Ornamental peppers can provide a range of pod shapes and colors complemented by varying degrees of green or purple foliage. Classification of ornamental peppers includes cultivars within all cultivated species: *Capsicum annuum* L., *Capsicum chinense* Jacq., *C. frutescens, C. pubescens* and *Capsicum baccatum* var. *pendulum* Willd. The genus Capsicum comprises economically important species around the world, among them the most cultivated is *Capsicum annuum* L., with great diversity of forms and colors of their leaves, flowers and fruits, which gives them great ornamental potential (Stommel and Bosland, 2006).

Turkey is a big producer for pepper production, but it hasn't got any ornamental pepper cultivar for pot and outdoor ornamental plants (Mavi, 2013). There are few commercial pepper varieties headed for landscaping purposes, although national germplasm bank for Capsicum genus holds in their collections, sample that might be used genetic improvement with the objective to develop new ornamental pepper cultivars. The current research had as objective to evaluate the genetic variability aiming to assess the ornamental potential of pepper samples through selection indexes. his study aimed to characterize 32 *Capsicum* spp.

genotypes based on qualitative and quantitative descriptors related to the potted plant ornamental potential; to estimate the dissimilarity between accessions and the relative contribution of the evaluated characters and to indicate potential for the use in hybridizations to develop a breeding program for potted ornamental purposes.

Materials and methods

Thirty-two *Capsicum* spp. genotypes from the germplasm collection of the University of Mustafa Kemal, Faculty of Agriculture, Department of Horticulture (Table 1) were studied. The experiment was conducted in a greenhouse in Antakya, Hatay, Turkey, from September 2010 to May 2015. Sowing was performed in polystyrene trays filled with peat moss. The seedlings were transplanted to three-liter plastic pots containing soil, sand and manure at the proportion 1:1:1. The study used randomized block design with three replicates, with four plants per plot.

Descriptors proposed by IPGRI (1995) were used for thirty-two genotypes, nine qualitative and eight quantitative ones, observing the vegetative and reproductive traits of plants. For the qualitative descriptors related to the vegetative part, data were obtained from the mode of observations taken in three plants per accession in each block and for the characterization of the reproductive part, five fruits per plant were considered. Pungency analysis was based on the staining of the placenta. Quantitative characteristics were based on the mean values observed in each treatment in which the following items were evaluated: 1) plant height (HGT, cm, measured from the base of the plant to the highest point of the canopy, when 50% of plants had ripe fruits); 2) number of days to flowering (DFL, calculated from the sowing up to the time when at least half of the plants had at least one open flower). Regarding the fruit characteristics, the following items were evaluated: 1) total number of fruits (TNF); 2) length of the fruit (LF); 3) diameter of the fruit (DF); 4) fruit weight (FRW); 5) days to fruiting (DFR) and 6) days to the change of maturity stage of the fruits (DMF). For the analysis of LF, FRW and DF, the means from five randomly selected ripe fruits were used. LF and DF were measured with a digital calipers, expressed in millimeters (mm). FRW was equal to the mass of the fruits obtained in grams (g) carried out on an analytical balance. DFR was calculated from the transplanting up to the time when 50% of plants had ripe fruits in the first and second bifurcations, and DMF was obtained by marking the fruits, just after setting, with colored woolen yarns and by counting the number of days for color change from its initial stage to the next, until complete ripeness.

Qualitative data weren’t analyzed. The quantitative data’s were analyzed multivariate analysis with SPSS. Means were grouped according to Duncan test.

Results and discussion

Quantitative traits

There was a significant difference for all of the studied traits, assessed by Duncan test ($p>0.05$) (Table 1). Means for plant height separated the genotypes, in which the highest means were 77.3 cm (MKU-86) and the lowest one 10.2 cm (MKU-84). Neitzke et al. (2010), reported that this feature is of great importance when it comes to ornamental plants, since smaller plants are preferred and attractive for cultivation in pots.

In relation to the length of the fruit, the highest means ranged from 77.6 mm (MKU-69) to 82.7 mm (MKU-86) and the lower ones varied from 14.0 mm (MKU-97) to 17.6 mm (MKU-43); for the diameter of the fruits, the highest means ranged from 39.0 mm (MKU-72) to 44.5 mm (MKU-19) and the lowest ones varied from 6.0 mm (MKU-52 and MKU-104) to 6.7 mm (MKU-97); for fruit weight, the highest means were between 14.9 g (MKU-69) and 16.6 g (MKU-75) and the lowest ones ranged from 0.6 g (MKU-97) to 1.3 g (MKU-106). Fruits of

smaller size and lower weight are ideal for ornamental purposes, due to the small size of the plants.

Table 1. Data and means for eight quantitative characters of the 32 genotypes of Capsicum spp. from the germplasm collection of the Mustafa Kemal University, Faculty of Agriculture, Department of Horticulture.

HGT =plant height; TNF=total number of fruits; LF= length of the fruit; DF= diameter of the fruit; FRW= fruit weight; DFL= days to flowering; DFR= days to fruiting; DMF= days to the maturity of fruit

Regarding precocity, the earliest accessions flowered between 28 days (MKU-84) and 32 days (MKU-97) and produced fruits between 33 (MKU-84) and 40 days (MKU-97 and MKU-82).

Qualitative traits

Twenty three genotypes (MKU-18, MKU-19, MKU-30, MKU-35, MKU-43, MKU-44, MKU-45, MKU-67, MKU-68, MKU-69, MKU-71, MKU-72, MKU-73, MKU-74, MKU-76, MKU-79, MKU-82, MKU-84, MKU-85, MKU-87, MKU-97, MKU-101 and MKU-106) showed intermediate growth habit, while 5 genotypes showed erect growth habit (MKU-50, MKU-52, MKU86, MKU-96 and MKU-104) and four genotypes (MKU-75, MKU-83, MKU-

92 and MKU-115) showed prostrate growth habit. According to Stommel and Bosland (2006), the choice of ornamental plants is directly related to the height of the plant, since consumers prefer the lower-sized plants for cultivation in pots, and the growth habit is associated with the size of the plants, therefore, they are more accepted in the market of ornamental plants.

Table 2. Some qualitative characters of the 32 genotypes of Capsicum spp.(Used IPGRI pepper descriptor)

Genotypes	GH	SC	LC	LS	PFL	PFR	SFR	PGY

MKU-87	5	1	4	3	7	2	3	+
MKU-92	3	1	4	3	3	1	1	+
MKU-96	7	3	5	2	7	2	1	+
MKU-97	5	1	4	3	7	2	1	+
MKU-101	5	2	4	3	7	2	3	+
MKU-104	7	1	3	1	7	2	1	+
MKU-106	5	1	7	3	7	2	3	+
MKU-115	3	2	3	3	3	1	1	+

GH= growth habit; SC= stem color; LC= leaf color; LS= leaf shape; PFL= flower position; PFR= fruit position; SFR= fruit shape; PGY= pungency

The color of the corollas were showed different color some of them showed figure 1.

Figure 1. Some of genotypes flower shape and corolla color (Left to right, upper row MKU-19, MKU-30, MKU-35, MKU-43 MKU-44, bottom row MKU-67, MKU-68, MKU-69, MKU-71 MKU-74)

As for flower position, four genotypes (MKU-18, MKU-45, MKU-50, MKU-67 and MKU-86) showed an intermediate flower position, 8 genotypes (MKU-19, MKU-30, MKU-68, MKU-72, MKU-75, MKU-83, MKU-92 and MKU-115) showed pendant flower and the other 19 accessions were erect.

Genotypes MKU-19, MKU-30, MKU-45, MKU- 67, MKU-68, MKU-72, MKU-75, MKU-83, MKU-92 and MKU-115 produced pendant fruits, genotypes MKU-18 produced fruits in intermediate position and the other genotypes produced erect fruits. According to Mavi (2013), erect fruits are more used for indoor decoration and the fruit shape on the plant is related to the extension of the ornamental effect.

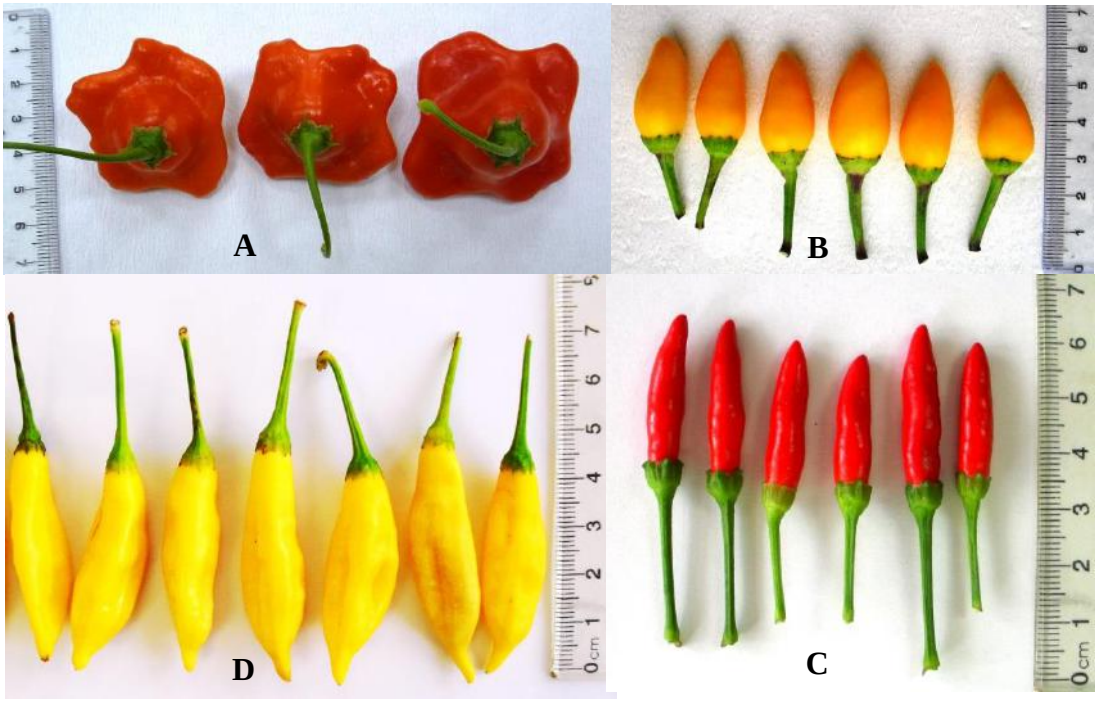

Figure 2. Some genotypes fruit shapes and, color A: MKU-19, B: MKU-35, C: MKU-52 and D: MKU-92

Considering the fruit shape, two genotypes were nearly round, eleven genotypes were triangular, three genotypes were campanulate, one genotype was cylindrical, and the other genotypes were elongated (Table 2 and Fig. 2).

The analysis of pungency of the fruits identified that only three (MKU-67, MKU-69 and MKU-71) of 32 genotypes are not pungent. The absence of pungency is important due to the use of these plants in environments that can be reached by children and genetic material to breeding.

Conclusion

A large number of tested pepper varieties differ in morphological and sensor characteristics (including colour), which determines the possibility and the mode of their usage. Not all pepper genotypes can be recommended for ornamental production, but must first be verified in production, through a series of agronomic and industrial pod plant demands. The greatest value of the genotypes tested, is their high content of genetic diversity, therefore all of the genotypes can be use for breeding program the potted ornamental plants.

Abstract

Turkey is an important producer and exporter of sweet cherry in the world. The most important sweet cherry variety in Turkey is 0900 Ziraat. The rain that falls during ripening period causes cracks in cherry fruits and impairs the quality of the fruits. Many applications are made by cherry producers to reduce the losses caused cracking. In this study, 0900 Ziraat cultivar grafted onto mahaleb (*Prunus mahaleb* L.) rootstock was used, pre-harvest calcium chloride ($CaCl_2$) and sucrose applications were made to determine the effect of fruit quality parameters, and cracking was examined. This study was carried out between the years of 2011 and 2012 in Eğirdir (Isparta-Turkey). Sprays of $CaCl_2$, sucrose and $CaCl_2$+sucrose were applied 7, 14 and 21 days before harvest. Also water was sprayed to the trees as the control application. Examples of fruit harvested were examined; some fruit quality criteria and artificial cracking tests were made. Treatment results affected some fruit quality criteria in the study. In terms of cracking index of the study, all three applications during the first year of experiment were not found to have an important effect on cracking. But all the trials compared to the control in the second year of study were determined to be effective for reducing cracking.

Keywords: *Prunus mahaleb* L.,calcium chloride, sucrose, cracking index

Introduction

Turkey is one of the leading countries in the world in terms of sweet cherry production and export. The positive developments that have taken place in export in recent years have positive impact on both production and quality. According to 2012 data, Turkey produced 480.748 tons and exported 46.477 tons (Faostat, 2014). Although there are different early and late ripening varieties in Turkey, mostly 0900 Ziraat is cultivated. 0900 Ziraat is the most important variety not only in production but also in export (Öztürk et. al., 2005).

In most of the regions in the world where sweet cherry is produced, cracks resulting from pre-harvest rainfall pose a serious problem (Sekse, 1995), limiting the number of sweet cherry production areas. Besides, cracking in sweet cherry eliminates fruit marketability. In subsequent stages, it incubates different diseases in cracked tissues, adversely affecting healthy fruits around the unhealthy ones. Intensive studies have been carried out with the aim of developing durable fruits, increasing resistance by means of different preparations, and providing mechanical protection so as to prevent fruit cracking in sweet cherry.

It is reported that there are a great number of reasons for cracking in sweet cherry. The most common idea is the crack of fruit skin as a result of surface tension caused by rainwater absorption through fruit skin (Verner and Blodgett, 1931; Sawada, 1931). In spite of differences between cherry varieties, fruits are susceptible to cracking especially 10 to 25 days before the date of harvest. The said susceptibility increases during the optimum harvest time (Christiensen, 1973). It is seen that, in some extreme years when cracking damage is high, more than 80% and even all of the fruits are lost (Christiensen, 1996; Csiszár, 2004).

Located in the cell wall structure, calcium is one of the main components functioning in the creation of plants main skeleton. It is possible to say that, calcium is particularly used in the studies aimed at reducing fruit cracking (Shear, 1975; Huang et al., 2005). Calcium leads to a change in fruit cuticular membrane and an increase in epidermal layer density (Marschner, 1995). Accordingly, calcium reduces cell membrane permeability and thus water absorption in sweet cherry (Verner, 1940). In other words, as the amount of calcium in fruit increases, transports through cell membrane decrease. On the other hand, resistance to cracking increases as the cell wall gains strength (Yamamoto, 1973).

Although some studies demonstrate that pre-harvest calcium applications are not successful in reducing fruit cracking in sweet cherry (Bangerth, 1968; Looney, 1985), there are many researches proving the opposite (Callan, 1986; Meheriuk et al., 1990; Yamamoto et al., 1992; Brown et al., 1995; Wermund et al., 2005). It is known that calcium applications affect not only cracking in fruit but also fruit quality criteria. $CaCl_2$ is one of the most widely-used substances for preventing cracking in fruits. Some researchers report that, in case of sweet cherry, applications containing salt or sucrose help balancing internal and external osmotic tension and also slow down the movement of rainwater absorbed through fruit (Schared and Sun, 2006.) Wójcik et al. (2013) applied $CaCl_2$ and $CaCl_2$+sucrose to Early Burlat variety in 2 different locations before harvest and found out that the applications reduced cracking. It is reported that $CaCl_2$ applied to 0900 Ziraat variety 10, 20 and 30 days before harvest decreased cracking by 62% compared to the control application (Erogul, 2014). Again, Demirsoy and Bilgener (2000) state that, as a widely-grown variety in Turkey, 0900 Ziraat is more resistant to cracking than sweet cherry varieties of Lambert and Van and has a thicker cuticle and epidermal layers.

This study is aimed at determining the effects of pre-harvest $CaCl_2$ and sucrose treatments on 0900 Ziraat sweet cherry variety cultivated under the conditions of Eğirdir, Isparta, Turkey.

Materials and methods

This study was conducted in Fruit Research Institute located in Eğirdir district of Isparta province between the years of 2011 and 2012. In the study, productive sweet cherry trees grafted onto Mahaleb (*Prunusmahaleb* L.) rootstock were used. Soil analysis results of the experimental orchards are given in Table 1.

As a high-quality sweet cherry variety having late ripening time, 0900 Ziraat has a very large, heart-shaped fruit. It has very firm texture and bright dark fruit skin (Akgül et al., 2005). Differences were observed between pre-harvest regional rainfall amounts of the two years of trial. Isparta's long years rainfall average for June is 31.7 mm. In 2011, monthly rainfall average for June was 46.5 mm, meaning an increase of 46.6% compared to long years average (Anonymous, 2015a). However, in 2012, monthly rainfall average for June was 22.3 mm, 31.6% lower than long years average. (Anonymous, 2015b).

Table 1.Soil analysis results of the cherry orchards

	Results	
Parameter	**0 - 30 cm**	**30 – 60 cm**
Saturation (%)	55	44
Salinity (ds/m)	0.307	0.242
pH	7.93	7.95
Lime (%)	14.67	14.67
Organic matter (%) (Smith Weldon)	2.23	1.12
Phosphor (Olsen-ICP) (ppm)	47	19
Potassium (A.Acetate– ICP) (ppm)	254	130
Calcium (A.Acetate – ICP) (ppm)	3665	3725

Magnesium (A.Acetate – ICP) (ppm)	421	204
Iron (DTPA – ICP) (ppm)	14.7	19.2
Copper (DTPA – ICP) (ppm)	5.8	2.3
Manganese (DTPA – ICP) (ppm)	4.6	6.6
Zinc (DTPA – ICP) (ppm)	1.6	0.5

$CaCl_2$, sucrose, $CaCl_2$+sucrose and water (control) were applied 7, 14 and 21 days before harvest depending on the weather (Table 2). $CaCl_2$, sucrose and $CaCl_2$+sucrose were sprayed to trees so that 0.5% solution of each material was applied per hectare (Wójcik et al., 2013).

Table 2.Treatment and harvest dates of the experiment.

	Date	
	1st year	**2nd year**
1stTreatment	29.06.2011	06.06.2012
2ndTreatment	05.06.2011	13.06.2012
3rdTreatment	12.06.2011	19.06.2012
Harvest	19.06.2011	27.06.2012

Fruits were harvested on 19.06.2011 and 27.06.2012 in the 1st and 2nd year of trial, respectively. 20 sweet cherry fruits to represent each tree were sampled for pomological assessments. On the other hand, for cracking studies, 50 sweet cherry fruits were sampled to represent each tree. For the purpose of determining cracking index, fruits were immersed in distilled water having a temperature of 20 ±1 °C in 2-liter vessels. Checking every 2 hours, cracked fruits were counted and put aside, while the remaining ones were re-immersed. At the end of 6 hours, cracking index was determined (Christensen, 1972).
In sampled fruits, fruit weight (g), fruit flesh firmness (N), pH, total soluble solids (TSS), and titratable acidity (TA) (g/100 ml) were set. Fruit flesh firmness was measured by penetrating with a tip having a diameter of 6 mm up to a depth of 8 mm at a speed of 10 cm/min. In the measurement, a texture analyzer (Güss FTA Type GS14 Fruit-Texture Analyser Model, Strand, South Africa) was used. TSS and TA were measured by digital refractometer and digital buret and digital pH meter (Hanna pH 330 model, WTW, Germany), respectively, after extracting juice from sample fruits. Ripening index was obtained by dividing TSS value by TA value. For measuring fruit skin color, a Minolta CR-400 (Konika Minolta Inc., Japan) chroma meter was used only in 2012. In the research, Randomized Block Design was replicated 5 times. Data obtained from the trial were put to an analysis of variance, using the JMP statistical software. Differences between varieties were grouped according to the LSD multiple comparison test ($P \leq 0.05$; $P \leq 0.01$; $P \leq 0.001$).

Results and discussion

There are numerous criteria determining sweet cherry fruit quality. These criteria are important for better marketability of products. Effects of the applications in this trial on fruit quality criteria are given in Table 3. In terms of the effect of applications on fruit weight, there was no difference in 2011. However, in 2012, sprays of $CaCl_2$, sucrose and control led to an increased fruit weight. Fruit flesh firmness is a crucial criterion for the marketability of sweet cherry. It was found that applications affected fruit flesh firmness in both years. Fruit flesh firmness increased in the 1st year of trial with sprays of $CaCl_2$, $CaCl_2$+sucrose and control, and in the 2nd year with sprays of $CaCl_2$ and $CaCl_2$+sucrose containing calcium. These findings comply with those obtained by researchers such as Rupert et al. (1997), Demirsoy and Bilgener (1998), and Erogul, (2014). Fruit flesh firmness is seen to be lower in

both years only in sprays of sucrose. For pH, control application had a higher value than the other three applications in the 1st year. However, in the 2nd year, no difference was detected. TSS differences were observed in the 1st year but not in the 2nd year. In the 1st year of application, sprays of $CaCl_2$+sucrose led to an increase in the TSS value. Besides, sprays of $CaCl_2$ and sucrose produced a higher TSS value than those of control. These findings are in accord with the findings that sprays of Ca increase the TSS value (Rupert et al., 1997; Demirsoy and Bilgener, 1998; Vangdal et al., 2008). Applications affected TA in both years. The applications which were significant in terms of TA values were sprays of sucrose and $CaCl_2$+sucrose in the 1st year and sprays of sucrose in the 2nd year. As can be seen, sprays of sucrose increased fruit TA in both of the years. Given the ripening index, a higher value was obtained from sprays of $CaCl_2$+sucrose and control in the 1st year and from sprays of $CaCl_2$ and control in the 2nd year. In both years of trial, control application's ripening index was higher. Ripening index was higher in ripe fruits compared to unripe fruits (Singh and Khan, 2010).

Fruits skin color and appearance are among the most important characteristics affecting customer choice. As is seen, L* value, as a determinant of lightness, is higher in sprays of $CaCl_2$ and $CaCl_2$+sucrose (Table 4.). On the other hand, a* value as the level of fruit skin redness is higher in 3 applications other than sprays of sucrose. In both years, applications containing $CaCl_2$ produced fruits having a redder and brighter skin. Fruit skin was lighter in sprays of $CaCl_2$ and $CaCl_2$+sucrose, where hue angle (h°) value was higher, but darker in sprays of sucrose and control. If color values are considered as a whole, it is possible to say that applications containing $CaCl_2$ delayed harvest.

Table 4. Effects of $CaCl_2$, sucrose, $CaCl_2$+sucrose and control treatments on fruit skin color (L*, a*, b*, C* and h°) values. * : $P \leq 0.05$, *** : $P \leq 0.001$

	Fruit Skin Color				
Treatments	**L***	**a***	**b***	**C***	**h°**
$CaCl_2$	30.45 a	25.11 a	10.20 a	27.12 a	21.72 a

LSD	1,02	1,83	2,40	2,40	0,93

In spite of cracking that occurs in certain years, 0900 Ziraat is resistant to cracking (Akgül et al., 2005). Differences between applications during the 1st year of trial were not found to be statistically significant. On the other hand, in the 2nd year, sprays of $CaCl_2$, sucrose and

$CaCl_2$+sucrose had lower cracking index values compared to the control (Table 5). Of all applications, the lowest cracking index was obtained from sprays of $CaCl_2$ (10.60). These findings are in accordance with those obtained by Wójcik et al., (2013) in Early Burlat sweet cherry variety. It was reported that resistance to cracking increased as fruit flesh firmness increased and thus fruits with higher flesh firmness were more resistant to cracking than those with lower flesh firmness (Christensen, 1996). According to the data obtained, in sprays of $CaCl_2$ and $CaCl_2$+sucrose, fruit flesh firmness was higher, while cracking indices were lower, showing the relationship between fruit flesh firmness and cracking. Given the entire trial, cracking index values of the 1st year were higher than those of the 2nd year. The reason is thought to be the pre-harvest rainfall in 2011 that occurred 46.6% (Anonymous, 2015a) higher than long years average.

Table 5.Effects of $CaCl_2$, Sucrose, $CaCl_2$+sucrose and control treatments on fruit cracking.* : $P \leq 0.05$, NS : Non Significance

Treatment	Cracking Index 2011	Cracking Index 2012	Decrease % in comparison with control (%) 2011	Decrease % in comparison with control (%) 2012

Conclusion

In this study, pre-harvest sprays of $CaCl_2$, sucrose, $CaCl_2$+sucrose and water were applied to 0900 Ziraat sweet cherry variety to analyze the effects of sprays on fruit cracking and quality criteria. As a result of the study, sprays of $CaCl_2$ positively affected fruit weight and fruit flesh firmness. Sprays of $CaCl_2$ enabled to produce firmer and more appealing fruits. In terms of cracking index data, no difference was observed between the data obtained in the 1st year. However, in the 2nd year, $CaCl_2$ and/or sucrose reduced cracking. In recent years, there has been an increase in the amount of precipitation in Turkey during the period of ripening and harvest for 0900 Ziraat sweet cherry variety. Even though being resistant to cracking as a variety distinguished in terms of production and export, preventive measures need to be taken against cracking, including pre-harvest sprays of Ca and some other minerals. In order to get the most appropriate result, similar studies may be repeated with different preparations, different doses, different application times, and combined applications.

DETERMINATION OF THE OPTIMUM FERTILIZER QUANTITY BY THE SOIL ANALYSIS IN TURKEY

Mehmet Arif ŞAHİNLİ*, Ahmet ÖZÇELİK, H.Tayyar GÜLDAL

Ankara University, Agricultural Economics, Ankara 06110, Turkey
*Corresponding author: asahinli@ankara.edu.tr

Abstract

Soil analysis is used to determine the needs of the soil fertilizer. A good fertilization, determination of the amount and the type of fertilizer needed by the plant at the right time according to the technique of this fertilizer is to be buried.

One of the inputs that affect most of the increase in efficiency at agricultural production is manure. In order to increase the incomes of farmers and crop production due to increased efficiency in mind, to use the correct type and amount of fertilizer is inevitable.

A significant portion of the material to be used in research, in Konya province made from wheat breeding survey of the farms the data to be obtained. By going to the company by way of interviews with operators in the sample data of 2013 and 2014 production period is finished the questionnaire.

Enterprises grow wheat for research; as soil analysis and make those checks is determined in two sets. The survey will be administered enterprises are determined by simple random sampling method (SRS). In the process of data analysis, SPSS or Eviews software package is used.

Keywords: Analysis of Soil, Wheat Breeding Agricultural Enterprises, Fertilizer.

Introductıon

The content of soil and plant nutrients yield ability to increase the agricultural production is important. Plants need the plant nutrients in the soil to grow. If there araen't enough nutrients in the soil for the cultivation of plants, the appropriate type and amount of fertilizer must be given to close the gap. If the soil is deprived of essential nutrients and fertilizer contribution yet, yield losses are seen after a while.

In this regard, soil analysis is used in determining the fertilizer required by the soil. A good fertilization, determining the amount and the type of fertilizer the plant needs at the right time according to the technique of this fertilizer is to be buried. The type and amount of fertilizer required for soil laboratories specializing in various soil samples taken from a certain land is determined. In favor of soil analysis, food ingredients required by the soil can be determined correctly.

One of the most affecting inputs increasing the yield in agricultural production is fertilizer. The share of fertilizers in productivity growth varies depending on various conditions. Fertilizer prices in the available resources to farmers in those with significant increases are required to use the most efficient and shipped to adopt new technologies. Otherwise, while fertilizer costs and the type and amount of fertilizer that farmers use unconsciously are increased, the efficiency to be obtained will decrease. In this context, soil analysis with minimal impact from rising costs and the efficiency of determining the appropriate type and amount of fertilizer will be provided in a significant increase in earnings. It is important in terms of proper fertilization techniques to conserve natural resources.

Turkey is a country with a growing population structure and that Turkey's annual growth rate of population for 2013-2014 is ‰13.3 (Turkstat, 2015). This is to increase the agricultural production for an adequate and balanced nutrition of the population, it is necessary to

strengthen the capacity for diversity and efficiency. Beside preserving natural resources sustaining their potential must be provided. Wheat has taken its place among the most important crops to feed our people in our country. There are factors that appears wheat production in Turkey and the countries outside Turkey such as drought, war, natural disasters and so on. When wheat prices with low elasticity of demand reduction for reasons both within and outside the country is going up. Wheat breeding have been selected for the most important area of Konya province in our country as the research areas. Approximately one third of agricultural land devoted to wheat production in Turkey.

The current status of wheat breeding in Konya is examined to provide solutions and suggestions to consciously use the important input putting out fertilizer efficiency and its impact on the income used as a result of making soil analysis in wheat breeding according to the analysis report. Also, an agricultural policy of the State applied to the soil analysis is to support the monitoring.

Materıals and methods

A significant portion of the material used in the survey, which was composed of wheat farming in the area of agriculture to data obtained by the enterprise survey. Survey by interviewing enterprises questionnaire forms have been filled out by going into enterprise.

Data for the period from 2013 and 2014 production of agricultural enterprises were collected by questionnaire. In addition to the primary data obtained well as research findings that were previously made on the subject, which has benefited from the secondary data records and published by various organizations.

Studies and surveys were identified and then a set of 110 enterprises were to be implemented by the random sampling method (SRS) (Yamane, 1967). Enterprises who have their soil analyzed grow wheat 82 enterprises and 28 enterprises taking out soil analyzes were determined in two sets.

The purpose of the study, scope and characteristics of agricultural holdings was arranged by considering the questionnaire. Questionnaires and interviews with enterprise owners were completed by researchers. With the data obtained by questionnaire population structure of the agricultural enterprises, education status, working widths, ownership, crop production and yields, soil analysis level of consciousness, to identify the relationship between the organizations concerned with agriculture, soil analysis made/not made my reasons, producers of fertilizer application pay attention to the situation and so on. As it is aimed to determine the social and economic indicators.

The information in the questionnaire data entry is made in the Excel environment. The primary data analysis using SPSS and Eviews entered into the computer program and evaluated in the process of statistical tables were prepared (Eviews, 2014).

Soil analysis for comparison during separate checks and make an appropriate econometric model that two groups work was conducted. A fertilizer variable is effecting the production considered the efficiency of the production modeling work was done.

In this study, Let us assume that hipotetical exponential model is as follows;

$$Y_i = \alpha X_1^{\beta_i} e^{u_i}$$

When we take a logarithm for e base both two side,

$$\ln Y_i = \ln \alpha + \beta_1 \ln X_1 + u_i \ln e$$

In this model, ln is natural logarithm and according to the e base that e=2.718.

At the above model, we arrange these variables and rewrite this model is as follows;

$\alpha = \ln \alpha$, $\ln Y_i = Y_i^*$ ve $\ln X_1 = X_1^*$

The new arranged model is as follows;

$$Y_i^* = \alpha + \beta_1 X_1^* + u_i$$

The new model is used as a linear model. After that, we can estimate the parameters by Ordinary Least Squares (OLS) (Gujarati, 1999).

Results and dıscussıon

Socio-economics indicators

Soil analysis based on the use of fertilizers and soil analysis of the company are formed in two groups to make use of fertilizers in wheat production, and comparisons are made.

Not taking of soil analysis 28 enterprises and the taking of soil analysis 82 enterprises built the business surveys are conducted. The socio-economic factors are analyzed and the results are given in Table 1.

71.4% of those taking soil analysis, observed that takes place in the 40-69 age range, while 89% of those who perform the soil analysis results were in the 30-69 age range.

Manufacturers have been examined in accordance with the distribution of education. The proportion of primary school graduates in each two groups are between 57% and 65%. 28.6% of those not taking soil analysis, performing soil analysis is 13.4% of the people graduates who are high school graduates.

Enterprises are examined by the distribution of the time they are engaged in farming. It was found that both groups have a duration of between 10 and 49 years. The proportion of enterprises engaged in the enterprise of taking over 50 years of farming ranged between 5% and 11% at taking and not taking soil analysis.

Land ownership of manufacturers have a fairly high rate of 86-88%. While manufacturers who do not take soil analysis have the average of 24 land size, producers who take the soil analysis have around an average farm size of 203. In both groups highlights the height of land ownership. It was observed that the leased land ranged 12-13% rate. While the average size of leased land analysis for not taking soil analysis is 24 da for taking soil analysis is 117 da.

While tractor ownership is 97% not taking soil analysis in the group who is 100% in the group not taking soil analysis. While the harvester ownership is 7.3% for taking soil analysis group there is no harvester the another group. Tractor ownership (1 tractor owner) was 93% for not taking soil analysis, 73% of those who make analysis. 2 and over tractors ownership of those for taking soil analysis were found to be higher. For taking soil analysis with enterprises has 7.3% harvester ownership.

Enterprises surveyed in those areas doesn't make soil analysis of wheat grown an average of 13.9, while those built in the analysis were found to be 139.7. Wheat yields in favor of those who make analysis of about 16 kg / da more.

Different Indicators

Manufacturer of a variety of ideas about the soil analysis are given in Table 2. How it was asked to determine the amount of fertilizer used in corn producer. Between 60% and 71% of farmers are seen to benefit from their experience, 39% stated that they did according to the fertilization of the soil analysis results. The highest share of wheat in determining the amount of fertilizer used in the enterprises surveyed were found to be their own experiences in both groups. The ratio of the company determines the amount of fertilizer according to soil analysis results is 39%.

Soil analysis done properly be said that the proportion of manufacturers to benefit from the fertilizer subsidy ranged from 82% to 71% in both groups.

While manufactırers who want to give support of manure as fertilizer in both groups ranged between 55% and 61% who want to give support as money in both groups ranged between 36% and 42%. Manufacturers would like manure support as a fertilizer. The proportion of enterprises that want the money the fertilizer subsidy is between 36-42%.

79% of producers who don't take a soil analysis, and do soil analysis, 50% producers who do a soil analysis of those checks to the analysis results obtained in the amount of fertilizer use products / yield believes that increase. 12.2% of manufacturers who stated that the change of soil analysis not increased efficiency. The proportion of enterprises believe will improve the efficiency of taking out soil analysis ranged from 50-79%. Those not taking out soil analysis, this rate is 79%.

Table 2. Different opinions belong to producers taking soil analysis and not taking soil analysis

Econometrics Model

Enterprises grow wheat as taking soil analysis and not taking soil analysis is determined in two sets at this research. In agricultural production among the most inputs affecting the yields increase is counted as a fertilizer.

During separate comparison checks for taking soil analysis and not taking soil analysis, multiple linear regression models were conducted.

The best double-logarithmic (log-log) model was represented by the results and the Least Squares (OLS) method was applied these data and given as follows.

The coefficient of determination (R^2), is known as one of the best indicators that describe the model (Johnston, 1991). R^2 is built on the model of the soil analysis was 27.8%. So, fertilizer as a independent variable indicate that explain the dependent variable of the yields rate of 27.8%.

In practice, we can expect the F calculated 3-4 times bigger than the F critical value. Otherwise, it is difficult to decide to comply with linearity. Accordingly, the FH = 30734> F0,05; 3; 78 = 2.68 hypothesis H0 is rejected and used for equation obtained at 95% confidence desired purposes.

Table 3. Statistics value for taking soil analysis				
Variable	Coefficient	Std. Error	t-Statistic	Prob.
Constant	3,692	0,414	8,909	0,000
Fertilizer	0,776	0,140	5,544	0,000
R-Squared	0,278			
F-statistic	30,734			
DW Stat	0,967			

R^2 is the model for not taking a soil analysis is 23.0%. So, fertilizer as a independent variable indicate that explain the dependent variable of the yields as a rate of 23.0%. Accordingly, the FH = 7.763> F0,05; 3; 24 = 3.01 The null hypothesis H0 is rejected and used for equation obtained at 95% confidence desired purposes.

Table 4. Statistics value for not taking soil analysis				
Variable	Coefficient	Std. Error	t-Statistic	Prob.
Constant	3,675	0,817	4,496	0,000
Fertilizer	0,758	0,272	2,786	0,009
R-Squared	0,230			
F-statistic	7,763			
DW Stat	1,102			

Conclusıon

Fertilizer and soil analysis in support of social enterprises in the study were examined in terms of economic and various opinions. Among the social situation of the firms surveyed are sex, age, education level, dealing with time farming, land tenure and size and so on. Also determine the amount of fertilizer used in wheat between various indicators, soil analysis commissioned the eligibility to benefit from the support of fertilizers, how it is given to the fertilizer support and soil analysis result to obtain fertilizer use product quantity / yield was examined submissions on that increase.

In the enterprise of taking over 50 years of farming who have their soil analyzed and haven't their soil analyzed ranged between 5% and 11%.

In both groups the height of land ownership is highlighted. While those taking the average size of leased land 24 da for not taking soil analysis, analysis of those 117 are built in.

Tractor ownership (1 tractor owner) was 93% for patients taking the soil analysis.

Enterprises surveyed in those areas weren't make soil analysis of wheat grown an average of 13.9, while those built in the analysis were found to be 139.7. Wheat yields, the analysis in favor of those who make about 16 kg / da more.

The highest share of wheat in determining the amount of fertilizer used in the enterprises surveyed were found to be their own experiences in both groups.

Manufacturers would like to the fertilizer as a support. The proportion of enterprises that want the money the fertilizer subsidy is between 36-42%. The support payment to producers of fertilizers in purchasing fertilizer will be more useful.

The proportion of enterprises believe will improve the efficiency of taking out soil analysis ranged from 50-79%. Monitıring of soil analysis support will be useful to decide next agricultural politics for Turkey.

Abstract

In this study, it was aimed to determine antifungal activity of methanol extract from *Vitex agnus-castus* L. which is growing naturally in Turkey. This plant was formerly classified in the family of *Verbenaceae*, but now phylogenetic classification situated the plant within the *Lamiaceae* family. *Vitex agnus-castus* was examined against 3 common plant pathogens which were *Alternaria solani, Rhizoctonia solani* and *Sclerotinia sclerotiorum* under *in vitro* conditions. Methanol extract of *Vitex agnus-castus* was dissolved with 50% acetone for each doses (50, 100 and 200 mg doses) and added inside the 100 ml PDA (40 ^{o}C). 5 mm diameter fungus mycelium discs were transferred to petri dishes used to keep PDA media (10 ml/petri dish). After that, petri dish were covered immediately and wrapped tightly with parafilm. They were incubated at 25±2ºC for 7 days in incubator. As a result of the study, the methanol extract of *Vitex agnus-castus* showed inhibitory effect against the mycelial growth of *A. solani*. The methanol extract inhibited mycelium development of *A. solani* depending on increasing doses, 27.73%, 32.98% and 40.08% respectively. In contrast, methanol extract of *Vitex agnus-castus* was not showed that inhibitory effect against mycelial growth of *R. solani* and *S. sclerotiorum.*

Keywords: *Vitex agnus-castus* L., Antifungal activity, *Alternaria. solani, Rhizoctonia solani, Sclerotinia sclerotiorum*

Introduction

Turkey is divided into 3 basic phytogeographic regions including Mediterranean, Iran-Turan, and European-Siberian region depending of its geographical location (Doğan and Mert, 1998). For this reason, it is prosperous in terms of plant diversity and endemism. Vitex agnus-castus L,which is a typical element of Mediterranean lemur vegetation, is a perennial plant in the family of Verbenaceae (Anonim, 2015). However, it has been involved in the family of Lamiaceae in the final classification.(Asdadi et al., 2014). *Vitex agnus-castus*, which is called with various names,such as,hayıt, acı ayıt, hayıd, and beş parmak otu , are the plants in the form of bush, rarely small trees, growing on the coast and rocky terrains (anonymous, 2015). Although the history of the information of usage of *Vitex agnus-castus* plant in medicine for healing wounds and piles extends back to at least years ago, (Chantaranothai, 2011) today, different parts of it are used to heal remenstrual, spasmodic dysmenorrhea, menopasual conditions and some discomforts, such as insufficient lactation ve acne (Maltaş et al., 2010). Besides, antioxidant, antimicrobial and antifungal activities of volatile oil and plant extracts of *Vitex agnus-castus* have been reported. Also it has been reported that volatile oil obtained from the seeds of *Vitex agnus-castus* exhibites a strong antifungal activity on *Candida* species (Asdadi et al., 2014), and *Vitex agnus-castus* methanol extracts including seven bacterial types have an antimicrobial effect against *Candida albicans* fungus (Maltaş et al., 2010). With this study, it has been revealed the antifungal activity of methanol extracts of *Vitex agnus-castus* plant growing normally in Turkey, on *Alternaria solani, Rhizoctonia solani and Sclerotinia sclerotium* plant pathogens leading to significiant losses in agricultural production.

Material and methods

Plant Materials

The Vitex agnus-castus plant materials used in this study have been picked up in August 2014, in Antalya province, and dried at room temperature in the shade. They have been stored until being used in trials.

Fungus Cultures

The fungi of plant pathogen used in the study (*Alternaria solani, Rhizoctonia solani* and *Sclerotinia sclerotorium*) were obtained from the stock cultures in Phytopathology laboratories of Department of Plant protection, Faculty of agriculture, Ahi Evran University.

Preparation of Extracts

For the purpose of obtaining of plant extracts, dried and ground plant materials of 100 g has been located in erlenmeyer of 1 lt, and methanol solvent has been added enough to cover it. It has been subjected to the process of rinsing through a orbital agitator at 120 rpm and room temperature for 24 hours.Then the extracts have been filtered through a filter paper. The solvents have been kept away by being evaporated at 400C by ratory evaporator. The remaining dry extracts have been dissolved with acetone, and finally, the different concentrations, such as 5% (50 mg), 10% (100 mg) and% 20 (200 mg), have been obtained for being used in our study (Kalkısım, 2012).

Antifungal effect of plant methanol extract

Obtained plant extract have been autoclaved in such a way that the last concentrations would be % 1 (10mg), %5 (50mg), %10 (100mg) and %20 (200mg),and then added to the sterile PDA's,which were cooled until 40^0. The PDA's have been transfered to 60 mm diameter petri vessels (in a way as being 10 mm.). The mycelium discs taken from 7-days fungus cultures previously have been transfered to 5 mm diameter petri vessels. After inoculation, fungus cultures have been subjected to incubulation at 25±2 0C for 7 days, and at the end of the period, developed radial mycelium have been taken (Hadizadeh et al., 2009). The development of mycelium has been calculated according to the formula given below (Pandey et al, 1982). As positive control, a standard fungicide has been used containing %50 captan. The trial was conducted in through four replications and repeated twice

$$MGI=100\times(dc-dt)/dc$$

MGI: percentage mycelial growth inhibition

dc; mycelial growth in control

dt; mycelial growth in treatment

Statistical analyses

The data were analyzed using the Analysis of variance (ANOVA) test. The means of treatments were grouped on the basis of least significant difference (LSD) at the 0.05 probability level. The SPSS 13.0 software was used to conduct all statistical analyses.

Results and Discussion

The effects of methanol extract of *Vitex agnus-castus* on the development of *Alternaria solani, Rhizoctonia solani* ve *Sclerotinia sclerotiorum* mycelium has been given below in Table 1 and Figure 1.

Although the effects differ depending on extract dose and diseases, it has been determined that methanol extract of *Vitex agnus-castus* has generally exhibited an activity on fungi. Methanol extract of *Vitex agnus-castus* has exhibited the highest effect on the development of *A. solani* mycelium with the highest rate of 40.08% (Figure 1).

Table 1. Effects on plant pathogenic fungi mycelium growth of *Vitex agnus-castus* methanol extracts

Application Dose	*A. solani*	*R. solani*	*S. sclerotiorum*
Negative Control	60,00 a*	60,00 a	60,00 a
Positive Control	0,00 e	0,00 b	0,00 b
50mg(%5)	43,66 b	60,00 a	60,00 a
100mg(%10)	40,21 c	60,00 a	60,00 a
200mg(%20)	35,95 d	60,00 a	60,00 a
LSD	**0**	**0**	**0**

* Means in the same column by the same letter are not significantly different to the test of ANOVA (a = 0.05).

The adverse effect on *A. solani* hasn't been realised on the development of mycelium of other important plant pathogen fungi that are *R. solani* and *S. sclerotiorum*. Even the highest dose of methanol extract of *Vitex agnus-castus* hasn't any effect on the development of mycelium of *R. solani* and *S. sclerotiorum.* However, through the trial observations, it has been determined that methanol extract of *Vitex agnus-castus* has caused development speed of mycelium of *R. solani* and *S. sclerotiorum* to be slowed down.

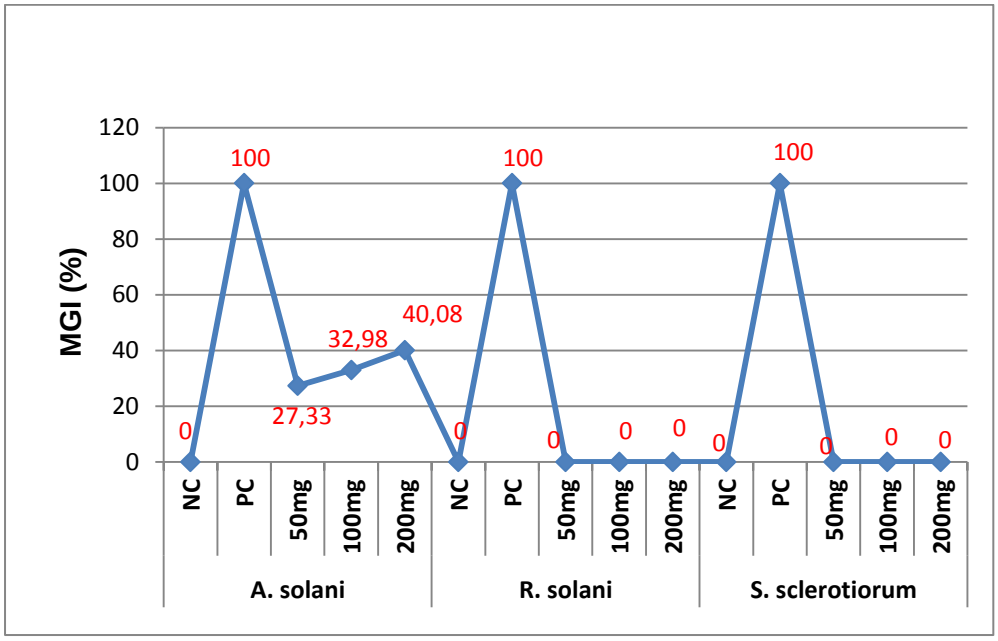

Figure 1. The inhibition ratio of methanol extract of *Vitex agnus-castus* on the development of mycelium of plant pathogen fungi.

The different effects of methanol extract of *Vitex agnus-castus* on pathogens is due to development differences of pathogens and tolerance degree of pathogens for the components contained in plant structure. The biological activity of vitex agnus-castus plant is due to the active compounds contained in its structure,such as, phenolic, flavonoid, diterpen and volatile oil (Stojković et al., 2011; Latovi et al., 2012). İt has been determined that 1,8-cineole compound isolated from volatile oil of vitex agnus-castus has been effective against aspergillus pathogen on fruit, and some volatile oil of it has exhibited important activity against some fungi and bacteria (Stojković et al., 2011). In another study,it has been reported that the methanolic extract of *Vitex agnus-castus* has exhibited important activity

against *Pythium ultimum* pathogen in the conditions of in vitro and in vivo (Švecová et al., 2013) and exhibited antioxidative and antimicrobial activity on tomato (Sarikurcu et al., 2009; Maltaş et al., 2010).

As a result, it has been revealed that methanol extract of *Vitex agnus-castus* hasn't been effective on development of mycelium of *Rhizoctonia solani* ve *Sclerotinia sclerotiorum* and exhibited antifungal activity against *Alternaria solani* pathogen. Today, importance of this and similiar studies has been increased since durability problem has been occured as a result of that synthetic fungicide used against plant pathogen fungi have damaged to the environment and people. Through this study, it has been revealed that vitex agnus-castus plant having different usage areas has exhibited antifungal activity on fungi.

INVESTIGATION OF VIRULENCE AND PRESENCE OF MIKOVIRAL dsRNA ON LEUCOSTOMA SPP. ISOLATES OF THE CHERRY PRODUCTION AREAS IN THE AEGEAN REGION/TURKEY

Melis TÖNGÜŞLÜ*, Serap AÇIKGÖZ

Adnan Menderes University, Department of Plant Protection, Aydın, Turkey
*Corresponding author: melistonguslu@gmail.com

Abstract

Leucostoma (Cytospora) canker is one of the major diseases that is cause to desiccation in partially or in whole of cherry trees. It was determined the presence of Leucostoma canker on various stone fruit species in different regions of Turkey. In ABD Michigan state, two *Leucostoma personii* isolates were determined in peach orchards. There are no studies on the presence of dsRNA on Leucostoma species in Turkey. In this study, it was determined Leucostoma isolates of the containing dsRNA in cherry field of the Aegean Region/Turkey. For this purpose, *Leucostoma* spp. isolates which is derived from maximum cherry production in Aegean region was evaluated for virulence using branches test and apples test. According to these tests 26 isolates were selected for dsRNA analysis and experiment was performed in three repeats. dsRNA profile was identified in six isolates for the first repeat but for seconds only in three isolates were determined, whereas no dsRNA profile in third assay. This uncorfirmation results may be obtained because of desiccation and freezing-thawing. More detailed investigation should be carried out in the future.

Keywords: Leucostoma canker, *Leucostoma* spp., Cherry, dsRNA

Introduction

Cherry (*Prunus avium)* is a fruit tree from the *Roseceace* family that is naturally present in Giresun, the South Caucasus, the Caspian Sea and Northeast Anatolia. Cherry has a wide spread in the world. However, it is commercially produced in countries such as Turkey, Iran and Italy. Even though it is changing according to years and seasonal conditions, Turkey is the first producer for cherry production in the world and it has a right to say in cherry exports (Anonymous, 2014). There might be important losses in production of cherry due to some diseases and pests (Karaca, 1972; Gökçe et al., 1998, Spotts et al., 1990). The desiccation parts in the branches or on the whole tree is one of the reasons of these losses. (Karaca et al., 1972; Gökçe et al., 2011). One of the most important diseases that lead to desiccation tree or branches and the stools in cherry trees is the Leucostoma canker (Cytospora canker). Leucostoma (Cytospora) canker generally appears as depressed dark areas around the leave traces and eyes in annual stools and can kill all the stools with backward deaths (Biggs, 1989; Ogawa et al., 1995). Leucostoma canker was first detected by Stewart et al. on peach tree, which is one of the stone-nuclei trees in the western areas of New York in 1900 (Biggs, 1989). Following this, in 1909, Rolfs reported that the disease was observed in the USA-Missouri and Gussow reported another observation from Canada in 1912 as damages on peach trees (Biggs, 1989). Leucostoma canker was also known as Cytospora Cancer and Valsa Cancer (Hayova and Minter, 1998). The disease is widely observed in cherry, nectarine and peach trees in areas with colder winters in Canada and the USA. It was reported in many European countries, including Turkey, that the disease was widespread in peach, apricot and cherry trees (Hayova and Minter, 1998). Hammar et al. (1989) detected dsRNA in *L. persoonii* cytoplasm in peach trees in Michigan State, the USA, and the cultural characteristics were defined. According to these findings, it was observed that the isolates which contained dsRNA were in lighter colors, developed mycelial in less density, and there were melting on

the hyphae tips, and did not form pycnidia. Jensen and Adams (1995) isolated dsRNA's from the cytoplasm of *L. persoonii* isolate which was encoded as NC14.4A and obtained from the Northern Carolina, the USA. Adams et al. (1990) reported that they determined the VCG (Vegetative Coherence Group) variety which is important in the spread of hypovirulence in *L. persoonii* isolates collected from two different peach orchards in Michigan, the USA.
The studies conducted on Leucostoma are extremely limited edition, both Turkey and in other countries. In addition, although dsRNA is detected in *Leucostoma* spp. which is causing damage in peach trees (Hammar et al., 1989; Jensen et al., 1995, Adams et al., 1989), we could not encounter any studies on dsRNA existence in *Leucostoma* spp. which causes problems in cherry tree. For this reason, in this study, the mycelial development of the *Leucostoma* spp. isolates obtained from the cherries in the cities in Aegean Region was investigated in terms of branch test, apple test, and containing dsRNA. The apple test in *Leucostoma* spp. isolates and the dsRNA existence obtained from cherry trees were first investigated with this study.

Materials and methods

Materials

The main material of the study are 100 *Leucostoma* spp. isolates. One year old 'Napolyon' (0900 Agriculture) shoots and Apple (Granny Smith) were used in the virulence test. Upon virulence test, the selected isolates were perfomed with dsRNA analysis.

Methods

Virulence Tests

Inoculation to Cut Branch

The virulence test was performed in isolates with Scorza and Pusey (1984) method for Chestnut Blight (*Cryphonectria parasitica)*. This test was used in yearly 'Napolyon' cherry branches. The scar was formed in the tip of each branch and the isolates were located on the scar. The branches were kept in the climate chamber in flowerpots by using Cut Branch method.

Apple Test

The isolates located on the Granny Smith apple fruits were used in the virulence test (Hammar et al., 1989). Apple fruits were selected, washed and the surface disinfection was performed by using 70% alcohol. The disk was removed from the surface of the fruit by cork borer and isolates were put in these holes.

dsRNA Analysis

Branch and apple test results were subjected to SPSS analysis and the 26 isolates which showed high and low virulence were examined whether or not they had dsRNA. dsRNA isolation was performed according to the method developed and used for *C. parasitica* (Morris and Dodds, 1979; Robins and Griffin, 1997; Valverde, 1990). Isolates were isolated with phenol and chloroform and CF II column chromatography was conducted for dsRNA.

Results and discussion

Virulence Tests

Inoculation to Cut Branch

The virulence degrees of the 100 isolates were determined with the virulence tests performed with the cut branch method on 'Napolyon' cherry. Lesions varying between approximately 1

and 14 cm emerged on the bark tissue of the branches which were inoculated. There were also branches which did not have lesions (Figure 1).

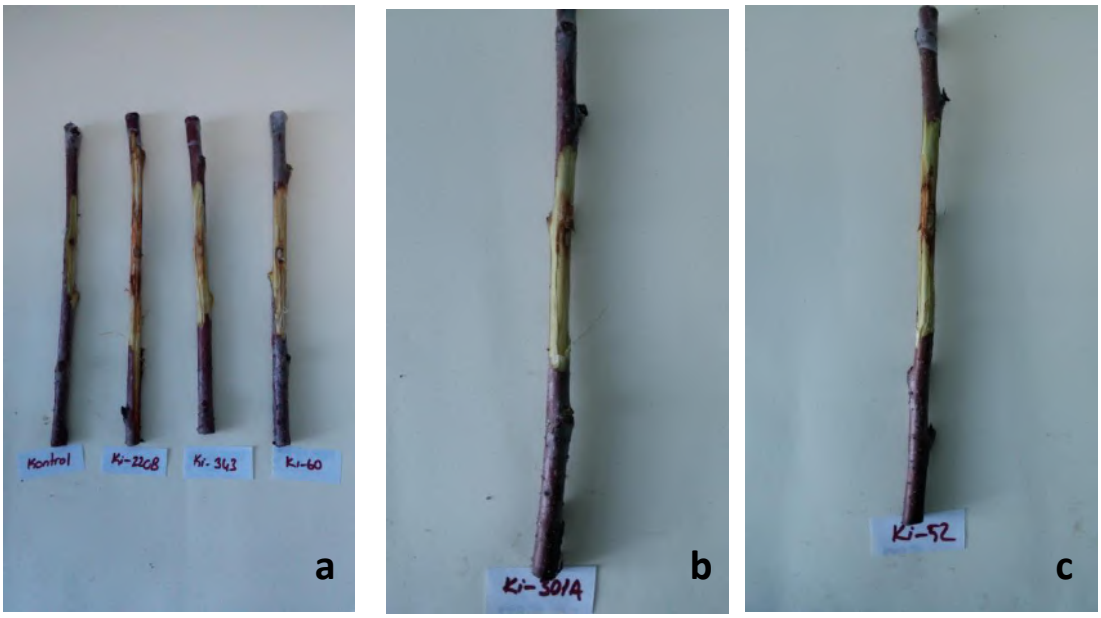

Figure 1. ‘Napolyon’ cherry created lesions by *Leucostoma* spp. a) High virulence reaction (Ki-222B) b) No indication of the lesion (Ki-301A) c) Low virulence reaction (Ki-52)

Upon the branch test, although 3 isolates (Ki-301A, Ki-194, Ki-343) did not show any lesions, all of the *Leucostoma* spp. isolates tested in the study conducted by Yılmaz (2013) were reported as being pathogen in cherry. In addition, it was reported in the same study that the plum, peach, apricot, almond species, which received cut branch test application, were sensitive to *Leucostoma* spp.

Apple Test

Inoculations were performed to evaluate the size of the lesions formed on apple fruit by 100 isolates obtained from *Leucostoma* spp. in terms of virulence, and it was observed that there were round, brown, soft and slightly depressed lesions in various sizes in the fruits (Figure 2).

Figure 2. Create different sized lesions on Granny Smith apple by *Leucostoma* spp.

The diameter of the lesions were measured five days after the inoculation and ten days after the inoculation. It was observed that the average lesion diameters on the fifth and tenth days were between 1,2-2 cm and 1,6- 3,8 cm, and iyt was also observed that there were no lesions on some fruits. Since the apple test with *Leucostoma* spp. has been applied for the first time in this study, the results were compared with those obtained in the study conducted with *C. Parasitica*.

In the apple test, while the diameters of some of the lesions formed on apple by *Leucostoma* spp. isolates were closer to each other in some groups, these values showed differences in some groups. While Bisiach et al. (1988) claimed that it was not reliable because the sizes of the lesions formed by virulent and hypovirulent isolates of the *C. parasitica* in apple test were closer to each other, Elliston (1985) and De Lange et al. (1998) found in the apple test results that the lesion diameters were different from each other and stated that virulent and hypovirulent isolates could be separated easily with this method, and also stated that the virulence of the isolates could be measured in a short time.

dsRNA Analysis

The dsRNA analysis of 26 isolates which showed low and high virulence were performed in three recurrences. Positive control and negative control isolates were used. The *CHV1* (USA-2) isolate, which we know that it is a hypovirulent of *C. Parasitica* was used as positive control. As the negative control, the Ki-778, which is a *Leucostoma* spp. isolate was used. Only in 6 isolates were the dsRNA profiles determined; however, in the second recurrence, it was observed that there were dsRNA profile only in 3 of these isolates. Then, in the third recurrence, no dsRNA profiles were determined in any of the isolates, in which dsRNA profile was determined previously (Figure 3). It was determined that the 6 *Leucostoma* spp. isolates in which we determined dsRNA profile were the isolates obtained from the cities of İzmir (Ki-394, Ki-280, Ki-301A, Ki-407), Manisa (Ki-376) and Denizli (Ki-52).

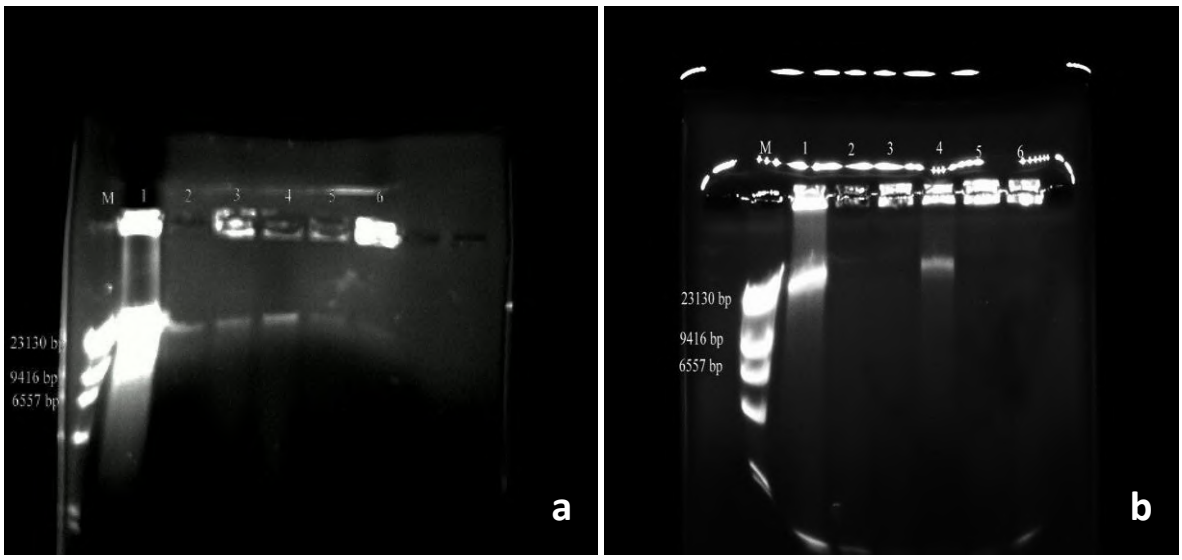

Figure 3. Agarose gel electrophoresis of dsRNA associated with isolate 6 of *Leucostoma* spp.;
a) Marker (M), USA-2 (1), Ki-394 (2), Ki-376 (3), Ki-280 (4), Ki-407 (5), Ki-301A (6)
b) Marker (M), USA-2 (1), Ki-778 pik. (2), Ki-451 (3), Ki-52 (4), Ki-236 (5), Ki-271 (6)

As a matter of fact, Márquez et al. (2007) reported that the dsRNAs, which were found in *Curvularia protuberata* factor were affected by desiccation or freezing- thawing processes and that the dsRNAs were eliminated after these processes. In this study, the reason that there were no bands observed in the recurrent analyses performed with the same isolates, in which

the dsRNA bands were observed, may be due to the reasons like desiccation and freezing-thawing. Peyambari et al. (2014) obtained dsRNA segments whose molecular weights were 1.85, 1.65 and 1.27 kbp from *Cytospora sacchari* isolate obtained from sugar canes in Iran. When they examined the genomic structure of this virus, they determined that it belonged to the *Partitiviridae* family. It was also reported in this study that although mycoviruses had a wide variation, the information on these viruses was insufficient; and that while the structures of some viruses were unstable, some viruses had resistant structures (Peyambari et al., 2014).

Conclusion

The Aegean Region in Turkey has an important place in the economy of the whole country in terms of cherry production. In recent years, the Leucostoma cancer increased seriously in cherry trees in the Aegean Region, and has become one of the complaints of the producers due to the desiccation parts in trees.

In the study, although the dsRNA profile (band) was observed in 6 isolates upon the dsRNA analysis, the dsRNA profiles were not observed in the recurrent isolates. These results, which do not confirm each other, may be explained with the results obtained in the study conducted by Márquez et al. (2007) to eliminate mycovirus from fungus. The structures of some viruses being unstable (Peyambari et al., 2014) make them become vulnerable to desiccation and freezing-thawing. For this reason, repeating this study and determining the isolates of the dsRNA profiles in the structure of fungus may help to find a possibility to fight the relevant factor biologically. However, before this, the effect of the dsRNA on the factor and the genomic structure must be studied. If a hypovirulent relation between the fungus and the virus is determined (just like in *C. parasitica*), the dsRNA, which has been detected with this study, may gain an importance as a biological warfare agent.

Abstract

Turkey is also the homeland of plum as well as many other fruits, because of the reasons like appropriate climatic and soil conditions, located on immigration routes, existed for living area of many civilizations since the ancient times of history. Being a liked and wanted fruit by consumers along with rich vitamin and mineral content, in terms of colour, taste and flavour is always increased the charm of plum fruit growing. Fruit plum generally exists on markets for a long-period such as 6-7 months. Especially as green plums, they take part an important place among early fruit varieties. Alongside with consumption as fresh fruits, plum is exploited on producing of compote, jam, dried fruits, fruit leather, mash, marmalade, and juice. According to 2012 data of FAO, Turkey grown 2.80% of global plum production which was 10.7 million tonnes, and it was on the 5th greatest grower position after China, Serbia, Romania, and Chile with 300.000 tonnes of plum fruit growing. According to data of Turkish Statistical Institute, Turkey's production of plum fruit was 305.000 tonnes in 2013 and 265.000 tonnes due to drought in 2014. Generally plum fruit growing in Turkey is on the shape of mixed gardens together with other fruits. In this study, some evaluations will be made by revealing the general conditions of plum farming and analyzing of agricultural marketing structure in Turkey. In this study, some researches, articles, presentations, thesis, and statistics were carried out by considering relevant subject.

Keywords: Plum, production, stone fruits, agricultural marketing.

Introduction

Plum is a fruit species, which is known with the latin name "Prunus domestica", belonging to Rosaceae family. According to ancient written documents, it is known that fruits of "Prunus domestica" known for 2000 years have been dispersed from around Caucasia and the Caspian Sea to the world, the homeland of another species named "Prunus institia" is Damascus region (Tunalioglu and Keskin, 2004).

Plum is the leading of mostly consumed fruits among stone fruit species. Its consumption as dried is quite common in the many regions of the world. Thanks to development of food technology, its use in the production of yoghurt, milk, mash, fruit leather, churchkhela, marmalade, jam, chocolate, and dessert and for numerous different products as raw material is gradually increasing as well rather than consuming freshly. One of the effective factors upon the increase in its consumption is that its contribution to health has been revealed as a result of studies conducted. In addition to the phytochemicals of plum and their anti-carcinogenic effects, it is known that plum provides significant benefits for regulation of digestion. Nutritional elements of fruits also make their use essential as mineral supplement as well (Gecer et al., 2015).

It has been determined to inhibitory to chronic diseases especially cancer and hearth disorders besides helping to delay glucose absorption and laxative effects through the phenolic compounds, fibre-rich, fructose, and sorbitol content contained in plum. Furthermore, fruits

consumed as dried are observed to protect cardiovascular health and have a significant role in preventing osteoporosis due to their potassium and boron contents. It is a product which is a must in dietary lists due to such characteristics (Stacewicz-Sapuntzakis et al., 2001).

Plum production in the world was 11.5 million tonnes in 2013. As the Table 1 was examined, it was observed that an increasing trend was obtained even though decreases were seen relatively year by years beginning from 2005. The most important reasons of this increasing trend can be summarised as development of different varieties, increase in number of species and variety adapted to different ecologies, increase of plum production parallel with rise of income level, development of the industry related to this fruit species, increase of its use in food products, and increase of wealth level of population subsisting on this fruit growing along with the increase in number of farmers performing plum production as agricultural activity.

Interest to plum growing is gradually increasing in the world and Turkey due to simplicity of cultural processes in plum growing, quite long harvesting season, and high nutritional values. In addition to high number of sub-species, it is possible to see plum varieties in country market for 5-7 months due to opportunities provided by different ecological regions in Turkey. As the harvest times are considered, it is possible to see plum in the market between 15 April and 15 October (Karamursel, 2011). The first plum harvest begins with green-papaz group belonging to Prunus ceresifera L. specie as early fruits in the Mediterranean region. The final plum harvest ends with late bloomer varieties from Prunus salicina and Prunus domestica group. Marketing period of late bloomer plums can be extended by keeping in different storage conditions regarding species. Marketing period of plum in Turkey extends approximately 9-10 months (Karamursel, 2011).

This study examined and evaluated current condition concerning production, foreign trade, marketing, and consumption of plum in Turkey.

Plum Production in Turkey

Turkey is at the fifth country growing plum in the world after China, Serbia, Romania, and Chile (Table 1). According to data of FAO, net agricultural production value of plum production in Turkey was 182.2 million dollars in 2013.

Table 1. Amounts of plum production in main countries between 2005 and 2013 (Anonymous, 2015a)

Countries	2005	2006	2007	2008	2009	2010	2011	2012	2013

Today, some of plum varieties growing in Turkey are domestic species and some others are foreign species. Domestic species occurred from two species and these were Prunus cerasifera and Prunus domestica species. The mostly grown plum types in Turkey are green plum, papaz plum, damson plum, and sweet thin-skinned plum. Culture varieties derived from Prunus cerasifera species are called "green plums". Major green plum varieties are Aynali, Can-1, Foca, Havran, Karsiyaka, Orta can, and Papaz. Fruits of Can-1, Havran, Orta can, and Papaz varieties are generally consumed freshly and this is a consumption type specific to Turkey (Tunalioglu and Keskin, 2004).

When the balance sheet of plum was examined; it was observed that 305.4 thousand tons of plum were produced in the marketing year covering the period between 1 July 2013 and 30 June 2014, losses occurred during production were 46.7 thousand tons; when import figure of 2.9 thousand tons was added to 258.6 thousand tons of the usable production figure remaining after harvest losses were deducted from production numbers, 261.6 thousand tons of plum were put upon the market (Table 2).

It was observed that 28.1 thousand tons of plum were exported and supplied for foreign consumption in the same marketing year. Therefore, 233.5 thousand tons of products from total production was allocated for domestic use. However, since approximately 18.7 thousand tons were reduced by wastage at processing stage before plum reached to end consumer, domestic consumption of plum in 2013/14 marketing year was 214.8 thousand tons (Table 2).

Table 2. Crop Products Balance Sheets; "Plum" 2005/2006-2013/2014 (Anonymous, 2015b)

	Production	Harvest losses	Supply=Use	Usable production	Imports	Domestic use	Human consumption	Losses	Exports

2005/'06	220.000	33.660	187.204	186.340	864	173.243	159.384	13.859	13.961

Within the past 10 years between 2005 and 2014, cumulative plum orchard lands reached from 144 thousand decare to 200 thousand decare by increasing at the rate of 39.08%. Production of plum, being 220 thousand tons in 2005, was 265.5 thousand tons in 2014 with the increase of 20.68% compared to 2005 (Table 3). Some factors providing the increase in production can be summarised as follows; different climate conditions of Turkey, development and plantation of species and varieties adaptable to various ecologies, formation of modern orchards, and developments in product processing techniques (Karamursel, 2011; Osmanoglu et al., 2013). When 10-year data found in Table 3 were examined, it was observed that mean plum yield per tree was the lowest with 28 kg in 2006 and the highest level with 37 kg in 2012. Although mean yield per tree was 36 kg in 2013, after a year ie in 2014 mean yield per tree was 31 kg by decreasing the rate of 13.89% (Table 3). The fact that late frost in spring and hail squalls occurred in that year was supposed to be effective upon this decrease. While 86.66% of 8.77 million of total tree number in 2005 were at fruit-bearing age, the number of fruit-bearing trees reached to 8.6 million with an increase of 13.92% in 2014 compared to 2005. According to estimated data of 2014, totally 10.3 million of plum trees were present in cumulative orchard lands of 200 thousand decare. The number of trees at fruit-bearing age in total tree number decreased to 84.07% in 2014 due to establishment of new orchards (Table 3).

Table 3. Plum production amounts in Turkey between 2005 and 2014 (Anonymous, 2015b)

Year	Area of cumulative orchards (decare)	Production(tonne)	Mean yield per tree (kg)	Number of trees at fruit bearing age	Number of fruitless trees	Total number of trees
2005	144.000	220.000	29	7.600.000	1.170.000	8.770.000
2006	140.040	214.416	28	7.571.521	1.150.815	8.722.336
2007	152.545	240.874	31	7.736.690	1.460.626	9.197.316
2008	155.122	248.736	32	7.750.463	1.575.247	9.325.710
2009	166.883	245.782	32	7.743.411	1.571.422	9.314.833
2010	166.244	240.806	31	7.815.844	1.847.120	9.662.964
2011	183.644	268.696	34	7.863.951	1.802.700	9.666.651
2012	193.304	300.046	37	8.187.640	1.794.829	9.982.469
2013	197.262	305.393	36	8.429.484	1.816.936	10.246.420
2014	200.271	265.490	31	8.657.765	1.640.867	10.298.632

*: Data of 2014 are estimated.

According to data of 2014, 31.31% of cumulative plum fields in Turkey are located in the Mediterranean Region, 29.36% in the Aegean Region, and 14.53% in the East Marmara Region. Additionally, 37.81% of plum production performed in Turkey was from Mediterranean Region, 22.16% from Aegean Region, and 16.58% from East Marmara Region (Table 4).

Table 4. Plum production based on agricultural zones (Anonymous, 2015b)

	2013				2014

Plum production is performed in many cities and particularly in Mersin, Hatay and Antalya in Turkey (Table 5). Demand of especially freshly consuming as green plum has increased and this has promoted the development of early grown. Early grown plum production not only provides advantage to consume fresh fruit before its season in terms of consumers but also brings a good income for producers due to high prices.

Table 5. Plum production quantities of some cities in Turkey by 2014 (Anonymous, 2015b)

Order	City	Production Quantity (tonne)	Order	City	Production Quantity (tonne)
1	Mersin	37.579	**11**	Afyonkarahisar	7.191
2	Hatay	21.779	**12**	Denizli	6.709
3	Antalya	17.629	**13**	Kocaeli	6.248

7	Kutahya	11.208	**17**	Isparta	4.227
8	Sakarya	10.004	**18**	Yalova	3.285
9	Izmir	8.512	**19**	Mugla	3.026
10	Canakkale	7.674	**20**	Samsun	2.968

Plum Consumption in Turkey

In Turkey, mean consumption was 214.8 thousand tons and consumption per capita was 2.8 kg according to data of 2013/14 marketing year. According to data of TSI between 2005 and 2014, plum consumption per capita in Turkey varied depending on yield and was about 2.4 kg. While consumption per capita decreased to 2.1 kg in years when the product was scarce, this quantity increased up to 2.8 kg in years when it was abundant (Anonymous, 2015b).

Foreign Trade of Plum in Turkey

As the export data between 2006 and 2015 were examined, it was observed that fresh plum export of Turkey increased gradually. According to data of 2014, 16.1 thousand tons of fresh plum were exported and in return, 11.8 million dollars of foreign currency receipts were obtained (Table 6). It was observed that export of dried plum showed large fluctuations year by year. In 2014, 841 tons of dried plum were exported and in return, 2.5 million dollars of foreign currency receipts were obtained. It could be asserted that import of fresh plum was not performed in large quantities as in export and it differed year by year. It was observed that according to data of 2015; while 12 tons of fresh plum was imported, 8.5 thousand dollars were paid in return of this quantity (Table 6).

According to data of 2006-2013, it could be asserted that even though export unit price of fresh plum changed by years, it had a downward tendency. Thus, it was observed that while export unit price of fresh plum was 1.24 $/kg in 2006, the price decreased to 0.73 $/kg in 2014, mean figure for the first 8 months of 2015 has decreased to 0.48 $/kg. On the other hand, a reverse tendency was observed in export unit price of dried plum. Mean export unit price of dried plum, which was 1.29 $/kg in 2006, reached to 2.99 $/kg in 2014 and increased to 3.45 $/kg based on the mean of 8 months of 2015 (Table 6).

As import unit price of fresh plum was analysed, it was observed that import unit price, like export unit price, was unstable in the same period and showed rise and fall year by year. Importat unit price of dried plum increased as export unit price. While 1.14 $/kg was paid for 1 kg of imported fresh plum in 2014, 2.29 $/kg was paid for 1 kg of imported dried plum (Table 6).

Table 6. Export and import values of plum between 2006 and 2015 (Anonymous, 2015b)

	Export			Import		
Year	Quantity (tons)	Value ($)	Export Unit Price $/kg	Quantity (tons)	Value ($)	Import Unit Price $/kg
			Plum (dried)			
2006	997	1.281.826	1.29	199	260.459	1.31
2007	798	1.652.579	2.07	343	594.944	1.73
2008	589	1.405.995	2.39	81	279.503	3.43

2013	24.311	14.752.959	0.61	13	11.561	0.87
2014	16.121	11.785.235	0.73	3	3.075	1.14
2015	24.639	11.849.788	0.48	12	8.502	0.72

*Data of 2014 and 2015 are temporary.

Ten countries to which Turkey mostly exported fresh plum most in 2014 were Iraq, Russian Federation, Bulgaria, Saudi Arabia, Germany, Turkish Republic of Northern Cyprus, Syria, Netherlands, England, and Georgia, respectively. The first ten countries for dried plum exportation were Germany, Belgium, Vietnam, Canada, Bosnia-Herzegovina, Azerbaijan, France, Netherlands, Switzerland, and Austria. While fresh plum was imported only from the Republic of South Africa and Chile in 2014, countries from which dried plum was imported were Serbia, USA, Iran, Kirghizstan, Chile, Morocco, and Moldova, respectively based on the import quantity.

Plum Farmer Take-Home Prices

Farmer take-home prices for plum reformed by producer price index based 2003 reached to the lowest level with 0.62 TL/kg in especially 2012 in last ten years and risen to the highest level with 0.96 TL/kg in 2011. On the other hand, it was observed that there were fluctuations at very low levels year by year at farmer take-home prices and finally mean price of 2014 was 0.83 TL/kg (Figure 1).

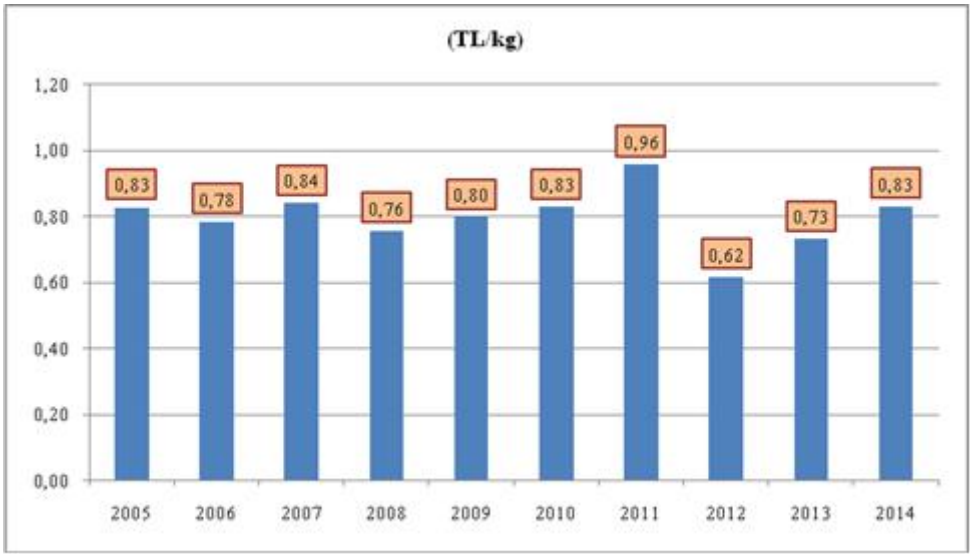

Figure 1. Plum's mean farmer take-home prices in Turkey between 2005 and 2014 (Anonymous, 2015b)

As means of plum farmer take-home prices in ten years by months were examined, it was understood that the price was formed between April and September. According to this, it was observed that while the highest price within the year was in May, the lowest price was in April (Figure 2).

Figure 2. Monthly mean plum prices in terms of farmer take-home prices (TL/kg) (Anonymous, 2015b)

Marketing Channels of Plum

The process in which property of products is passed in other hands and which includes the steps between producer and consumer is called as marketing channel. Structural development of the sector affects the marketing system, as well. Thus, small enterprises with limited marketing opportunities generally dominate in agriculture. This situation cause that enterprises can not sufficiently or never carry out numerous marketing functions such as price formation, standardisation, storage, packaging (Albayrak, 2013). In case that large yield loss

and high expenses are observed because of problems caused by physical processes such as classification, packaging, storage performed for marketing as well excess hand-over of agricultural products until they reach consumer markets and distribution irregularities (Anonymous, 2011). In agricultural product markets; producers, middlemen, brokers, merchants, broker merchants, forwarder merchants, private firms, public institutions, commodity exchanges, wholesale food markets, wholesalers, retailers, cooperatives, and producer unions carry on business (Anonymous, 2011; Albayrak, 2013).

Even though marketing channels for fresh fruits and vegetables in Turkey have showed a configuration focused on actors (middleman, merchant, exporter, producer, etc.) defined basically within the scope of Marketplace Law, different constructions can form based on the product type, target markets (domestic market or export), and regions. Thus, slightly different marketing channels compared to others can be observed in findings of several field studies examining agricultural product marketing and conducted on different products and fields (Sayin et al., 2012). Wholesale food markets are of capital importance trade of fruit and vegetable. According to data of August 2010 from the Ministry of Industry and Trade, there are 203 wholesale fruit and vegetable markets and 9.864 workplaces being still active in these wholesale markets throughout Turkey. In wholesale food markets, producers can both sell their products by themselves and sell the product to brokers in the return of a certain service charge (Canik and Alparslan, 2010).

Conclusion and Recommendations

Plum is a significant fruit type taking place in the third place of the world’s stone fruit production after olive and peach/nectarine by 2013. According to TSI data in 2014, plum production comes after olive, peach, cherry, and apricot production in Turkey and our country takes place among significant plum growing countries of the world with averagely 300 thousand tons of production. Plum is used as table, dried or industrial product; in other words, it can be consumed as raw material in many food products along with its fresh consumption like other several fruit species. In addition to use of plum, having a significant place both in worldwide market and domestic market, for nutrition, value of this fruit type has gradually been increasing as its contributions to health are understood as a result of scientific studies. Improvement of current production and marketing conditions can be realised as a result of using species and varieties appropriate to different ecologies, establishment of protected gardening, choosing correct rootstock, performing regular cultural processes, maintaining plant conservation and nutrition activities, efficiency of harvest and after-harvest processes, market status, and elimination of marketing problems.

As a result of this study, plum production and world ranking status of Turkey was investigated and it was revealed that Turkey can reach a further position thanks to different climate and soil characteristics Turkey has.

Abstract

The aim of this study was evaluation of antifungal activity of *Cornus mas* L. and *Morus alba* L. plant extracts against *Rhizoctania solani* and *Botrytis cinerea* under the *in-vitro* conditions. Plant extracts were dissolved with 50% acetone for each doses (10, 50, 100 and 200 mg doses) and added 10 ml PDA (40 ^{o}C). 5 mm diameter fungus mycelium discs were transferred to petri dishes and kept them 7 days for growing fungus mycelium at 25±2ºC in incubator. Fungus mycelium was calculated by compassand compare with control.As a result of the study, 10, 50 and 100 mg doses of plant extracts of *C.mas* and *M. alba* were not inhibited mycelium development of *R. solani* and *B. Cinerea* except 200 mg dose. 200 mg dose plant extracts of *C.mas* was inhibited *R. solani* and *B. cinerea,* 25.60 % and 74.81% respectively. 200 mg dose plant extracts of *M. alba* was inhibited *R. solani* and *B. cinerea,* 60,97% and 80,40 % respectively.

Keywords: C*ornus mas* L., *Morus alba* L., Antifungal

Introduction

Cornelian cherry (*Cornus mas* L) is a species of *Cornaceae* family which drops its leaves in winter and which can grow up to 5-8 meters with a body diameter of 25-45 (Baytop, 1984).*Cornus mas* L., a kind of fruit havinghard cores, is commonly available in our country, especially on coastal regions as well as in mountainous and forestry regions and inside the valleys with a suitable climate (Selcuk and Özrenk, 2011). Mulberry (*Morus spp.*), grown in generally warm and subtropical regions of northern hemisphere, is a species of Morus of *Moraceae* family of Urticales team. Mulberry types which are commonly grown and the fruits of which are derived in our country are *Morus alba* L. (White Mulberry), *M. nigra* (Black Mulberry) and *M. rubra* (Red or Purple Mulberry) as well is its tens of other species (Anonymous, 2015). Usage of natural products became important because of the insufficiency of active substances of synthetic medicines against currently increasing diseases as well as their effects on human health. With this aim, it is ambidextrously researched in terms herbal chemistry, microbiology and pharmacology even as well as in terms of vegetable defense mechanism in the recent years when biological war is a matter of agenda (Kalaycıoğlu and Öner, 1994; Dağcı et al., 2002). This case caused a surprising increase in the number of studies on medical plants which have recently had an antimicrobial activity. Flavonoids having a large number of antimicrobial activities among these plants as well as such chemicals as phenolic compounds, anti-cyanine and tannin protect the plants against infections and wounds (Dildar et al., 2000). It has been known for long years that various herbal extracts have an antimicrobial activity on bacterial and fungal diseases (Dığrak et al., 2002). Lots of herbal extracts have been studied so far throughout the world, but there are few studies regarding *Cornus mas* L. and *Morus alba* L. This study aims at determining antifungal activities of *Cornus mas L.* and *Morus alba L.* against *Rhizoctania solani* and *Botrytis cinerea*.

Material and methods

Plant Materials

The *Cornus mas* L. and *Morusalba*L. Plant materials used in this study have been picked up in August 2014, in Antalya province (Turkey), and dried at room temperature in the shade. They have been stored until being used in trials.

Fungus Cultures

The fungi of plant pathogen used in the study (*Rhizoctania solani* and *Botrytis cinerea*) were obtained from the stock cultures in Phytopathology laboratories of Plant Department of the Faculty of agriculture, University of Ahi Evran.

Preparation of Extracts

For the purpose of obtaining of plant extracts, dried and ground plant materials of 100 g has been located in erlenmeyer of 1 lt, and methanol solvent has been added enough to cover it. It has been subjected to the process of rinsing through a orbital agitator at 120 rpm and room temperature for 24 hours. Then the extract shave been filtered through a filter paper. The solvent shave been kept away by being evaporated at 40 ^{0}C by rotary evaporator. The remaining dry extracts have been dissolved with acetone, and finally, the different concentrations, such as, (1% (10mg) 5% (50 mg), 10% (100 mg) and %20 (200 mg), have been obtained for being used in our study (Kalkisim et al., 2012).

Antifungal effect of Plant methanol extract

Obtained plant extract have been autoclaved in such a way that the last concentrations would be % 1 (10mg), %5 (50mg), %10 (100mg) and %20 (200mg), and then added to the sterile PDA's, which were cooled until 40 ^{0}C. The PDA's have been transferred to 60 mm diameter petri vessels (in away as being 10 mm). The mycelium discs taken from 7-days fungus cultures previously have been transferred to 5 mm diameter petri vessels. After inoculation, fungus cultures have been subjected to incubation at 25±2 0C for 7 days, and at the end of the period, developed radial mycelium have been taken (Hadizadeh et al., 2009). The development of mycelium has been calculated according to the formula given below (Pandey et al.,1982). As positive control, a standard fungicide has been used containing %50 captan. Thetrial was conducted in through four repetition sand two iterations

$$MGI=100\times(dc-dt)/dc$$

dc; mycelia growth in control

dt; mycelia growth in treatment

Results and Discussion

The effect of *Cornus mas* L. and *Morusalba* L. methanol extract on *Rhizoctonia solani* and *Botrytis cinerea* mycelium development is displayed in (Table 1) .

Table 1. Effects on plant pathogenic fungi mycelium growth of *Cornus mas* L. and *Morus alba* L. methanol extracts (mm).

Application dose	*Cornus mas* L.		*Morus alba* L.	
	***R. solani* mycelium growth (mm)**	***B. cinerea* mycelium growth (mm)**	***R. solani* mycelium growth (mm)**	***B. cinerea* mycelium growth (mm)**
Positive control	0,00c*	0,00c	0,00c	0,00c
Negtative control	60,00a	60,00a	60,00a	60,00a
10mg	60,00a	60,00a	60,00a	60,00a
50mg	60,00a	60,00a	60,00a	60,00a
100mg	60,00a	60,00a	60,00a	60,00a
200mg	44,60b	15,11b	23,41b	11,76b

*According to DUNCAN, The averages with different letters at the same column are different at $p<0.05$ significance level

Although there are differences in the effect depending on the dose of applied herbal extract and diseases, it has been determined that *Cornus mas* L. and *Morus alba* L. methanol extract generally has an activity. The highest dose of *Cornus mas* L. methanol extract prevents the development *Rhizoctonia solani* and *Botrytis cinerea* mycelium development respectively in the rates of 25,6 % and 74,81 %. On the other hand; the highest dose of *Morus alba* L. methanol extract prevents the development of *Rhizoctonia solani* and *Botrytis cinerea* mycelium development respectively in the rates of 60,97 % and 80,40 % (Figure 1) .

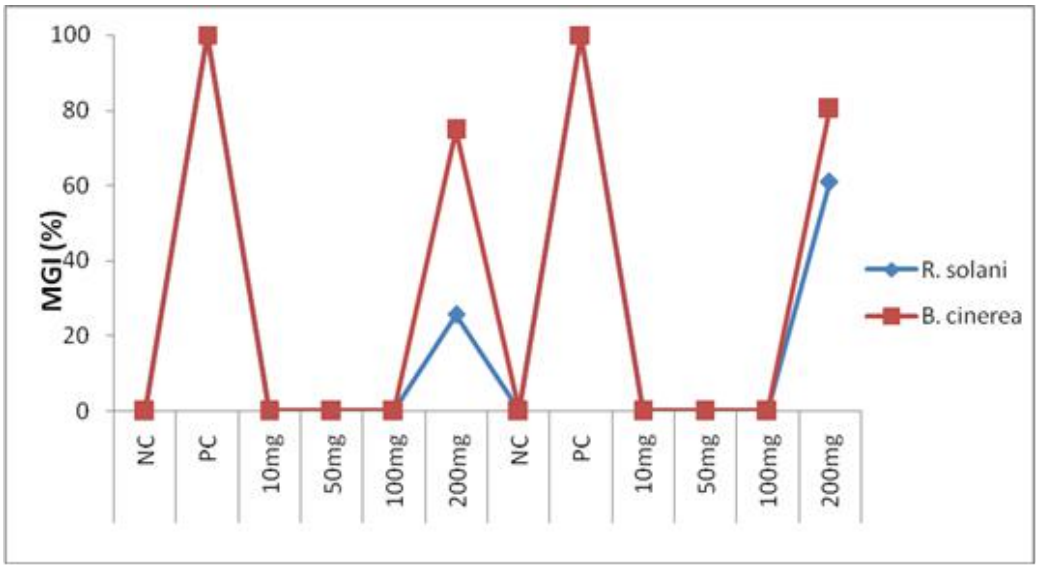

Figure 1. The inhibition ratio of methanol extract of *Cornus mas* L. and *Morus alba* L. on the development of mycelium of plant pathogen fungi.

Cornus mas L. and *Moru salba* L. plants arise out of such compounds as phenolic and flavonoids which are active compounds having biological activity within themselves (Danica et al., 2014; Pawlowska et al., 2010). It has been determined that *Morus alba* L. methanol and water extracts have antifungal and antibacterial activities (Jha and Srivastava, 2013). On the

other hand; *Cornus mas* L. has a high level of antimicrobial activity (Anthony and Dinda., 2015).

Conclusions

This study was made of *Cornus mas* L. and *Morus Alba* L. The methanol extracts to determine the anti-fungal activity. *Cornus mas* L. 200 mg dose of study results *Rhizoctonia solani* and *Botrytis cinerea* mycelium development in the rates of respectively 25,6% and 74,81%. *Rhizoctonia solani* and *Botrytis cinerea* study results *Morus Alba* L. 200 mg dose mycelium development respectively in the rates of 60,97 % and 80,40 %. Our results show that methanol extracts of *Cornus mas* L. and *Morus alba* L. plants have antifungal activities against *Rhizoctonia solani* and *Botrytis cinerea*.

Abstract

According to the estimates, after last year's floods the main damage is reflected in the loss of return on agricultural crops. Agricultural cultures have long been under water. With the arrival of the spring period, it was found that significantly more damage done to the land, and in order to improve the quality and restore the land to the level before the floods it will be necessary to invest substantial funds for a longer period.

Depending on the length of the impact of floods on land depends the level of changes in physical and chemical properties of the soil. Land that was under water for a short time has expressed: pH change , change of compaction of soil and nutrient content.

During the spring a higher percentage of weed plants was found and poor effective herbicides as well. In areas where water was retained longer period the increased concentration of heavy metals was determined. For quality of sowing soil preparation is necessary to apply a much more scientific farming operations. Some operations have had to be repeated several times to land led to a favorable condition for planting. In respect of land which was not flooded, for the treatment of flooded land consumption of fuel, lubricants and time increased by 30 to 50%. When processing flooded soil abrasion machines for processing higher by 30%.

Agronomists should give a recommendation and clear instructions that measures should be implemented to restore the quality of the soil.

Keywords: *land, flood damage, pH, compaction, weeds.*

Introduction

The soil and especially the soils that are used in an intensive agricultural production are exposed to various degradation processes. The soil limits the fulfillment of goal, increased food production, because every day there is a reduction in surfaces and quality of agricultural soil. The soil quality is defined as the ability of soil to perform its functions within the limits of the ecosystem, maintaining the biological activity too, and providing the environment for plants and animals (*Doran et.al., 1994*). It is considered that the notion of soil quality includes physical, chemical and biological properties. In the long run, the high quality soils ensure the productivity of plants with a minimal impact on the environment (*Baere et al., 1997*). The soil fertility is closely related to the soil quality, and represents the ability of soil to ensure a satisfactory crop production with the minimal use of fertilizers and manure (*Hansen et al., 2001*). In addition to the direct negative effect of heavy metals on human health, they also disturb the delicate balance in the ecosystem and negatively affect the living world, which indirectly endangers man’s position in biogeocenosis for a longer time period (*Bennett et al., 2001*). About 135 million tons of phosphate ores is produced yearly around the world, which leads us to conclusion that there is a constant danger of intake of around 21000 tons of uranium in the soil through mineral fertilizers (*Dangić, 1995*). The production capacity of soil

is reduced by processes of continuous reduction and damage to agricultural areas. The floods that during 2014 affected the region of former Yugoslavia caused enormous harm to agricultural soil. At the territory of BiH, the floods caused a series of direct and indirect damages to the soil.

Materials and Methods

The investigations were carried out during the spring in 2015 at the territory of Semberija region (Republic of Srpska, Bosnia and Herzegovina) that has suffered the damages caused by floods. The soil sampling has been performed at the flooded territories for determining the changes in pH value of soil, the contents of humus and easily available phosphorus. This part of investigations was performed during February and March, while the second part of investigations was continued during March, April and May. In this part of investigations the condition of agricultural soil was analyzed and the level of soil degradation caused by flood was being determined. During soil cultivation, it was analyzed how much time it was needed for soil preparation, which agro technical operations were included, and how much material and fuel was spent. Weediness and effectiveness of herbicides was being monitored on the production plots.

Results and Discussion

During the investigation, a special emphasis was put on the division of the areas according to the duration of retention of flood wave at the flooded area as the assumption was that the duration of the retention of water on the agricultural soil was in correlative relation with the damages, i.e. the degree of soil degradation. The results show that there is no firm relationship between the stated values and that they cannot be related in any respect. Of all collected samples, the largest number had the changes in pH value which ranged in an interval from 5.7 to 6.5. Compared to the previous state of pH value, which ranged in an interval from 6.8 to 7.2, it is clear that there was a transition of pH value of soil into the class of acid to slightly acid soils which was influenced by flood. The change in pH value of soil can be related to the influence of a number of factors of which the most important are the flushing and loss of carbonate complex, flushing of humus layer, loss of the organic matter and movement of nutrients into the deeper layers.

The analysis of the humus content in the soil confirms the indications, since a medium to low humus content was determined in all soil samples. The humus content ranged from 1.5 to 2% (20 samples) and in an interval from 2 to 2.5% (ten samples). It is clear that the effect of flood is obviously evident on the humus content in the soil because under the influence of water there is a loss of humic matter in the soil. We came to the same results by analyzing the content of easily available phosphorus and potassium, where the determined values ranged from 8 mg P_2O_5/100g and 8 mg K_2O/100g of soil up to 15 mg. Compared to the previous condition of soils that were well provided with phosphorus and potassium (with a content of over 20mg/100g), we now determined a significant loss of nutrients.

The results of the analysis match the indications obtained in an investigation by *Kljajić et al. (2012).* The duration of flood wave, which retained on the plots for longer than five days, caused irreversible losses of nutrients.

During the vegetation period, the analyzed plots were monitored where we tried to determine the visual condition of crops. The general conclusion is that all the plots had very bad visual image. It was reflected in unequal development of crops where ’waves’ are noticeable i.e. much emphasized symptoms of lack of nutrients. Small, underdeveloped and stunted plants with an emphasized yellow-chlorotic color dominated on the plots of Semberija. This phenomenon was emphasized not only in the flooded area but also on all the plots that had been under the influence of long-term rainfalls, and therefore intensive flushing. According to

Vučić (1992), it is difficult to separately observe the effect of various chemical agents that are being applied in agriculture only on soil without the wider reflection on nature and the environment. When it comes to the pollution of soil the problems should not be solved but prevented. There are a lot of the polluters of soil, they come from different parts, they are not equally distributed, all of which complicates consideration of the degree of qualitative and quantitative level of pollution and proposal of measures for its repairs.

Very great damages to the agricultural soil are reflected through the loss of soil structure. Good soil structure is a good basis for the increased soil fertility because one of the basic conditions is fulfilled for the intensive growth of the roots of the plants, which is a good water-air regime. Under the influence of water, which had been laying on the soil for days, structural aggregates compact, fine porous structure of the soil is lost whereby macro and micro aggregates are completely lost. The changes in soil structure cause the changes in air regime where there is obvious lack of oxygen for root respiration, microbiological activity is slowed and the possibility for accumulation, storage and supply of water is minimal. During the vegetation, there is a constant problem which is connected with the increased compactness of soil, which is that only the surface layer of soil has the ability of accumulating the rainfalls, and which leads to a constant occurrence of excess or lack of humidity.

Unstructured soils are unfavorable and difficult to cultivate because it is necessary to use more agro-technical operations in order to properly prepare the soil for planting. The compacted soil is more difficult to cultivate and our investigation moved in that direction. We wanted to come to an answer how much more fuel, tools and time is spent for soil cultivation compared to the period before the flood.

The fuel consumption was highest in plowing and it ranged up to 25 l/ha, which, compared to the consumption in the cultivation of the soil that was not flooded, means the increase of 40 to 50%.

For disking, the fuel consumption was increased for about 35% (disking in two passes) while for the harrowing the fuel consumption increased for about 30%.

All of these agro-technical measures could not adequately respond to the task, i.e. to properly prepare the soil for sowing but the preparation of soil was mostly combined with the use of power harrow and seed bed tiller. The fuel consumption when using the power harrow was increased for 35%, and for 25% when using seed bed tiller, compared to the cultivation of soil that was not flooded. The increased compactness of soil has led to the increase in fuel and time consumption, and for the preparation of 1 ha of soil, the time of preparation increased for 30 to 40%, on average.

The change in structure and other properties of soil should lead to the change, i.e. harmonization of the applied agro-technical measures, so that better effect i.e. better soil preparation would be achieved with the minimal fuel and time consumption.

By monitoring the parameters of certain working operations, we came to the conclusion that it is necessary to include undermining at the depth of 30 to 40 cm within soil preparation. By including of the afore-said measures within the cultivation of soil we come to conclusion that with such tools for soil cultivation soil preparation is far better and economic where it is evident that small crumbly fractions of soil dominate in the seeding layer.

After undermining, the plowing is lot easier and it is done with a reduced consumption of fuel and the total fuel consumption for undermining and plowing is 28 L/ha, which is by three l more than in the case of the single measure of plowing, and the effect is much more greater.

Under the influence of the flood, during the autumn and spring period, a significantly higher occurrence of weed was recorded. On the soil that was not treated from 370 to 470 of weed seedlings per m^2 was recorded. The largest number of weed plants belongs to:

1. Ambrosia artemisiifolia-ragweed,

2. Omenopodium sp.-meldweed,
3. Convolvulus arvensis-field bindweed,
4. Galium sp.-hedge bedstraw,
5. Sinapsis arvensis-field mustard,
6. Abutilon theophrasti-abutilon,
7. Amaranthus retroflexus-amaranth and
8. Datura stramonium-jimson weed.

During the May in 2014, the dominant weed species were not in the phase of the formed seed, but it was most often the vegetative phase. Such a mass phenomenon of weeds can be explained only by raising the seeds from the lower layers to the surface layer of soil. Another logical explanation can be linked to the application of an enormous number of seeds of various weed species from the upper streams of rivers so that brought seeds would deposit in the plains of Semberija.

After the sowing of corn, the effectiveness of herbicides on the occurrence of weed plants in crops was analyzed. The analysis included 60 plots which differed in soil type, but the plots that were treated with the same combination of herbicides were selected. The treatment of spraying was carried out after the sowing and before seedling emergence of maize. The satisfactory effectiveness of herbicides was recorded on 10 out of 60 plots of maize. The herbicides did not have the satisfactory effectiveness on the remaining 50 plots because even after the treatment the emergence of more than 80 saplings of weed plants per m^2 was recorded. The analyzed plots were sampled cross diagonally with the distance of sampled square of 20 meters. The low effectiveness of herbicides can be attributed to the extremely high temperatures during the treatment, the change in pH value of soil, reduction of humus and organic matter in the soil, change in the soil structure, and a very high abundance of weeds.

Conclusion

There was a considerable change in physico-chemical properties of soil on all the flooded areas in Semberija. The analysis of samples confirmed that the degradation effect of flood caused the change in pH value of soil. The effect of the flood is reflected in an intensive flush and loss of humus, too, as well as other nutritive macro elements.

The intensive occurrence of weed plants, as well as weak effectiveness of the herbicides, is only one of the negative effects of the flood that is subsequently reflected. The floods have drastically changed the physical properties of soil which is reflected in the change of the structure i.e. the compactness of soil. After the flood, it is very difficult to cultivate the soil well, and that leads to significantly higher fuel and time consumption and a higher amortization of machinery. A comprehensive analysis of soil should provide a clear guidance on how to prevent the further loss of soil quality and what is necessary to apply in order to improve the soil, i.e. to bring the soil back to the state of quality it had before the floods.

Proper use of machinery for cultivation of soil, a constant control of soil fertility and a rational use of limestone, organic and mineral fertilizers, as well as cultivation of crops that lead to the improvement and protection of soil must be the first steps in the improvement of soil quality.

Abstract

The paper presents the results of two-year study of the impact of the variety and size of planting material of potato in the area of Lukavica (East Sarajevo). In years of research, the highest yield in the experiments was found in the variety Faluka, while the lowest yield was found in the variety Agria and in the variety Aladin in 2013 and 2014 respectively. The largest number of tubers in all studied years was found in the variety Aladin (in 2013 – 12.30 and in 2014 – 10.55), while the lowest number of tubers was found in the variety Agria (in 2013 -8.25 and in 2014-8.14). Tubers with a maximum mass were obtained at variety Faluka (121.25 g in 2013 and 101.44 g in 2014), while the smallest tubers were found in the variety Aladin (103.75 g in 2013 and 90.81 g in 2014).

In situations where we planted larger tubers per plant, we got a larger number of tubers (by planting tubers weight of 40 g we got 9.29 tubers in 2013 and 7.42 tubers in 2014, and by planting tubers weight of 60 g we got 10.89 tubers in 2013 and 9.46 tubers in 2014), but their weight was lower compared with alternatives where we planted smaller tubers. By planting small tubers we got yield of 50.24 t ha^{-1} and 42.86 t ha^{-1} in 2013 and 2014 respectively, and by planting large tubers we got yield of 52.43 t ha^{-1} and 44.97 t ha^{-1} in 2013 and 2014 respectively.

During the growing season (April-August) the average daily temperatures were 17/26 ° C, and 16/10 ° C in 2013 and 2014 respectively, while the total amount of rainfall during the growing season in 2013 was 359.5 mm and 610 mm in 2014. Adverse conditions in the early stages of growth and development of potatoes in 2014 due to excessive rainfall affected the number of formed tubers, tuber weight and yield. In 2013 the weather conditions were more favorable, with the exception of July where there were deficit of rainfall (27.3 mm), but due to the adequate application of agro-technical measures the lack of rainfall in July had not affected the yield of potato tubers negatively.

Key words: *variety, potato, tuber number, tuber size, weight, yield.*

Introduction

Potato production in Bosnia and Herzegovina is lagging behind potato production in developed countries. The average yield of about 11 t ha^{-1} puts us at the bottom of the European potato producers. Such low yields are mainly due to the use of low-quality seedlings, poor cultivation practices, production without irrigation, traditionally superficial approach towards production (Đorđević, 2000a and b; Ćota et. al., 2000; Milić and Bogdanović, 2009; Milić et.al, 2012). Production is often carried out in conditions of extremely unfavorable impact of environmental factors, mainly high temperatures and precipitation deficit during pollination and grain filling tubers. Inadequate water-air regime of the soil and high air temperatures usually occur in June and July, at the time of intensive growth and development of potato respectively. Whit the action of unfavorable external factors, extensive and inadequate land cultivation and crop care cannot provide optimal conditions for the growth and development of potato plants.

By selecting appropriate varieties, optimal planting deadline, proper selection of the size of planting tubers and appropriate agricultural techniques adverse impact of external factors can be overcome, because some varieties, with the faster growth, good coverage of soil, and early seeding of tubers, pass the critical stages of development in favorable conditions (Jovović et al., 2012; Poštić et. al., 2012a; Poštić et. al., 2012b; Dardić and Dimitrić, 2009). By knowing the production potential of varieties and choosing certain factions for planting we can influence on increase in the productivity of the crop - yield and tuber, yield structure, tubers and better technological and nutritional quality.
The aim of this study was to determine, on the basis of field trials, the optimal size of tubers as planting material and the potential for yields of selected varieties.

Material and method

The study of genetic yield potential of some potato varieties (factor A - Agria, Aladin and Faluka) depending on mass planting tubers (factor B - tubers weight 40 g or tuber weight 60 g) was performed in the low lime soil (table 1), at an altitude of 550 meters in Lukavica (East Sarajevo) in 2013 and 2014 (factor C-year). The field experiment was conducted in a randomized block design, in 4 replicates and plot size was $30m^2$. Primary treatment, preparation and soil fertilization were performed in a way standard crop of potatoes calls for. The protection of crops from weeds, pests and disease-causing agents were conducted in a timely manner.
Determination of the average number of tubers and the average mass of tubers ere performed at each iteration of a sample of 10 homes after maturation. The total yield per hectare was made by theoretical categories for crop density (about 48000 plants per hectare).
Statistical analysis was done by the method of factorial analysis of variance (ANOVA), using the statistical package Statistics 5.5 (Windows, analytical software), and the score differences between means was performed using LSD test.

Research results and discussion

The number of formed tubers, as well as the uniformity of their size, depends on not just the inherited characteristics of the variety, but also on external influences. In years with normal climatic conditions tuber formation begins 4-5 weeks after sprouting. If, during this period, moisture is sufficient tubers will be formed at all stolons. In the absence of moisture during this period the plant reduces the number of stolons and forms a small number of tubers. The measurement results (tab. 3) shows that the largest number of tubers in all the studied years, was found in the variety Aladin (12.30 and 10.55 in 2013 and 2014 respectively) while the lowest number of tubers was found in the variety Agria (8.25 and 8.14 in 2013 and 2014 respectively). The variety Aladin, in comparison with the varieties Agria and Faluka, had a highly significant greater number of tubers. The total number of tubers grows when planting bigger seed potatoes, and planting them at longer row spacing leads to formation of large tubers (Broćić et al., 2000). To achieve high and stable yields the best varieties are those that stirs about 10 tubers per plant (Bugarčić et al., 2000). Analysis of the average number of tubers per plant, depending on the size of planted tubers, for tubers of 40 g gave the following results (9.29 and 7.42 in 2013 and 2014 respectively), and for tuber weight of 60 g (10.89 and 9.46 in 2013 and 2014 respectively). By planting larger tubers we got a statistically significantly greater number of tubers per plant compared with the number of tubers in the trials where we planted smaller tubers.

Table 3. Number of potato tubers per plant

Tuber weight / Variety	2013		Average	2014		Average	Two-year average
	I	II		I	II		
Agria	7.62	8.87	8.25	7.10	8.95	8.03	8.14
Aladin	11.35	13.25	12.30	7.70	9.92	8.81	10.55
Faluka	8.90	10.55	9.70	7.74	9.50	8.48	9.09
Average	9.29	10.89	10.08	7.42	9.46	8.44	9.26

LSD	A	B	C	AxB	AxC	BxC	AxBxC
0.05	0.621	0.507	0.507	0.769	0.769	0.717	1.243
0.01	0.778	0.675	0.675	1.025	1.025	0.965	1.657

The average number of tubers regardless of variety, tuber size and year was 9.26. In 2013, the average number of tubers per house was 10.08 and, in comparison with 2014 (8.44), it was statistically significantly higher. Larger number of tubers in 2013 was due to weather conditions that were favorable compared to 2014 (table 2). Average monthly temperatures in April and May in 2013 that were higher compared to 2014, resulted in the faster and more uniform germination and sprouting of potatoes, forming stolons and the number of tubers. A large number of rainy days, as well as large amounts of rainfall in April and May in 2014 adversely affected the growth and development of potato. Due to unfavorable weather conditions there were delays in the implementation of some agro-technical measures. Frequent shifts of rainy and warm days influenced the occurrence of disease.

Size of the tubers is varietal characteristics, but it also depends on the level of agricultural measures, type of soil and its structures, as well as on the meteorological conditions during the vegetation season (Ilin et al., 1992). Availability of water from early formation to maturity of tubers of plants is is very important for the manifestation of hereditary characteristics of a variety in terms of uniformity of tuber size and height of the total yield (Suvajdžić and Šilić, 1984).

Tubers with the greatest mass were obtained in variety Faluka (121.25 g and 101.44 g in 2013 and 2014 respectively), while the variety Aladin had the smallest tubers (103.75 g and 90.81g in 2013 and 2014 respectively). Analysis of variance of the average weight of tubers showed a statistically significant increase in mass of the cultivar Faluka compared with all other varieties in 2013, whereas the difference in 2014 was in comparison with the variety Aladin.

Size of tubers is conditioned by number of canes that are formed by a single plant, and if the number of primary canes is higher the number of tubers formed is higher, but not their masses and vice versa (Bugarčić, 2000 b; Butorac and Bolf, 2000; Jovović, 2002; Jovović et. al, 2010). These results are in line with our results. In cases where we planted larger tubers per plant, we got a larger number of tubers, but their weight was lower compared with alternatives where we planted smaller tubers. This difference in 2013 (average weight of tubers at planting smaller tubers of 117.5 g, and average weight of tubers at planting larger tubers 102.5 g) was significantly higher, while in 2014 that difference had not statistical significance (average weight of tubers at planting smaller tubers was 99.17 g and average weight of tubers at planting larger tubers was 93.58 g).

Table 4. The average mass of potato tubers in g

Tuber weight / Variety	2013		Average	2014		Average	Two-year average
	I	II		I	II		
Agria	95.00	115.00	105.00	103,50	90.25	96.87	100.95
Aladin	120.00	87.50	103.75	85.63	96.00	90.81	97.28
Faluka	137.50	105.00	121.25	108.38	94.50	101.44	111.34
Average	117.50	102.50	110.00	99.17	93.58	96.37	103.18

LSD	A	B	C	AxB	AxC	BxC	AxBxC
0.05	7.205	5.957	5.957	10.318	10.318	8.425	14.592
0.01	9.727	7.942	7.942	13.756	13.756	11.233	19.456

The average mass of tubers regardless of variety, tuber size and year was 103.18 g. In 2013, average mass of tubers 110 g and compared to 2014 (96.37 g) it was significantly higher.

Achieving high yields of potatoes is conditioned by a number of factors. In addition to favorable climatic conditions during the vegetation season the other factors are: the variety, adequate amounts of fertilizer and application of appropriate tillage soil system. In both years the highest yields were found in the variety Faluka (53.92 t ha^{-1} and 47.15 t ha^{-1} in 2013 and 2014 respectively). The varieties and Aladin had the lowest yield (Agria-46.35 t ha^{-1} and Aladin-41.74 t ha^{-1}) in 2013 and 2014 respectively. In 2013, the variety Aladin and Faluka, in comparison with the variety Agria, had a statistically significantly higher yield, while in 2014 the variety Faluka had a statistically significantly higher yield compared to varieties Aladin and Agria.

Size of planting material is an important factor for successful potato production. Size of tubers is important for the initial pace of growth when the plant lives at the expense of spare nutrients from stem tubers. Soon after the release of root the initial effect of size is lost. This is an important fact to keep in mind, with regard to the participation of planting material in the total cost of potatoes production (Ilin et. al, 2000). Đorđević and Jovanović (1994) achieved the lowest yield during planting tubers weighting of 35-40 grams. By planting the tubers weighting 75-80 grams, the yield was higher than the first combination for 20,46%. Based on examination results regarding influence of planting tubers size on potato yield Jakovljević and Šušić (1965) concluded that the small tubers (30-40 g) give lower yields compared to the larger tubers (70-80 g). The results obtained in this study are consistent with results of previous authors because yield after planting small tubers was 50.24 t $ha^{-1}$and 42.86 t ha^{-1} in

2013 and 2014 respectively, while yield after planting larger tubers was 52.43 t ha^{-1} and 44.97 t ha^{-1} in 2013 and 2014 respectively. These differences were statistically significant.

Table 5. The yield of potato (t ha^{-1})

Tuber weight / Variety	2013		Average	2014		Average	Two-year average
	I	II		I	II		
Agria	45.25	47.45	46.35	42.71	43.00	42.85	44.60
Aladin	52.70	54.77	53.73	41.13	42.35	41.74	47.74
Faluka	52.77	55.07	53.92	44.75	49.56	47.15	50.54
Average	50.24	52.43	51.33	42.86	44.97	43.91	47.62

LSD	A	B	C	AxB	AxC	BxC	AxBxC
0.05	1.975	1.613	1.613	2.794	2.794	2.281	3.951
0.01	2.633	2.150	2.150	3.323	3.323	3.041	5.265

The average yield regardless of variety, tuber size and year was 47.62 t ha^{-1}. In 2013, average yield was 51.33 t ha^{-1} while in 2014 it was 43.91 t ha^{-1}. Difference in yield in two years was statistically significant.

Conclusion

Based on the results of two years of research about the influence of the variety and tuber size on the productive characteristics of the potato in field trials conducted in Lukavica, the following conclusions can be deduced:

According to the analysis of climate and soil data, conditions for growing potatoes as the main crop, planting in the period from the beginning of the third decade of April, in the area of Lukavica, were relatively favorable. By timely planting of potatoes in this area physiological activities of plants with favorable natural conditions of the area can be matched and thus high and stable yields can be achieved.

The number of formed tubers, as well as uniformity in size, depends on the hereditary characteristics of the variety, as well as from external influences. Variety Aladin had the highest and variety Agria the lowest number of formed tubers per plant. The total number of tubers formed is higher by planting large tubers.

Size of the tubers is varietal characteristics, but it also depends on the level of agricultural measures, type of soil and its structures, as well as on the meteorological conditions during the vegetation season. The variety Faluka had the largest tubers while the variety Aladin had the smallest ones.

Achieving high yields of potatoes is conditioned by a number of factors. In addition to favorable climatic conditions during the vegetation season the other factors are: the variety, adequate amounts of fertilizer and application of appropriate tillage soil system. In both years the highest yields were found in the variety Faluka, while the variety Aladin, due to various meteorological conditions, proved to be unstable variety.

Abstract

We examined the productive characteristics of some potato varieties (yield and commercial yield of potatoes) in agro-ecological conditions of Sarajevo-Romanija region during 2013 and 2014. Regarding the qualitative characteristics we examined the content of dry matter and starch. Varieties showed variability in yield and commercial yield of tubers. The greatest variability was found in a variety Aladin which in 2013 and 2014 had a yield of 52.90 t $ha^{-1}$and 40.25 t ha^{-1} respectively. The smallest variation in yield was found in the variety Desiree 36.72 t ha^{-1} and 34.40 t ha^{-1} in 2013 and in 2014 respectively. The variety Aladin had the highest yield of marketable potato. The variety Agria is suitable for processing into French fries and potato chips. This variety had the highest dry matter content, which ranged from 21.27 % to 22.50%, while the variety Kondor had the highest starch content (from 18.22% to 18.97%). In 2013, due to favorable weather conditions, we achieved better results both in productive and in the qualitative characteristics of the potato.

Key words: *potatoes, variety, productive characteristics, quality, yield.*

Introduction

For achieving high and stable potato yields, apart from favourable climate factors during the vegetation period, key factors are also potato variety, application of adequate amounts of mineral fertilizers and application of appropriate cultivation systems and plant care (Jovović, 2010; Milić et Bogdanović, 2009; Milić et al., 2012). For better usage of genetic potential of the potato varieties it is necessary to examine productive and qualitative characteristics of potatos in different agroecological environmental conditions (Bugarčić i sar., 1991: Đukić i sar., 2000). Except for achieving high and stable potato yield it is important to achieve high yield of mercantile tubers-commercial yield (Broćić et al, 2000) as well as select varieties meeting technological characteristics of potato for production of potato chips and French fries (Jackson et Berga, 2003; Henryk, 2012).

The aim of this study is to select varieties which, based on field experiments, produce high yields of mercantile potatoes-commercial yield and meet needs of food industry regarding the quality.

Material and method

The study of genetic yield potential of some potato varieties was conducted in Lukavica (East Sarajevo) in 2013 and 2014, on the slightly lime soil (table 1), at an altitude of 550 m. The following potato varieties with different vegetation period and skin color were tested: Agria, Aladdin, Faluka, Kondor and Desiree. The field experiment was conducted in a randomized block design, in 4 repetitions with basic plot of $15m^2$.

Basic processing, preparation of the soil and fertilization were carried out as standard procedure for potatoes. Weed control, treatment of causes of diseases and pests were carried out in a timely manner.

Digging of the physiological mature tubers determined the total yield while the mercantile/commercial potato yield is determined by taking healthy, properly developed tubers weighing more than 70 g.
The content of starch in the tubers was determined by Ewers, and dry matter content was determined by drying at 105^{o}C.
Statistical analysis was done by the method of factorial analysis of variance (ANOVA), using the statistical package Statistics 5.5 (Windows, analytical software), and the difference between means was performed using LSD test.

Research results and discussion

In the two years examination the average yield of potato tubers was 43.39 t ha^{-1}. In 2013, the variety Aladin had the highest average score (52.90 t ha^{-1}), while the variety Dezire had the lowest one (36.72 t ha^{-1}). Estimated differences were statistically significant. The varieties Agria, Faluka and Kondor in comparison with the variety Desiree had statistically higher yield, while the yield differences between these varieties did not have statistical significance. In 2014 the variety Kondor had the highest average score (43.12 t ha^{-1}), while the variety Dezire had the lowest one (34.40 t ha^{-1}). The differences were not statistically highly significant, and the differences between the other varieties in comparison with the variety Desiree. The average yield for all varieties was 47.14 t ha^{-1} and 39.66 t ha^{-1}. in 2013 and 2014 respectively. Variety Desiree had a minimal variation in yield, while the variety Aladin had the greatest variation. To achieve high yields of potatoes even distribution of rainfall is required and during the growing season it should be 350-400mm (Mitcherlich, 1971). Potatoes gives the highest yields with the annual precipitation of 700 to 800mm, while in very humid conditions (800-1000 mm) yield may be reduced by 4%. In 2013 during the vegetation period there was 359.5 mm of rain falls while in 2014 there was 610 mm, which significantly reduced the yield of potatoes in 2014.

Table 3. The total yield and the yield of marketable tubers

Varieties	Tuber yield (t ha^{-1})			Marketable tuber yield (t ha^{-1})		
	2013	2014	Average	2013	2014	Average
Agria	47.45	39.55	43.50	37.96	29.81	33.88
Aladin	52.90	40.25	46.57	44.43	31.28	37.86
Faluka	47.90	40.98	44.44	43.12	31.56	37.33
Kondor	50.72	43.12	46.92	41.08	31.91	36.49
Dezire	36.72	34.40	35.56	29.01	24.08	26.54
Average	47.14	39.66	43.39	39.12	29.73	34.42

	2013		2014		2013-2014	
	$LSD_{0.05}$	$LSD_{0.01}$	$LSD_{0.05}$	$LSD_{0.01}$	$LSD_{0.05}$	$LSD_{0.01}$
Tuber yield	5.765	7.111	3.278	4.602	2.823	3.806
Marketable tuber yield	4.505	6.321	2.475	3.474	2.405	3.242

The average yield of marketable tubers was 34.42 t ha^{-1}. In the two years examination the average yield the variety Aladin had the highest average yield of marketable tubers (37.86 t ha^{-1}), while the variety Dezire had the lowest one (26.54 t ha^{-1}). The varieties Agria, Aladin, Faluka and Kondor in comparison with the variety Desiree had statistically higher yield of marketable tubers. The varieties Aladin, Faluka and Kondor in comparison with the variety Agria had statistically higher yield of marketable tubers. In 2013, the variety Aladin had the highest yield of marketable tubers. In 2014, the variety Kondor had the highest yield. Variety Desiree had a minimal variation in yield, while the variety Aladin had the greatest variation.

For the further processing of potatoes, the size and shape of the tubers are important. Long and oval tubers larger than 50 mm are ideal for the preparation of French fries, while round tubers, between 40 and 60 mm, are ideal for the preparation of potato chips. Processing chips from tubers with a diameter greater than 60 mm would give large slices that would be damaged after packing. Size of the tuber is varietal characteristics, as well as the shape and irregular folds that lead to waste and losses during stripping. Irregular shape may be the result of secondary growth. Varieties with small folds are the most desirable for processing. Tubers with good circle pattern or oblong tubers can weight between 200 and 300 g, while larger tubers can weight even 500 g, and as such are acceptable for the preparation of French fries, but not for the chips. In addition to the shape and size of tubers the content of dry matter, sugars and color at the intersection of tubers are an important as well. If the dry matter content is too low, French fries or potato chips will be too soft or too moist and it is necessary to consume more energy when burning to evaporate water. If the dry matter content is too high, the finished product will be dry. Dry matter partly determines the texture and oiliness of finished products, which meet the needs of consumers. Potatoes with dry matter content of 20-24% are ideal for the production French fries, while those with dry matter content of 24% are ideal for the preparation of potato chips. As part of dry matter is lost during the peeling, cutting and blanching, it is better to have the higher initial dry matter content, as more content will remain after frying.

Variety Condor in both years had the highest starch content (18.97% and 18.22% in 2013 and 2014 respectively), while the variety Faluka had the lowest starch content (14.43% and 13.9% in 2013 and 2014 respectively). All studied varieties in comparison with the variety Faluka had statistically higher starch content in tubers. The variety Agria in comparison with the varieties Desiree and Aladin had statistically higher starch content, while Aladin in comparison with the variety Desiree had statistically significantly higher starch content.

Table 4 presents the results of dry matter content and starch in tubers. In both years the variety Agria had the highest percentage of dry matter (22.50%, and 21.27% in 2013 and

2014 respectively), while the variety Faluka had the lowest percentage of dry matter (17% and 16.37 % in 2013 and 2014 respectively).

Table 4. The content of dry matter and starch

Varieties	The content of dry matter (%)			The content of starch (%)		
	2013	2014	Average	2013	2014	Average
Agria	22.50	21.27	21.88	18.45	17.30	17.87
Aladin	19.10	17.87	18.48	16.33	15.25	15.78
Faluka	17.00	16.37	16.68	14.43	13.97	14.20
Kondor	21.77	20.70	21.22	18.97	18.22	18.60
Dezire	17.80	17.02	17.41	15.40	14.30	14.85
Average	19.63	18.65	19.13	16.72	15.81	16.26

	2013		2014		2013-2014	
	$LSD_{0.05}$	$LSD_{0.01}$	$LSD_{0.05}$	$LSD_{0.01}$	$LSD_{0.05}$	$LSD_{0.01}$
Dray matter	0.361	0.507	0.424	0.593	0.262	0.352
Starch	0.358	0.503	0.275	0.355	0.211	0.285

The variety Agria in comparison with other varieties had statistically higher dry matter content. The variety Kondor in comparison with varieties Aladin, Faluka and Dezire had statistically higher dry matter content. The variety Aladin in comparison with varieties Faluka and Dezire had statistically higher dry matter content, while the variety Dezire in comparison with variety Faluka had statistically higher dry matter content. The variety Agria can be used in processing to obtain French fries and potato chips. The dry matter content is an important indicator of the quality of potato tubers. Varieties of early maturation, as a rule, contain a smaller percentage of dry matter (***Quasemu***,1978; ***Đukić et. al***, 2000) which was confirmed by the results of these studies, since the early variety Faluka had the lowest dry matter content. ***Đokić et. al.*** (1988) found that the total dry matter content in tubers of some varieties of potatoes is in the range from 20 to 25%, of which starch accounts for 70-75% in average of the total dry matter or 14-26% of the fresh tubers.

The chemical composition of potato tubers depends on the genetic characteristics of the variety, soil and weather conditions, time of use, length of days, the number of plants per hectare and so on. Starch is a very important ingredient of tubers and significant in determining the value of potatoes for human consumption in the manufacturing industry (***Stoiljković***, 1987). It is known that the weather conditions during growth and development of plants have a significant effect on the starch content in the tubers. According to ***Huuniusa*** (1972) in complex weather conditions the effect of solar radiation, light intensity, air temperature, amount and distribution of rainfall have the most significant impact. Dry years bring low yields, but the tubers are rich in starch and moist, while cold and poorly sunny years have lower yields. **Suvajdžić and Šilić** (1984) considered that the temperature conditions were expressed as integral factors in the formation of yield and partially in quality of potatoes.

Conclusion

Based on the results obtained in the experiments the following can be concluded:

Varieties demonstrated a great variability in yield.

Variety Kondor had the highest average tuber yield (46.92 t ha^{-1}), while variety Aladin had the highest yield of marketable potato (37.86 t ha^{-1}).

Desiree variety had the lowest yield in general and in marketable potato tubers.

The highest dry matter content was found in variety Agria. The variety Agria is suitable for processing into French fries and potato chips.
Variety Kondor had the highest starch content.
By using quality seed and application of appropriate agricultural practices it is possible, in our agroecological conditions, to achieve high yields and high-quality tubers that can be used in the food industry.

Abstract

During the 2010-2013 period, in the experimental field of Crop Science Department at the Agricultural University - Plovdiv a field experiment was conducted. Randomized complete block design was displayed with three replications and size of the experimental plot 10 m^2. Eight new Bulgarian wintering oat lines and two varieties (Dunav 1 and Resor 1), as a standards for yield and quality in Bulgaria, were researched. Yield structural elements formation in different oat genotypes, depending on the agro-meteorological features over the years was traced. The statistical processing of the experimental data was made by SPSS V.9.0 for Microsoft Windows. The highest number of tillers in all studied wintering oat genotypes formed line №1 (4,2) and line M-K (3,6). These two genotypes formed and highest number productive tillers. From all structural elements of panicle with highest number of spikeletts per panicle proven stands line 08/Z 2 (59,3), followed by 07 / Z 1 (27,3). Line 08 / Z2 formed and the highest number of grains per panicle - 98, but with less grain weight.

Keywords: *winter oat, genotypes, elements of the yield*

Introduction

The changes in the weather conditions significantly affect the development and thus determine the regions that are favourable for growing different varieties of crops, including grain crops (Kuzmova, 2009). Oats are a crop which prefers moist and cool weather, which is the reason why it is grown in these regions of the country (Dimitrova – Doneva, M., D. Tanchev, 1999). The changes in the climate necessitate creating new varieties that are more adaptable to the changing conditions. The high and the low temperatures of the air, the uneven distribution of the rainfall throughout the year, especially during the periods that are critical for the growth of the oats, significantly affect the development of the plants and thus the formation of the structural elements of the yield (Valchev, Dr., T. Savova, 1995; Savova, T., 1996). The shortening of the stages of development is caused by the high temperatures of the air and also by the lack of moisture in the soil (Palfner, 1991).The rise of the air temperature and the lack of sufficient rainfall during the spring-summer period shorten the period of ear formation, tasseling and ripening (Savova, T. 2002; Larson, 1988). The high temperatures and the lack of moisture from the end of the tillering period to the beginning of the stem elongation cause the growth of shorter panicles with fewer ears on them. The stem elongation is considered to be the most critical period of the development of the winter grain crops regarding the moisture in the soil. The conditions in which the tasseling takes place are also very important. The lack of moisture and the high temperatures during the formation of the grain lead to the growth of small and shrivelled grains. This adversely affects the yield and the quality of grain. The studying and the creation of high-yielding genotypes of winter oats adaptable to the certain agro-climatic conditions is the main purpose of this survey.

Materials and Methods

The field experiment was conducted within the period 2011-2013 in the experimental field of the Department for Plant Production at the Agricultural University – Plovdiv on the soil order Mollic Fluvisols based on FAO (Popova R., and Sevov, A., 2010).

8 winter lines of oats were included in the survey: № 1, 07/ Z1, 08/ Z2, M-K (selection of the Agricultural University-Plovdiv, Bulgaria), Radolishta, Kucevishte (selection from the town of Štip, the Republic of Macedonia), Kt 651, Kt 718 (selection of the Agricultural Institute – Karnobat, Bulgaria) and 2 winter cultivars – Dunav 1 and Resor 1 which are said to be yield and quality standards in Bulgaria.

The sowing was performed in mid October based on a block method in three repetitions, over an area of 10,5m^2 and a sowing rate of 500 k.s./ m^2 . The land had previously been planted with sunflower. The used fertilization rate was $N_6P_8K_8$.

The statistical processing of the experimental data was performed using SPSS V.9.0 for Microsoft Windows.

Results and Discussion

The weather conditions during the period of growth of the crop are the main factor determining the development of the plants and the formation of the structural elements of the yield.

Within the period of the survey, the vegetation year 2010-2011 was characterized as being favourable for the growth of oats.

The frequent and heavy rainfall in October delayed the sowing and as a result it was conducted in late November and the presence of low average temperatures of 10,8 °C (which is 1,8 °C below the norm) delayed the growth of the plants.

The period of panicle emergence, blossoming and grain formation was accompanied by heavy precipitations and the quantity of rainfall in May and June was above the norm while the temperatures were close to the long-term ones. The wax ripeness and the overall ripeness take place under temperatures that are 1,5 to 2,2°C above the norm (June-July) as well rainfall that is 5,5 mm above the norm (June). The combination of these conditions during the period of formation and ripening of the grains has a positive influence on the nutrition and some of the quality indicators of the grain. (Table 1 and Table 2).

Table 1. Average diurnal temperature in periods of ten days (°C), 2010 – 2011.

Months / Periods of ten days	X	XI	XII	I	II	III	IV	V	VI	VII
I	11,6	12,7	7	0,2	4,5	0,7	13	13,6	22,3	24

Average for the period 1965- 1995	47	35	36	40	48	44	39	32	36	42

The vegetation year 2011-2012 was not very favourable for the growth of the winter oats (Table 3 and Table 4).

The large quantity of the rainfall in October 2012 (70,4 l/m^2) again delayed the sowing of the winter genotypes of oats. This increased the likelihood of freezing of the plants. The positive temperatures in the winter months prevented the plants from freezing, owing to which the lines Radolishta and Kucevishte developed successfully. The spring months (March – April 2012) were characterized by favourable temperatures and rainfall, which determined the formation of panicles with more ears on them.

The period of grain formation and ripening (May-June) was characterized by temperatures close to and a little above the norm for the long-term period and also by heavy precipitations in May and quantity of the rainfall above the norm in June. This combination of weather conditions was favourable for the formation and the nutrition of the already existing grains on the spicelet, which is a prerequisite for a relatively high weight of the grains in the panicle.

Table 3. Average diurnal temperature in periods of ten days (°C), 2011- 2012

Average for the period 1965- 1995	47	35	36	40	48	44	39	32	36	42

The third vegetation year 2012-2013 was characterized by high temperatures and rainfall unevenly distributed during the months (Tables 5 and 6). The high temperatures in October and the rainfall above the norm allowed the fast and simultaneous germination of the crops. This guaranteed the normal duration of the period of development, the occurrence of the third-leaf phenophase and the initiation of the tillering stage before the drop of the temperatures. During the winter months, positive temperatures above the norm were registered, which contributed to the successful wintering of the plants. However, the small quantity of the rainfall in that period reduced the moisture of the soil which is necessary in the spring. In February and March, when the spring vegetation starts, the rainfall is below the norm, which shortens the duration of the tillering stage. This has a negative effect on the formation of the overall and the productive tillering of the plants.

Average for the period 1965- 1995	47	35	36	40	48	44	39	32	36	42

In May, when the plants are in their tasseling and milky ripeness stages, minimum quantity of the rainfall of 3,4mm/m^2 was registered, considering the fact that the norm for the long-term period is 32mm/m^2 . These conditions and temperatures 2,8° C above the norm provide prerequisites for the abnormal pollination of the blossoms of the panicle and the growth of a smaller number of grains. This disrupts the normal formation of the grains.

The heavy rainfall in June - 109,5mm/m^2 contributed only to the nutrition of the grains already formed in the panicle. Under these conditions, we have well-nurtured but fewer grains on the panicle.

The tillering of the studied genotypes varied widely over the years depending on the agro-climatic conditions (Table 7). For the Macedonian genotypes Radolishta and Kucevishte, this indicator has not been registered during two of the years of the experiment because of the large percentage of freezing of the plants.

The largest number of tillers was registered for line No. 1 – 4,2 tillers, followed by line M-K – 3,6 tillers. These two lines have the largest number of productive tillers between 2,2 and 2,4. The lowest overall tillering was registered for line 08/Z2 – 2,1 tillers. Of all the studied

genotypes, the least productive tillers on average for the entire period of survey were registered for the cultivars Resor 1.

Table 7. Overal and productive tillering (number of tillers/ plant), 2011 – 2013.

Cuceviste	-	2,2	-	2,2	-	2,0	-	2,0

Regarding the length of the panicle, table 8 shows that there are great differences between the winter genotypes of oats included in the experiment. The shortest panicle is that of line 07/Z1, reaching 16,8 cm and the longest one is that of line 08/Z2 – 20,8 cm. These two lines are distinguished from all the rest for having the largest number of spicelets, the largest number of grains on the panicle and, respectively, the highest weight of the grains on the panicle. The panicle with the largest number of ears (59,3) and the largest number of grains (98) is that of line 08/Z2. Regarding these indicators, it surpasses all the other genotypes included in the survey but is inferior in terms of size of the grain (with the exception of lines Radolishta and Kucevishte) and hectoliter weight (Zorovski, P et al, 2014).

Table 8. Structural elements of the panicle at wintering oat genotypes, average for the period of study 2011-2013.

Genotypes	Panicle length (cm)	Spikelets per panicle (number)	Grains per panicle (number)	Grain weight per panicle (g)

Conclusions

The conditions throughout the year largely affect the degree of tillering of the studied winter genotypes of oats. The largest overall and productive tillering was registered for line No. 1, followed by line M-K. Of all the studied genotypes, the largest number of spicelets on a panicle was registered for line 08/Z2 (59,3), followed by line 07/Z1 (27,3). These two genotypes also have the largest number of grains on the panicle and the largest weight of the grains on the panicle. They prove to be the most suitable to be grown in the respective agro-climatic region.

Abstract

The Present research work introduces a multi-nut post harvesting mechanism in single platform for shelling, cracking, cutting, de-hulling like operations by just exchanging a tool and fixture set. The different types of nuts such as Marking-nuts, Wal-nuts, Cashew-nuts, Areca-nuts, Almond, Amla, Pistachio, Mango etc. by using a same vertical cut plane post-harvesting mechanism. The Computer Aided Engineering Analysis (CAE) by Finite Element Method (FEM) to perform a simulation for design optimization MNHM (Multi nut harvesting Machine) is done by considering an actual processing condition parameters to perform a simulation cycle for the structural analysis. The post processor report resulted that sum of the reaction forces 38482N (along X-axis), -3641N (anticlockwise along Y–axis) and 20757.5N (Z-axis). The average Product material efficiency of multi nut dehuller for *marking nut, Almond, Walnut and Areca nut*: 87.22, 85.29, 72.23 and 97.00%. Average mechanical damage: 12.78, 14.71, 27.77, and 0.0%, whereas throughput capacity: 0.60, 0.60, 2.48 and 3.5kg/hr (areca of 0-15 mm) respectively. The average calculated parameters for 100 pieces in MNPH-processing unit mechanism observed Product material efficiency: 87.37%, operational time: 85.29%, Shelling efficiency: 97.64%, Mechanical damage: 11.37%, Throughput capacity: 1.17 (Kg/hr), the punches, cutters and MNPH processing unit tools are easier to exchange. The Cost of modified machine is Rs.3100.00/- ($50).

Keyword: *Multi-nuts, ergonomic analysis, CAE analysis*

Introduction

The Present research work introduces a flexible multi-nuts shelling,cracking,cutting , dehulling like operations by just exchanging a tool and fixture set .The different types of nuts such as Marking-nuts, Wal-nuts, Cashew-nuts, Areca-nuts, Almond, Amla, Pistachio etc. by using a same vertical cut plane post-harvesting mechanism. The use of CAD/CAM/CAE-Software technology results in identifying scope in designing and redesigning the machine tool components by structural analysis in software environment.

Objectives of proposed research work:

To Study the existing Shelling, Cutting, Cracking and Dehulling Mechanisms.

Preparation of a new conceptual design of tools and mechanism in Software
-environment for simulation cycle and confirmation of design specification.

Fabrication and performance evaluation of the MND-machine tools.

Ergonomic performance evaluation of MND-Machine.

Materials and methods

The study of the operational functionality of the multi-nut post harvesting mechanism, during de-hulling by stone hammering most of the seed kernels becomes blackish so their market value decreases. The breaking of marking nut is very tedious, laborious and time consuming in traditional method. There were some dehuller like curved blade type dehuller, notch type dehuller, shell and blade type dehuller, hold and press type dehuller designed by other researchers. Following points were considered in the design of MNPH-Processing Unit Mechanism.

- Separation of kernel without or with less damage in cracking.
- More than one kind of nuts for their cutting, slicing, cracking, squeezing, shelling and DE hulling like operations separate processing tools are designed to operate in single mechanism.
- Prevention of splashing during cracking on the facing body parts of the workers.
- Minimization of efforts of the workers in cracking.

The physical dimensions of nuts derived for designing the cutting tool geometry specification to be fixed in vertical cut plane mechanism as mentioned below in Table No.1.

Table No.1. Physical dimensions for cutting tool geometry design specifications

Nuts	Physical Dimensions	Operation Type / Force
Marking Nut	H=18.94 to 26.45; W=15.74 to 18.70; t =1.86 to 2.78; m=2.36 to 2.57.	cracking , shelling
Walnut	H= 34.25 to 40.80; W=27.58 to 32.50, t=2.80 to 3.41; m= 9.13 to 13.27.	cracking , shelling
Almond Nut	H=34.25 to 40.80; W=27.58 to 32.15; t=2.82 to 3.41; m=9.13 to 13.27.	cracking , shelling
Areca Nut	H=20.98 to 22.87; W=29.49 to 30.23; m=14.78 to 16.45.	slicing
Aonla	D =40.7; d (seed) =15; m=35.	Hollow cutting
Mango	H=4 -10; W= 3 –6; h= 2– 6; w = 2– 4.	cutting ,slicing

Where H-height in mm, W-width in mm; m-mass in gm.; t-thickness in mm, d-diameter of seed, h-height of seed.

Design consideration:

Following points were considered in the design of MNPH-Processing Unit Mechanism.

- Separation of kernel without or with less damage in cracking.
- More than one kind of nuts for their cutting, slicing, cracking, squeezing, shelling and DE hulling like operations separate processing tools are designed to operate in single mechanism.
- Prevention of splashing during cracking on the facing body parts of the workers.
- Minimization of efforts of the workers in cracking.

Ergonomic Evaluation:

Statistical analysis of anthropometrics data

The design of agricultural implement or tractor requires anthropometric data of user population for enhancing operator’s comfort, safety and efficiency. The selected anthropometric data of Indian agricultural workers are given in Table.2. (IS 12239/1:1996)

Table.2: Normal range anthropometric data of Indian agriculture workers

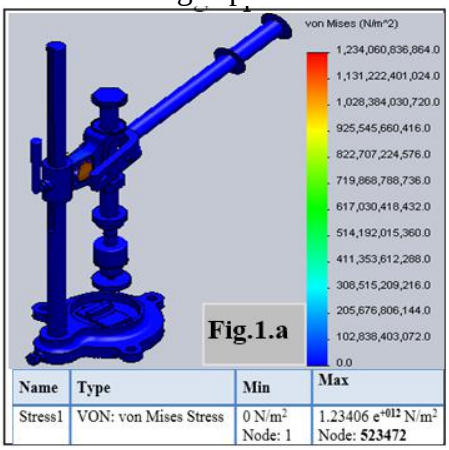
Table 6.shows the two types of blood pressure of male and female operators of MNPH Machine and vibrations measured during operations for each operator. It was observed that blood pressure and pulse rate increases in moderate limit and the vibrations are also within

safe limit. The cutting tools and respective fixtures after CAE-simulation cycle see in fig1.a confirmed design specifications. The CAD-drawings of all cutting tools mentioned in fig.1.b



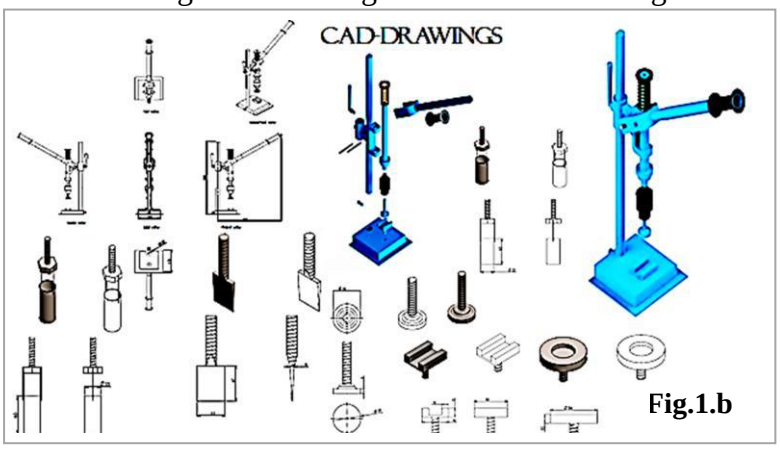


Fig1.**a**.CAE-Simulation of MNPH machine; **b**. CAD-drawings of MNPH cutting tools and fixtures

Results and discussion

The performance evaluation of marking nut, walnut, Almond, Areca nut as shown in fig.2. and according to ergonomic evaluation the performance by each operator for different nuts and tools as from table 5. is as shown in fig.3.for blood pressure ,pulse rate and vibration effect after operation. The overall performance for all selected four nuts and two fruits such as aonla and mango on MNPH machine are graphically represented as in fig.4 and 5 .

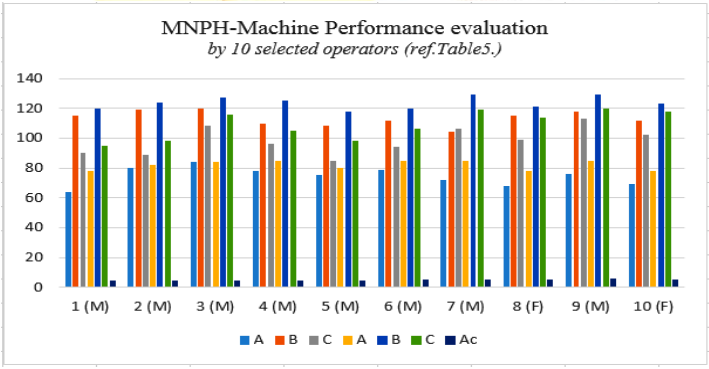

Fig.2. Performance test of MNPH machine

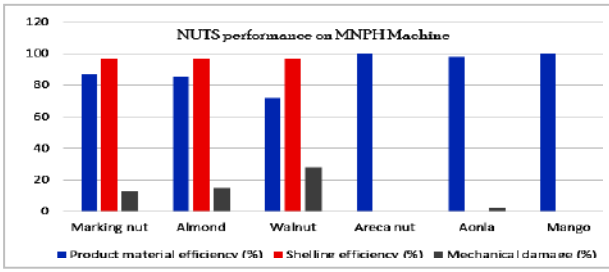
Fig.3. Performance by each operator for different nuts



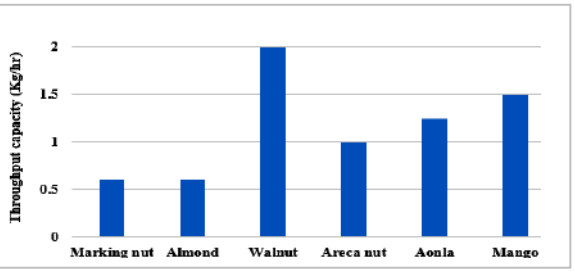


Fig.4. MNPH machine performance Fig.5. Throughput capacity (Kg/hr) of MNPH

Conclusion

The Computer Aided Engineering Analysis (CAE) by Finite Element Method to perform a simulation for optimization MNPH Machine is done by considering an actual field condition parameters to do the structural analysis and also ergonomic evaluation according to ISO and ILO standards for operator machine interface. It is experienced to be comfortable with less fatigue in operator's energy cycle.

The sum of the forces in the structural simulation along X-axis:38482N, Y–axis:-3641N, Z-axis: 20757.5N was observed. The structural analysis resulted in safe limit for all parts.

It was observed that blood pressure and pulse rate increases in moderate limit and the vibrations are also within safe limit. It is observed that throughput capacity (Kg/hr) of marking nut, walnut, areca nut, aonla and mango was ranging from 1-3kg/hr.

The cutting tools with accessories in MNPH machine for processing operations are easier to exchange.

The Cost of modified machine is Approx.$50.00(Approx. INR 3100)

USING PRINCIPAL COORDINATES ANALYSIS FOR INTERPRETING GENOTYPE × ENVIRONMENT INTERACTION IN PLANT BREEDING PROGRAMS

Mehdi MOHEBODINI[1]*, Naser SABAGHNIA[2]

Abstract

One of the major breeding objectives for many crops is improved yield performance and after identifying the high yielding genotypes it is essential to evaluate them for yield stability over diverse environments. The success of any breeding program depends on several factors, including understanding and selection of suitable breeding and test locations. Conventional statistical models of stability analysis provide little or no insight into the pattern of the GE interaction while the principal coordinates analysis can account more effectively for the underlying GE interaction patterns. According to grand means of test environments and total mean yield, environments are classified to two main groups as H (high mean yield) and L (low mean yield). The identified most stable and high mean yield genotypes (G5) are based on the minimum spanning tree plots and centroid distances which could be recommended for unfavorable or poor conditions. Also, genotypes (G11) which were located more times in the vertex positions of high cycles, according to the principal coordinates analysis, are the most stable ones with high mean yielding properties. The principal coordinates analysis can provide useful and interesting ways of investigating GE interaction of genotypes. Finally, the results of principal coordinates analysis in general confirmed the breeding value of crop genotypes, obtained on the basis of the yield stability evaluation. Such an outcome could be regularly employed in the future to delineate predictive, more rigorous recommendation strategies as well as to help define stability concepts for recommendations for crops in other areas of the world.

Keywords: adaptation, GE interaction, stability, yield performance

Introduction

Plant breeders perform multi-environment trials for evaluation of new improved genotypes across test environments, before a specific genotype is released as a commercial cultivar to be produced by growers. In such experiments, genotype × environment (GE) interaction is a common phenomenon (Kang, 1998, Annicchiarico 2002; Yan et al. 2007) which is refer to the differential ranking of genotype among environments and may complicate the process of selection and recommendation of genotypes to target environments (Ebdon and Gauch, 2002; Gauch, 2006). It may also reduce the efficiency of selection in different breeding programs because in the presence of GE interaction, the measured trait is less predictable and cannot be interpreted using main effects and need more analysis (Gauch et al. 2008). Also, GE interaction is one of the most important reasons for the failure or efficiency decrease of breeding efforts to serve small resource-poor farmers in the arid and semi-arid areas (Ceccarelli et al. 2006). Plant breeders perform multi-environment trials to select favorable genotypes based on the both mean yield and stability performance, and to determine whether the test environment is homogeneous or should be divided into various mega-environments (Yan and Kang, 2002; Gauch, 2006).

The adaptation strategies maybe focus on responses of a set of genotypes across different test environments to obtain some good predictions because the plant materials may be produced

from the genetic bases of which the tested genotypes are assumed to be a representative sample (Annicchiarico, 2002). The adaptation strategies maybe focus on cultivar recommendation which is involves several statistical methods including parametric univariate, nonparametric univariate, and multivariate procedures (Flores et al. 1998). Among these methods, the most widely used is the joint regression model (Finlay and Wilkinson, 1963) which is uses only one statistic, the regression coefficient, to describe the pattern of response of a genotype across environments and, most of the information is wasted in accounting for deviation. Principal components (PC) analysis is a common generalization of above model that overcomes this difficulty by using the scores of PC axes as an extra statistic to explain the response pattern of a genotype (Eisemann et al., 1990).

Principal coordinates analysis is a generalization of famous PC analysis and involves with measurement of similarity between different variables such as genotypes or environments (Gower, 1966; Westcott, 1987). This method assumes that the original variables define a Euclidean space and so the similarity between them is modeled by Euclidean distance and its main target is to transform the data from one series of coordinate axes to the other series (Medina et al., 1999). Like PC analysis, this method preserves most of the original configuration of the dataset in the first axes and so, some original information is inevitably lost. The principal coordinates analysis can effectively reduce the pattern of a two-way dataset of multi-environmental trails, dimensions in a subspace of fewer dimensions (Ibanmez et al., 2001). Also the mentioned two-way structure can be conceptualized as environment points in genotype dimensions.

Ordination approaches such as the principal coordinates analysis may have some limitations. In dimension reduction of dataset, distortions may occur. In other word, if the percentage of variance explanted by the first axes is small, individuals that are really far part may be indicated by points that are close together (Gower, 1971). Also, a lack of association between variables prevents few dimensions from explanting for most of the observed variation. In contrast to ANOVA (additive model), multivariate methods such as the principal coordinates analysis assumes a multiplicative model without any explanation of the main effects (Zobel et al., 1988). In some cases the first axes of multivariate methods do not have any clear association to environmental factors (Gauch et al., 2008). Finally, the nonlinear relationships prevent from effective explanation of the real relationships between genotypes through multivariate methods (Gower, 1971). The aim of the present study was to quantify and interpret the GE interaction on performance stability using principal coordinates analysis which should help to interpreting genotypes adaptability for grain yield, which is a complex trait particularly susceptible to GE interaction.

Principal coordinates analysis

Analysis of variance was performed for individual environments to plot residuals and identify outliers. The Anderson-Darling normality test and the Levene variances homogeneity test were assessed. Each of the four location and 18 genotypes were regarded as fixed variables while three years were regarded as random variables. Combined analysis of variance was conducted using by SAS 9.1 program (SAS, 2004). The principal coordinate analysis (Westcott, 1987) was used for stability analysis. A measure of similarity between two genotypes, *m* and *n*, in a given test environment is:

$$S_{i(m,n)} = [H_i - (m_i + n_n)/2]/(H_i - L_i)$$

where *Hi* is the highest mean yield of a genotype in test environment *i* ; *Li* is the lowest mean yield of a genotype in test environment *i* ; m_i is the mean yield of genotype *m* in test environment *i* and n_i is the mean yield of genotype *n* in test environment *i*. Similarity index between two genotypes (*m* and *n*) was defined as the average of $S_{i(m,n)}$ across test environments when more than one test environment was used. The analysis was based on the sequential accumulation of the test environments according to their rank order, the

environments being ranked in ascending order according to their overall means. Each analysis produced a two-dimensional plot based on the first two principal coordinates scores. Also, the minimum spanning tree plots were drawn and the most stable genotypes with high mean yield performance were those that across sequential cycles were observed most distant from the centre of the plot. All calculations and plots of the principal coordinate analysis were performed by GENSTAT 12.1 software (VSN International, 2009).

Interpretation

According to these grand means and total mean yield, test environments are classified to two main groups as H (high mean yield) and L (low mean yield). There are seven H test environments and five test environments which analyzed in the sequential cycles. Yield is first analyzed for the lowest test environment (cycle L1); the second cycle (L2) involves analyzing the two lowest environments, and so on. A typical plot for the cycles is shown in Figure 1 where the scatter point diagram indicates the results of analysis for the first low cycle (L1). Plot of first two principal coordinates analysis axes in cycle L1 (Figure 1) indicated genotypes G7 and G10 were different from the other genotypes.

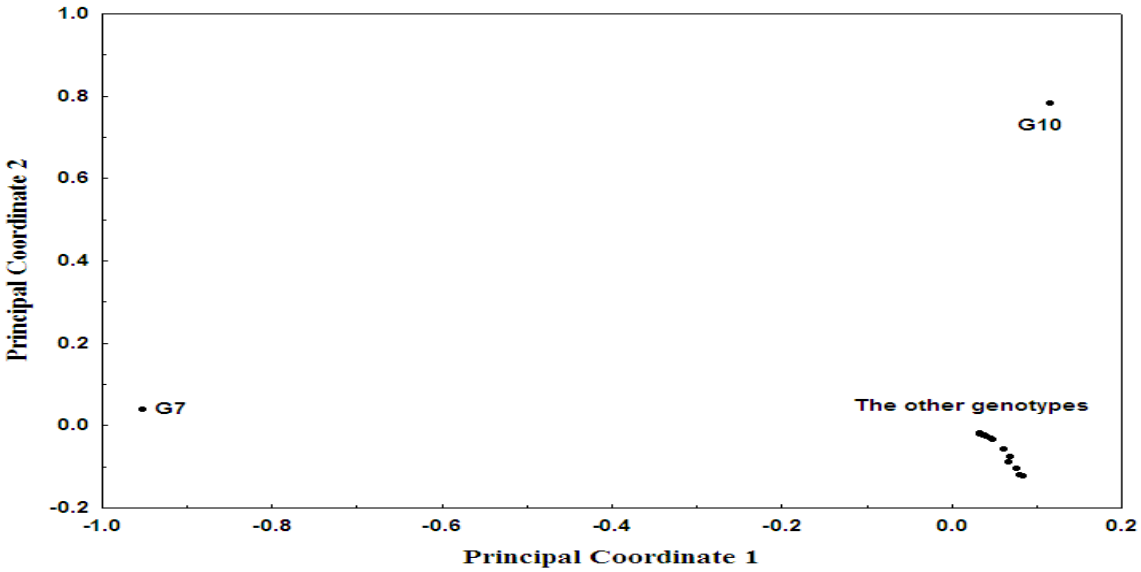

Figure 1. Plot of the first two principal axes from a principal coordinate analysis in twelve environments, in cycle L1.

This plot uses only first two principal coordinates analysis axes and so ignoring some information of the other principal coordinates axes and a minimum spanning tree plot could be useful. The high-yielding genotypes are those which are furthest from the centre, and so genotypes G1, G2 and G11 were detected as the high yielding genotypes in L5 cycle (Figure 2).

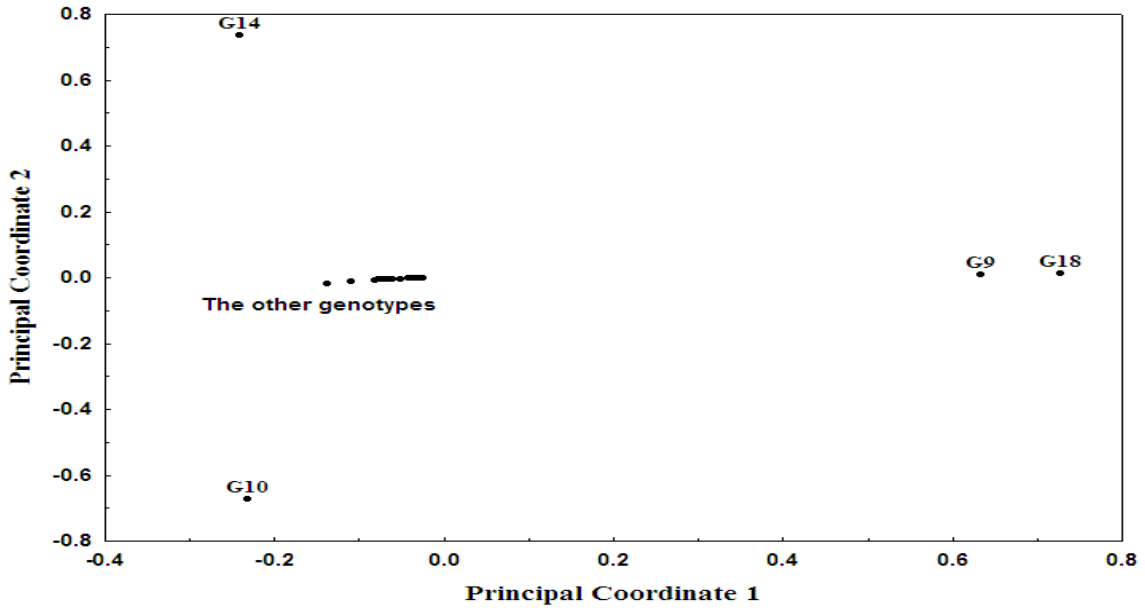

Figure 2. Plot of the first two principal axes from a principal coordinate analysis in twelve environments, in cycle H1.

The differences in the lengths of the branches are grotesque relative to the differences between studied genotypes, because the minimum spanning tree is represented in two dimensions ignoring information in the next principal coordinates axis. Regarding this limitation, Flores et al. (1996) proposed using a parameter as centroid distances which is benefits from all principal coordinates dimensions. Rather than including all five scatter diagrams of L cycles, the stability patterns of the genotypes are described in the text and only centroid distances, corresponding to all L cycles are presented. According to centroid distances values, genotypes G2, G3 and G7 were the favorable genotypes in cycles L1 and L2 while genotypes G1, G2, G11 and G12 were the favorable genotypes in cycles L3, L4 and L5. According to obtained results for all low cycles, genotypes G1, G11 and G14 were the favorable stable ones. Among these genotypes only G2 and G11 were located three times in the vertex positions of five low cycles and so these genotypes (G2 and G11) were the most stable ones with high mean yielding properties. The most stable genotypes are the ones that are consistent over cycles (Westcott, 1987; Flores et al., 1996). The identified most stable and high mean yield genotypes had acceptable mean yield; G2 and G11, and therefore could be recommended for unfavorable or poor conditions.

Seven test environments were as H (high mean yield) which analyzed in the sequential cycles. Yield is first analyzed for the highest test environment (cycle H1); the second cycle (H2) involves analyzing the two highest test environments, and so on. According to scatter point diagram of the first high cycle (H1), genotypes G9, G10, G14 and G18 were different from the other genotypes (Figure 3).

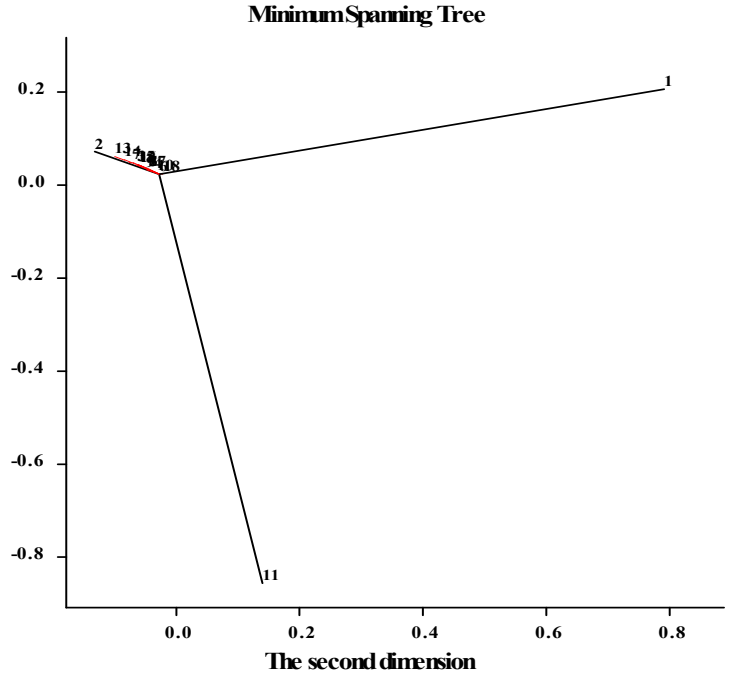

Figure 3. Plot of the first two principal axes from a principal coordinate analysis in twelve environments, in cycle L5. Part of the minimum spanning tree is superimposed on the plot.

Similar to L cycles, minimum spanning tree plot was used and showed that genotypes G5, G9 and G14 were high-yielding genotypes because they were furthest from the centre in H5 cycle (Figure 4).

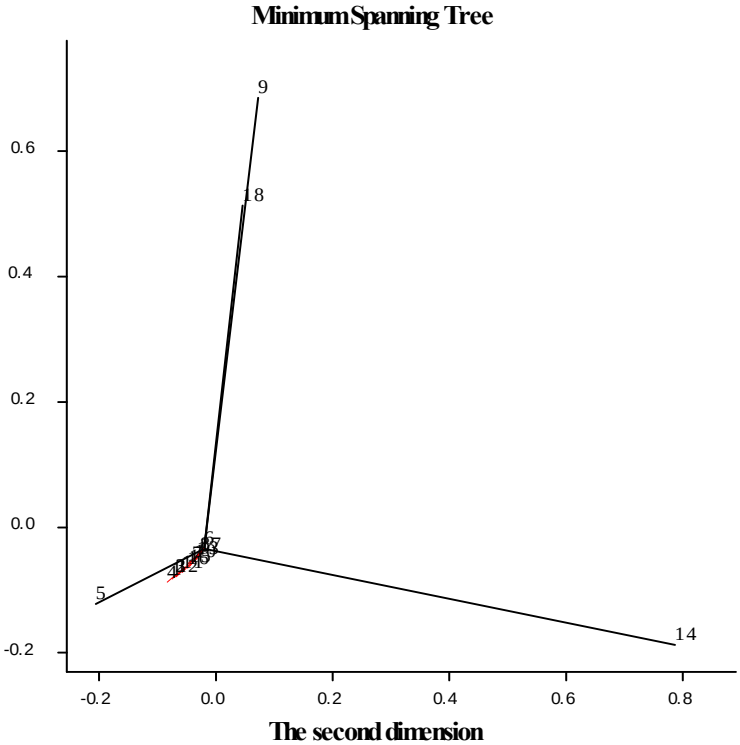

Figure 4. Plot of the first two principal axes from a principal coordinate analysis in twelve environments, in cycle H5. Part of the minimum spanning tree is superimposed on the plot.

Rather than including all seven scatter diagrams of H cycles, the stability patterns of the genotypes are described using centroid distances. According to centroid distances values, genotypes G2, G10 and G14 were the favorable genotypes in cycle H1; genotypes G9, G10

and G14 were the favorable genotypes in cycle H2; genotypes G5, G9 and G18 were the favorable genotypes in cycle H3; genotypes G9, G14 and G18 were the favorable genotypes in cycle H4; genotypes G5, G9 and G14 were the favorable genotypes in cycles H5 and H6; genotypes G1, G2, G5 and G14 were the favorable genotypes in cycle H7. Among these genotypes only G5, G9 and G14 were located four, five and six times in the vertex positions of seven high cycles, respectively and so these genotypes were the most stable and high yielding.

Discussion

Breeder's awareness of the importance of GE interaction has led genotypes to be ordinarily assessed in multi-environment trials for recommendation to farmers or for the final stages of elite breeding material selection. Many complex traits like grain yield are influenced by both genetic and environmental factors but GE interaction has considerable affect on this trait (Yan et al. 2011). The GE interaction makes it difficult to select favorable genotypes that produce high yields and that are more stable in plant breeding programs and reduces the selection progress. The investigation of the GE interaction permits the classification of genotypes by their behavior in two different environmental conditions. There are many statistical methods available to analyze the GE interaction including combined ANOVA, univariate stability analysis, nonparametric methods and multivariate procedures. Combined ANOVA is often used to detect the existence of GE interaction in multi-environmental trials but its main limitation is the assumption of homogeneity of variance among environments needed to determine genotype differences (Annicchiarico, 2009). Among univariate stability analysis, linear regression model was used extensively but it has several limitations from both the biological and statistical points of view.

The principal coordinate analysis seems necessary for an adequate description of the GE interaction, because conventional methods confound GE interaction and main effects and are unable to explain non-linear genotypic response to the environments. This method appears to be able to extract a large portion of the GE interaction and is thus more efficient in analyzing GE interaction pattern in different crops, as demonstrated by Flores et al. (1996), Medina et al. (1999) and Ibanmez et al. (2001). Also the detected most favorable genotypes in both cycles or condition (favorable versus unfavorable) are relatively the most high yielding genotypes and so it seems that this strategy can select the most stable genotypes based on the dynamic stability concept. However in the semi-arid regions and rain fed condition, where fluctuations in growing conditions are unpredictable, additional investigations are needed to obtain an integration of GE interaction analysis with environmental factors.

Multivariate statistical analysis has three main targets; elimination noise in the data set, summarizing the information and reveal a pattern in the data (Gauch, 2006). Methods based on PC analysis, such as AMMI and SREG, are linear-bilinear models with an additive component and a multiplicative component (Gauch et al., 2008). The SREG model is recommended when the environments are the main source of variation in relation to the contributions of the genotypes and the GE interaction with respect to the total variability. Our principal coordinate analysis results are useful for comparing the merits of different crop genotypes, and show which ones are capable of stability across different environmental conditions. Flores et al. (1996) found that both AMMI and principal coordinate analysis procedures obtained equally satisfactory results while Medina et al. (1999) reported that principal coordinate analysis might be more straightforward than AMMI model when there are values that are conspicuously separated from the majority of other values. According to this investigation, for the crop genotypes, the principal coordinate analysis seems necessary for an adequate description of the GE interaction. The present dataset and other similar studies (Flores et al., 1998; Ibanmez et al., 2001) encountered problems, because most conventional

stability models confound GE interaction and main effects and are unable to explain non-linear genotypic response to the environments.

Also, the identified most favorable genotypes in both cycles (favorable versus unfavorable conditions) were the highest yielding genotypes. However in the semi-arid regions and rain fed condition, where fluctuations in growing conditions are unpredictable, additional investigations are needed to obtain an integration of GE interaction analysis with environmental factors. The yield stability refers to a genotype's ability to perform relatively consist across a range of environmental conditions. The stability approaches relate to either of two contrasting concepts of stability as static and dynamic. From dynamic stability concept implies for a stable genotype a response in each test environment that is parallel to the mean response of the tested genotypes. It seems that the results of principal coordinate analysis are mostly associated with the dynamic concept of stability. The development and use of principal coordinate analysis method can enable incorporation of stability in the selection process. There are several methods of simultaneous selection for mean yield and stability performance and relationships among them.

Abstract

The paper presents results of productivity of five Dutch potato white flesh varieties in the mountainous regions of Montenegro (Nikšić, 800 meters of altitude). The experiments were conducted during 2013 and 2014, and following varieties were tested: Arrow, Messi, Volare, Dido and Kennebec. Variety Kennebec was used as a standard. The highest tuber yield in two-year average had variety Messi (37.1 t.ha^{-1}), while the lowest yield was measured in the crop of Kennebec variety (27.3 t.ha-1). Variety Messi had significantly higher yields compared to all other investigated varieties. Variety Messi yielded averagely biggest tubers (109.9 g), and established differences in size of tubers compared with all other varieties are indicated as statistically significant. The largest numbers of tubers in the experiment was determined in varieties Dido (10). Increased the number of tubers in Dido variety in comparison with all others was statistically significant.Higher potato yields were obtained in 2014 (35.1 t.ha^{-1}) as the result of the higher total amount of rainfall during the potato vegetation period and better monthly distribution as well.

Key words: white flesh potato varieties, number of tubers, average tuber weight, yield

Introduction

Potato (Solanum tuberosum L.) is the most important non-cereal crop in the world (http://faostat.fao.org). Potato is one of the most important agricultural cultures in Montenegro as well and it is particularly important for the people in the mountain area of Montenegro. In the structure of production on arable land potato is planted on just over 20% (http://www.monstat.org).

Several thousand of potato varieties exist in the world today, among which varieties with yellow skin and flesh colour dominate. Despite this, the most cultivated varieties in Montenegro are with white flesh, mainly variety Kennebec. Its share in the total area under potatoes until recently accounted for a whopping 60% (Jovović et al., 2013).Although Montenegro is a traditional market of white flesh varieties, there is an evident trend of increased production of yellow flesh varieties in recent years. In addition, popularity of red skin varieties is gradually increasing in recent years as well (Jovović et al., 2013b). Although skin and flesh colour do not affect the quality of tubers, it significantly determines customer interest. Stability of flesh colour after cooking significantly affects its marketability (Momirović et al., 2000).

Despite the extraordinary consumption quality, Kennebec is a very old variety, with a very low genetic yield potential, but also some other problems and it is no longer able to respond to modern trends in this production. All this imposes a totally different concept of development of potato production and increased demand for new varieties.

Some potato varieties have the ability to provide stable yield of tubers in very divergent environmental conditions and in longer terms (Annicchiarico, 2002). That is why the study of

different genotypes of potatoes is of great importance as it is the most reliable way to find varieties best adapted to given environmental conditions (Yang, 2002, and Jovović et al., 2012) able to consistently give high yields in a wide range of environmental factors (Haldavankar et al., 2009).
The aim of this study was that to estimate genetic potential of some new varieties of potato with white flesh colour and compare them with dominant cultivated variety Kennebec in the conditions of the mountain areas of Montenegro.

Materials and methods

The study of productivity of five Dutch white flesh potato varieties was done in 2013 and 2014. Following varieties were studied: Arrow (very early variety) and Messi, Volare and Dido (medium early varieties). Variety Kennebec was used as a standard. The experiments were conducted in Nikšić, at an altitude of 800 m, on acid brown soil.
The study was carried out using field trials in a randomized block design with 4 replications. The plot size was 21 m^2. Planting of potatoes was done manually with 70 cm between row distance and 33 cm within row plant distance respectively, achieving the density of 43300 plants per hectare. Standard agricultural practice for the potato crop was applied. Potato harvesting was done after full maturation of canopy. The potato yield in the experiment was determined by measuring the tubers at each elementary plot, and then the yield per hectare was calculated.

Table 1. Chemical characteristics soil on experimental field

Depth (cm)	Locality	pH		$CaCO_3$	Humus	Soluble mg/100 g	
		H_2O	nKCl	%	%	P_2O_5	K_2O
40	Nikšić	6.57	5.97	1.75	3.05	9.3	17.3

Soil on which the experiments were carried out is characterized by favourable water and air properties and high humus content. This soil is poor in phosphorus and calcium and with moderate potassium content (Table 1).Meteorological data is given in Table 2.

Table 2. Meteorological conditions during the experiments

Locality	Year	Month					Average
		April	May	June	July	August	
Air temperature (^{0}C)							
Nikšić	2013	12,2	14,7	18,8	22,6	23,4	18,3
	2014	10,2	13,7	18,7	19,8	21,0	16,7
	Amount of rainfall (mm)						Total
	2013	194,1	145,0	58,3	36,3	57,7	491,4
	2014	151,2	115,4	165,3	187,7	17,6	637,2

Results and discussion

The results of investigation given in Table 3 show that the largest number of tubers in this study was determined in the cultivar Dido -10, while the lowest number had variety Kennebec - 7. Variety Dido had significantly higher numbers of tubers compared with all other varieties. On the other hand, the variety Kennebec compared to other studied varieties gave lowest number of tubers.

Table 3. Results of the investigation

Parameter	Average tuber number			Average tuber weight (g)			Tuber yield (t.ha^{-1})		
Year (B)	2013	2014	Average (A)	2013	2014	Average (A)	2013	2014	Average (A)
Variety (A)									
Arrow	7.3	9.4	**8.4**	89.5	84.8	**87.2**	28.3	34.4	**31.4**
Messi	7.9	7.7	**7.8**	97.5	122.3	**109.9**	33.4	40.7	**37.1**
Volare	8.9	9.4	**9.2**	84.3	90.5	**87.4**	32.3	36.7	**34.5**
Dido	9.8	10.1	**10.0**	78.3	79.2	**78.8**	33.1	34.5	**33.8**
Kennebec	6.9	7.1	**7.0**	85.3	94.8	**90.1**	25.4	29.2	**27.3**
Average (B)	**8.2**	**8.7**		**87.0**	**94.3**		**30.5**	**35.1**	

	A		B		A*B	
	LSD 0.05	LSD 0.01	LSD 0.05	LSD 0.01	LSD 0.05	LSD 0.01
Average tuber number	0.482	0.661	0.305	0.418	0.682	0.935
Average tuber weight (g)	5.669	7.775	3.585	4.917	8.017	10.995
Tuber yield (t.ha^{-1})	2.156	2.956	1.363	1.870	3.048	4.181

The average number of tubers is a very important parameter of potato productivity. It significantly depends on the number of primary stems formed on one potato plant. It influences the production per plant, and finally the total yield per unit area. According to Bugarić et al., (2000) the high and stable yields gave the varieties forming 10 tubers per plant. Tubers with the highest average weight were measured on variants where variety Messi (109.9 g) was planted. The smallest tubers were found in Dido variety (78.8 g). Analysis of variance of the average tuber weight showed a statistically highly significant increase in mass of the variety Messi compared with all other varieties. Differences in tuber sizes between Dido variety and all other applied treatments were also statistically significant. Tubers size, as well as their number is determined by the number of sprouts that are formed by a single plant. Size is important characteristic of tuber productivity and basically represents a varietal characteristic. However, it dominantly depends on the level of agricultural practices, soil type and weather conditions during the vegetation season. According to Butorac and Bolf (2000) and Jovović (2012b) the higher number of primary shoots gives the higher number of tubers formed, but not their weight, and vice versa. The results obtained are in favour to these conclusions.

Highest potato yield in two years study was obtained in variety Messi - 37.1 t.ha^{-1}, and lowest in Kennebec – 27.3 t.ha^{-1}. High potato yields had also varieties Volare and Dido (34.5 and 33.8 t.ha^{-1}, respectively). Differences in yields obtained between variety Messi and all other varieties were statistically significant. Also, all varieties gave significantly higher tuber yield compared to Kennebec.

In the two years studies, higher average yields of potatoes were measured in 2014 – 35.1 t.ha^{-1} (average yield of potato in 2013 was 30.5 t.ha^{-1}). Among the studied years statistically significant differences in the average tuber yield was found. These results are explained by higher precipitation in 2014 (637.2 mm) and a better distribution of monthly rainfall. Lower rainfall in 2013 in June and July (58.3 and 36.3 mm, respectively) contributed to these results. Given the relatively low average potato yields in Montenegro achieved yields can be considered quite high.

Conclusion

The two-year research results of investigation of productivity of different Dutch white flesh potato varieties in mountainous region of Montenegro allow us to conclude:

All studied varieties of potato had significantly higher tuber yield in comparison with the variety Kennebec that was used as a standard in these studies.

Bearing in mind obtained tuber yields, all four studied white flesh potato varieties can be very reliable substitute to still dominantly cultivated variety Kennebec.

Abstract

The aim of our research was to investigate the content of Mn, Cu and Zn in soil and their effects on mineral uptake and quality of alfalfa and grasses. During 2013 soil (n=28) and plant (n=28) samples from 15 different localities on the territory of Vojvodina province and West Serbia were collected. Soils from these sites can be classified in four soil types: chernozem, fluvisol, arenosol and pseudogley. The total and available (DTPA extracted) concentrations of Mn, Cu and Zn were analyzed, as well as basic soil properties. The above plant mass concentrations of Mn, Cu and Zn were determined and correlated to soil concentration of the analyzed elements and soil properties. The results have shown that most of soils were well supplied with Mn and Cu. However, from the aspects of ruminant nutrition, on some locations plants were not sufficiently provided with these microelements. The concentration of available Zn in soil were sufficient on almost all locations (1.6 mg kg^{-1} under alfalfa and 2.1 mg kg^{-1} under grassland), but analyzes of plant material showed that Zn level was very low in all collected alfalfa (9.68 mg kg^{-1}) and grass samples (8.31 mg kg^{-1}). Thus, certain agricultural methods should be applied in order to increase Zn content in plants used for animal feed.

Key words: *manganese, copper, zinc, alfalfa, grasses*

Introduction

Manganese, copper and zinc are recognized as essential for optimum growth and reproduction of most crops, but they are also vital for livestock and humans (Gupta and Gupta, 2005). For crops, soil is the main source of these elements, but only a small part of the total content is available to plants. The mobility and availability of trace elements are controlled by many chemical and biochemical processes such as precipitation-dissolution, adsorption-desorption, complexation-dissociation, and oxidation-reduction (He et al., 2005).

The soil plant transfer of trace elements is part of a complex chemical element cycle in the nature. The most important factors that affect the availability of trace (micro) elements are: pH and redox potential, soil texture, organic matter-quantity and quality, mineral composition, temperature and water regime, as well as interaction between the chemical elements (Kebata-Pendias, 2004). In their study, Lombnaes and Singh (2003) report that the inclusion of soil parameters like clay content and total concentration in soil, in addition to soil extraction data represent the tool for improving models for simple determination of phytoavailable Zn and Cu.

The interest to quantify the levels of trace elements in cattle forage lies in the importance of micronutrients for animal health and the connection between the quality of forage and the nutritional aspects of cattle health (Moscuzza et al., 2012).

Copper is an important microelement for normal functioning of numerous processes in the animal organism. It is required as a catalytic cofactor of selective oxidoreductases and it is important for ATP synthesis, normal brain development and neurological function, immune

system integrity, cardiovascular health, and bone density in elderly adults (Barker and Pilbeam, 2006).
Manganese plays an essential role in photosynthesis and in catalysing the conversion of free oxygen radicals to hydrogenperoxide as part of the enzyme superoxide dismutase, due to its capability to easily change oxidation states (Hooda, 2010). Manganese deficiency during pregnancy could affect the offspring as irreversible incoordination of muscles, that leads to uncontrolled movements by an animal (Barker and Pilbeam, 2006).
Zinc is a microelement required in low but necesarry quantities and if its available content is not appropriate, plant and animals will suffer from different physiological stress. These stresses are caused by dysfunctionality of several enzyme systems and various disorders of metabolic functions in which zinc has an important role (Alloway, 2008).
The aim of the research was to examine the content of Mn, Cu and Zn in soil, as well as other soil properties and their effects on the uptake and quality of alfalfa and grasses.

Material and method

During 2013 soil and plant samples were collected from 15 different locations on the territory of the Vojvodina province and West Serbia (Kolubara county). From the selected sites, soil samples were taken from under the grassland (n=15) and alfalfa (n=13), as well as appropriate plant material. Soils from these sites can be classified in four soil types: chernozem, fluvisol, arenosol and pseudogley.
Soil samples were collected from the 0-30 cm depth. The pH was measured in a ratio 1:2.5 soil:water and soil:1M KCl suspension. The $CaCO_3$ content was determinated volumetrically using Scheibler calcimetar. The total C content was determinated by the Tjurin method. Available phosphorus and potassium were extracted using the ammonium lactate solution (Egner and Riehm, 1960). The content of phosphorus was determinated by spectrometery and potassium by flame photometer. The total concentrations (pseudo total) of Cu, Mn and Zn were determinated after digestion with HNO_3 and H_2O_2 and the concentration of available microelements in soil after the extraction using the DTPA solution. After digestion or extraction of elements, concentrations were measured by the atomic adsorption spectrophotometer (Shimadzu 6300), with flame technique.
Forage samples were taken at the beginning of May 2013. The above-ground plant mass was collected randomly from the same fields as the soil samples. The samples were digested with a mixture HNO_3:$HClO_4$ and the concentrations of Mn, Cu and Zn were determinated by the atomic adsorpiton spectrometer (flame technique).
The data obtained in the study were processed by the correlation-regression analyses. A statistical analysis was performed by a statistical software STATISTICA 12.

Results and discussion

Table 1 shows the mean value and range of basic properties of soil from different locations in Serbia. On the localities in Vojvodina, soils are with neutral to alkaline reaction, medim to extremely calcareous. On the localities in West Serbia, because the soil type is pseudogley, the soil reaction is extremely acid under the grassland and slightly acid under the alfalfa, with a low content of $CaCO_3$. The average concentrationsof plant available phosphorus and potassium under alfalfa and grasses were on optimum level for plant production. Only on few locations soils were insufficiently rich with these elements.
The world's soils average concentration of Cu is 20 mg kg^{-1}, while Zn varies in the range of 10-300 mg kg^{-1} (Xie and Lu, 2000). Comparing the data presented in Table 2, the Cu concentration was slightly below the world’s average, while the average concentration of Zn corresponds to the world's average. Also, in comparison to previous studies in Serbia, the content of copper is similar to the average results in Vojvodina (17,1 mg kg^{-1}) (Ubavić et al.

1993), while the Zn content varies considerably in relation to the average (60.3 mg kg^{-1}). The average value of the measured total Mn in soil under grassland (629.82 mg kg^{-1}) and alfalfa (610.09 mg kg^{-1}) are above the world's soil mean of 437 mg kg^{-1}(Kebata-Pendias, 2000).

Table 1. Mean and range of basic soil properties

	Soil property					
	pH		Percent		mg $100g^{-1}$	
	H_2O	**KCl**	**$CaCO_3$**	**Humus**	**P_2O_5**	**K_2O**
Soil under grassland						
Mean±SD	7.66 ± 1.18	6.69 ± 1.25	9.69 ± 8.44	2.62 ± 0.72	23.44 ± 18.99	20.87 ± 11.96
Range	5.3-9.4	3.88-7.83	2.49-26.79	1.78-4.62	0.85-57.13	6.50-46.07
Soil under alfalfa						
Mean±SD	7.79 ± 0.89	6.91 ± 1.06	7.93 ± 5.13	2.32 ± 0.71	17.75 ± 11.75	16.65 ± 5.48
Range	5.52-8.37	5.27-7.64	2.08-18.99	1.0-3.22	0.21-41.36	7.29-26.58

In all soil samples the concentrations of available Cu and Mn are above critical concentration of 0.2 mg $kg^{-1}$and 1 mg kg^{-1}, respectively (Lindsay and Norvell, 1978) and therefore at an adequate level to satisfy plant nutrition. Out of 28 analyzed samples, at two sites concentration of available Zn were insufficient, less than 1 mg kg^{-1}.

Table 2. Mean and range of total and available content of the observed microelements

	Micronutrient status (mg kg^{-1}) in the soil					
	Manganese (Mn)		**Copper (Cu)**		**Zinc (Zn)**	
	Total	Available	Total	Available	Total	Available
Soil under grassland						
Mean± SD	629.8±249.3	29.6±32.4	18.7±5.3	8.0±3.0	25.9±6.0	2.1±0.8
Range	232.8-1058.3	1.7-95.8	11.1-37.8	4.4-16.0	19.7-41.2	0.9-4.4
Soil under alfalfa						
Mean± SD	610.1±270.4	29.35±22.93	17.8±6.2	10.9-30.8	25.6±10.0	1.6±0.9
Range	201.0-1193.0	4.82-107.65	6.2±2.3	3.4-12.1	13.8-52.0	0.02-3.8

In previous studies in Vojvodina, measured concentration of Mn, Cu and Zn in alfalfa samples in were 0.1-46 mg kg^{-1}, 0.1-8.3mg kg^{-1} and 0.08-26.3 mg kg^{-1}, respectively.(Čuvardić et al., cited by Manojlović and Singh, 2012). Comparing with the date in Table 3, concentration of Mn and Cu in few alfalfa samples were higher than the defined range. In Serbia, concentration of copper in grass samples varies from 2-12.2 mg kg^{-1}(Danon and Jakoviljević, cited by Manojlović and Singh, 2012). In more then 26% grass sample collected in this research, Cu concentration was higher than 12.2 mg kg^{-1}.

Tabel 3.Mean and average value of Mn, Cu and Zn content in grasses and alfalfa

Micronutrient status in grasses and alfalfa (mg kg^{-1} on dry matter basis)					
Manganese (Mn)		**Copper (Cu)**		**Zinc (Zn)**	
Mean± SD	Range	Mean± SD	Range	Mean± SD	Range
Grasses					
82.59±49.37	25.85-214.79	7.03±1.78	4.74-12.00	8.31±1.70	5.11-11.46
Alfalfa					
38.48±10.14	19.87-53.58	8.54±2.74	0.44-11.93	9.68±1.77	6.55-13.07
Sufficiency levels in livestock feeds (Gupta and Gupta, cit. Manojlović and Singh, 2012)					
Ruminants : 40 mg kg^{-1}		Sheep: 6-10 mg kg^{-1}		Dairy cattle and Bulls :50 mg kg^{-1}	

Frequently, Cu, Mn and Zn levels in crops that are sufficient for optimum crop yield are not adequate to meet the needs of livestock animals (Gupta and Gupta, 2005). The data given in Table 3. in comparison to sufficiency levels for various classes of livestock, has shown that in average, grasses and alfalfa are sufficiently provided with Mn and Cu. However at few sites concentration of these microelements in plant material are lower than the ruminants requirements.

Table 4.Correlation coefficients (R) between soil parameters and plant concentrations (alfalfa+grasses)

Correlation coefficients (R) between soil parameters and plant (alfalfa+grasses)							
	Plant				Plant

			Manganese in plants		x	-0.290	-0.090
			Copper in plants			x	0.236

*Correlation in bold is significant at the 0,05 level

Although soils in almost all locations were well-provided with available Zn, the results have shown that plant content is considerably below cattle needs of 50 mg kg^{-1}. Lindsay (1972) listed nine major factors affecting zinc availability (and hence likely to be related to the deficiency) which included: soils with low zinc content, soil with a restricted root zone, calcareous soils, low organic matter, microbiologically inactive zinc, cool soil temperatures, plant species and varieties, high levels of available phosphorus, and the effect of nitrogen.
Table 4 presents correlations coefficients betwen basic soil properties and the content of Mn, Cu and Zn in grasses and alfalfa, as well as the correlations among the total and available content in soil and the content of these elements in plant material.
Significant correlation was found between Mn content in plants (grasses and alfalfa) and the concentration of available Mn (R=0.484) and total Cu in soil (R=-0.390), respectively. There was no significant correlation between soil properties and Cu and Zn content in plants, except significant negative correlation between Zn content in plants and pH in soil.

Conclusion

The average content of total copper in soil samples under grasses and alfalfa (18.7 mg kg^{-1} and 17.8 mg kg^{-1}, respectively) was slightly lower, while the total concentration of manganese (629 mg kg^{-1} and 610 mg kg^{-1}) is higher in comparison to the world's soil average. The zinc concentration corresponds to the world’s average. Most of the examined soils are well-supplied with available Mn and Cu and from the aspects of ruminant nutrition, plants were insufficiently stocked only in few locations. The concentration of available Zn in soil was sufficient in almost all locations (2.1 mg kg^{-1} under grassland and 1.6 mg kg^{-1} under alfalfa), but Zn content in alfalfa (9.68 mg kg^{-1}) and grasses (8.31 mg kg^{-1}) was very low in comparison to dairy cattle needs. Thus, certain agricultural methods should be applied in order to increase Zn content in plants used for animal feed. There was no significant

correlation between the observed soil parameters and the content of Mn, Cu and Zn in grasses and alfalfa, except few correlation in case of Mn and Zn. Apart from the observed soil characteristics, other soil factors should be included in modeling phytoavailable microelements to grasses and alfalfa.

SPATIAL ANALYSIS OF TEMPORAL TRENDS IN GROWING SEASON LENGTH FOR SERBIA OVER THE PERIOD 1961–2010

Mirjana RUML[1]*, Enike GREGORIĆ[1], Slavica RADOVANOVIĆ[2], Gordana MATOVIĆ[1], Mirjam VUJADINOVIC[1], Ana VUKOVIC[1]

Abstract

The study aimed to evaluate spatiotemporal changes of growing season length (GSL) in response to observed warming in Serbia for the period 1961–2010, using temperature observations from 26 meteorological stations uniformly distributed over the country. GSL was climatologically defined as the number of days between the first span of at least 6 days with Tmean > 5°C and the first occurrence after 1 July of at least 6 consecutive days with Tmean < 5°C. Temporal trends were evaluated by a least-squares linear regression method for each station and for the entire Serbian territory using the average series. Trends were assessed for data spanning the 1961–2010 and 1986–2010 time intervals. It was found that GSL had increased in Serbia, with the greater magnitude in the recent-past. Nationally averaged rate of change was 5.1 days/decade for the entire period and 14.8 days/decade for the period 1986–2010. The greatest increase in GSL was observed at Negotin, with overall trend of 9.7 days/decade and change of 26.7 days/decade over the second half of the observation period. Shortening of growing season was observed only at Pozega, with trends of –1.3 days/decade for the entire period and 3.8 days/decade for the period 1986–2010. In addition, the relationship between the GSL and large-scale circulation features was examined. It was found that the inter-annual variation of GSL was significantly correlated with the East Atlantic (EA) pattern.

Key words: *growing season length, climate change, Serbia*

Intorduction

The globally averaged surface air temperature increased by 0.85°C (0.65–1.06°C) over the period 1880–2012, according to the IPCC (Intergovernmental Panel on Climate Change) Fifth Assessment Report (IPCC, 2013). Most of the warming occurred from 1951 to 2012, with warming rate of 0.12°C per decade. In association with this global warming, the growing season (GS) start, end and length have changed over most of the Northern Hemisphere during the late 20th century (e.g. Pamersan and Yohe, 2003; Linderholm, 2006; Jeong et al., 2011). Extension of GS was mainly attributed to earlier start of GS (e.g. Menzel and Fabian, 1999; Linderholm et al., 2007; Gordo and Sanz, 2010; Irannezhad and Kløve, 2015). Changes in the timing and length of GS may have profound impacts on plant and animal ecosystems (e.g. White et al., 1999; Root et al., 2003; Piao et al., 2007).

There is no universal definition of GS. It can be phenologically defined (e.g. Menzel and Fabian, 1999) and based on developmental stages, such as bud-burst, flowering, leaf unfolding (determining the start of GS), and leaf coloring and leaf falling (determining the end of GS). Since phenological data are scarce in many parts of the world, the normalized difference vegetation index (NDVI) obtained from satellite data is commonly used indicator of phenological dynamics on larger scales (e.g. Tucker et al., 2001). The GS can be also climatologically defined using different thresholds related to climatic conditions in particular area (e.g. Irannezhad and Kløve, 2015). For instance, it can be defined as the period between the dates of last spring frost and first autumn frost. The period with daily mean temperature

(Tmean) greater than 5°C is usually considered as GS for most crops grown in temperate zone. A number of studies based on satellite, meteorological and phenological observations showed evidence of a lengthening of GS in different parts of the world (Linderholm, 2006).
Inter-annual variation in GS has been linked to large-scale atmospheric phenomena in many studies (e.g. Jones et al., 2002; Menzel, 2003; Aasa et al., 2004; Irannezhad and Kløve, 2015). Large-scale atmospheric circulation patterns describe long-term deviations in natural occurrence of chaotic atmosphere behavior. Dominant atmospheric teleconnection patterns in the part of Europe where Serbia is located are North Atlantic Oscillation (NAO), East Atlantic (EA) pattern (EA) and East Atlantic/West Russia (EA/WR) pattern.
This study aimed to spatially analyze historical trends in climatologically defined growing season length (GSL) in Serbia and explore relationships between large-scale atmospheric circulation patterns and GSL.

Materials and methods

Temperature data were provided by the Republic Hydrometeorological Service of Serbia for 26 meteorological stations, quite uniformly distributed over the Serbian territory. Recent data were not available for the Autonomous Province of Kosovo and Metohija situated in the southwestern part of Serbia (Figure 1). The acronym, name, geographical location and altitude of selected station are given in Table 1.
In this study, GSL was defined as the number of days between the first span of at least 6 days with Tmean > 5°C and the first occurrence after 1 July of at least 6 consecutive days with Tmean < 5°C. Temporal trends were assessed by a least-squares linear regression method for each station and for the entire Serbian territory using the average series. The statistical significance of the change was determined using a *t*-test. Trends were calculated for the entire observational period form 1961 to 2010 and for the recent half of the period from 1986 to 2010. Pearson correlation coefficient was computed in order to investigate relationships between the large-scale atmospheric circulation patterns and GSL. The pattern index values were downloaded from the NOAA Climate Prediction Center website (ftp://ftp.cpc.ncep.noaa.gov/wd52dg/data/indices/tele_index.nh).

Results and discussion

The mean GSL and decadal trends for each station over the periods 1961–2010 and 1986–2010 are shown in Table 1. Belgrade was the station with the longest GS over both periods, followed by Kragujevac considering the entire observation period, and by Smederevska Palanka considering recent decades. The shortest GS was observed at the highest stations Sjenica and Zlatibor over both periods. The mean GSL averaged across all station was 267.8 days for 1961–2010 and 274.7 days for 1986–2010. The extension of GS was more pronounced in the more recent period. The greatest increase of GSL after 1985 was observed at Negotin (26.7 days/decade) and Dimitrovgrad (25.9 days/decade) and the smallest at Pozega (3.8 days/decade). The largest trend in GSL over the entire period was recorded at Negotin (9.7 days/decade) and Zajecar (9.1 days/decade), while the smallest, even negataive trend was observed at Pozega (–1.3 days/decade). On average for all station, the increase of GSL was 14.8 days per decade over the last 25 years of the observation period and 5.1 days per decade for the entire period (Fig. 1). Spatial variability displayed for GSL trends had different patterns for two periods (Fig. 2). This can be explained by a decreasing trend in GSL over the first half of examined period at some stations, which resulted in a decreasing trend in GSL averaged across all stations over the same period (Fig. 1). The decreasing trend in GSL at the beginning of observation period can also explain negative overall trend at Pozega, despite increasing trend over the second half of examined period. Dimitrovgrad, having the second highest trend since 1985, was among stations with the smallest overall trend and had

nearly the same GSL over two examined periods (Table 1) for the same reason – a negative trend in GSL at the beginning of observation period. The similar pattern of change, due to cooling trend, was observed at Vranje.

Obtained trend of GSL in Serbia over the period 1961–2010 is in line with earlier results of extension of GS in the Northern Hemisphere, even though been somewhat greater than those reported in previous studies. Menzel et al. (2003) found a lengthening of the climatological GS in Germany during the period 1951–2000, with change rate of 0.11–0.49 days/year depending on the definition used. According to Liu et al (2010), the GSL in China increased by 6.9–8.7 days over the period 1951–2000, depending on the base temperature chosen. Irannezhad and Kløve (2015) reported an increase of GS by 0.30 days/year on national scale in Finland for the period 1961–2011, for GS defined as the period with mean daily temperature permanently exceeding 5°C.

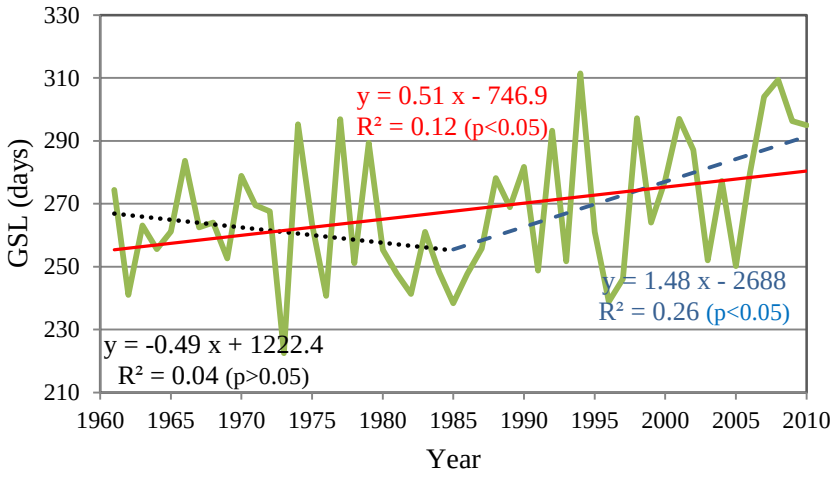

Figure 1. Inter-annual variation of growing season length (GSL) averaged over 26 stations during 1961–2010. The red solid, black dotted and blue dashed lines represent best-fit linear regressions for the periods 1961–2010, 1961–1985 and 1986–2010, respectively.

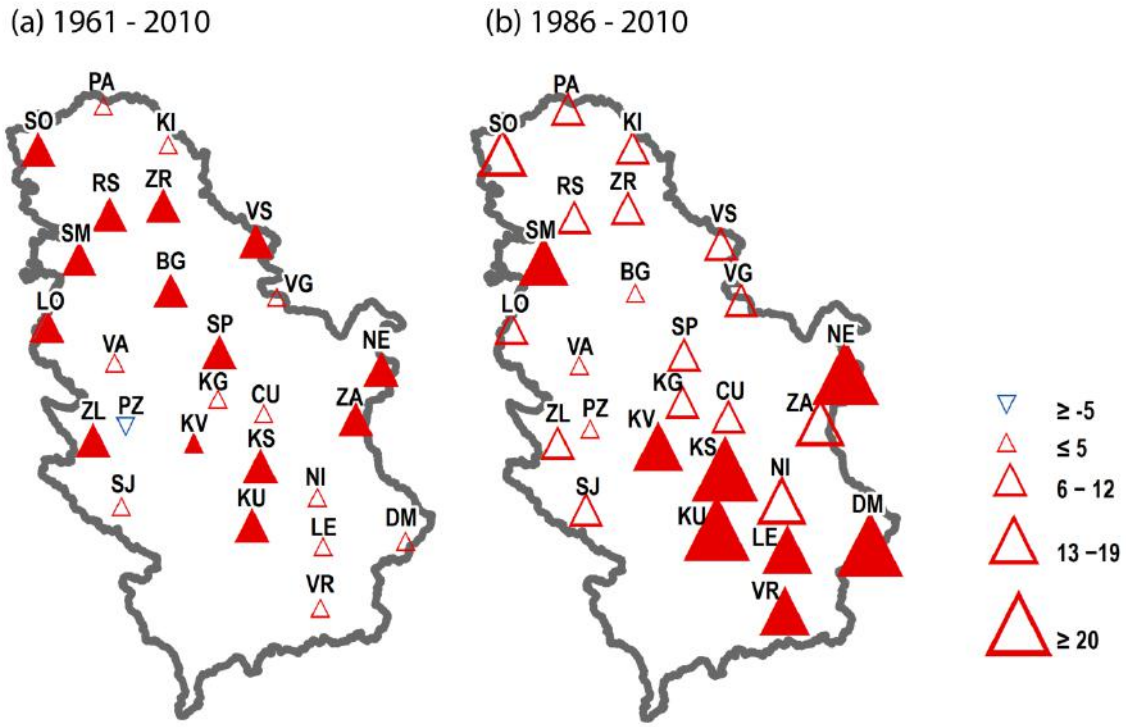

Figure 2. Spatial distribution of trends in growing season length (days/decade) in Serbia over the periods (a) 1961–2010 and (b) 1985–2010. Upward and downward pointing triangles show increasing and decreasing trends, respectively. The filled triangles correspond to statistically significant trends at the 0.05 level.

Results of correlation analysis showed that GSL was significantly correlated only with EA pattern (Fig. 3), considered to be the second dominant teleconnection pattern across the North Atlantic. The positive phase of the EA pattern is associated with above-average temperatures in Europe throughout the year. Significant correlation found between the EA and GSL variability suggests that global warming may not be the only explanation for extension of GS in Serbia.

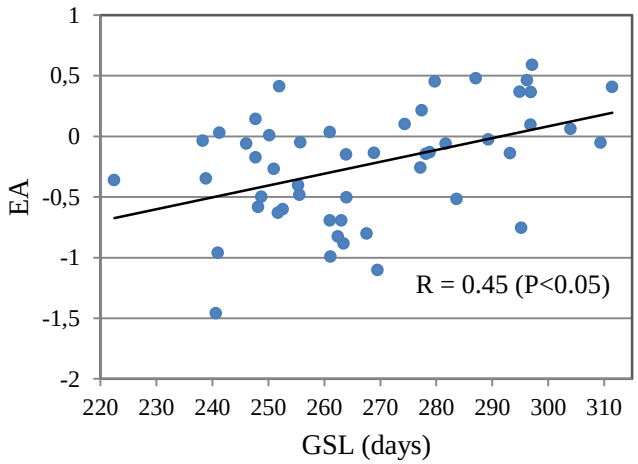

Figure 3. Scatter plot of correlation between growing season length (GSL) and most significant associated large scale circulation pattern East Atlantic (EA).

Conclusion

This study examined trend in GSL and the link to large-scale circulation patterns, using long-term daily mean temperature dataset for the 26 meteorological stations across Serbia. On average for all stations, GSL significantly increased by 5.1 days per decade during the period 1961–2010 and by 14.8 days per decade during the period 1986–2010. Increase in GSL during recent decades was most pronounced in the southeastern part of the country, with the greatest trend observed at Negotin. The correlation analysis revealed that the East Atlantic Pattern (EA) had much stronger association with annual temperature indices than he North Atlantic Oscillation (NAO) and East Atlantic/West Russia Pattern (EA/WR).

Observed lengthening of GS may enhance the potential for crop production and increase crop yields, but may also cause an invasion of weedy and other mobile species, and disturbance of species interaction such as those between plants and pollinators.
