Abstract

Weed management is a major issue in sustainable farming systems. The growing of cover crops is one alternative to herbicides, but using cover crops for weed control without adverse effects on main crop growth is important. The objective of this study was to determine the effect of winter grown cover crops (common vetch, oat and fodder kale) on floristic composition of weed community in sweet maize. The cover crops were sown in two growing seasons on slightly calcareous chernozem (the locality of Zemun Polje) after winter wheat as a previous crop. Plots without cover crops were used as a control: dead organic mulch-soil covered with straw in autumn and winter time, and conventional variant-bare soil uncovered during autumn and winter time. Mowing of the above-ground biomass of cover crops was performed 7-10 days before planting of sweet maize. The estimation of weed infestation in sweet maize was conducted in early July. The average number of species of weeds in sweet maize was from 7.1 and 7.9 (common vetch and dead organic mulch) across 7.8 and 9.6 (fodder kale and conventional variant) to 13.1 (oat). The number of weed plants was also higher in the variant cover crop with oat. However, aboveground fresh and dry weights of weeds had the highest value in control variant in both investigation years. It can be concluded that perennial weeds could be controlled effectively by sowing cover crops in sustainable farming systems in a semi-arid regions.

Key words: *cover crops, dead organic mulch, sweet maize, weed infestation*

Introduction

On the infestation of a crop affect a large number of factors, especially cropping system, weather conditions, soil properties and type of cultivated crops. If a crop is grown in the sustainable and organic agriculture, the problem of weed control is more pronounced. Investigations conducted in countries around the world point to greater diversity of weed community, larger population and higher biomass weed production in these systems compared to conventional production. The most trusted extent of weed control in sustainable and organic agriculture systems is alternative measures and increasing biodiversity in agro-ecosystem. Cultivation of winter cover crops (dead mulch) or spring cover crop (living mulch), in terms of weed control, does not have an alternative. There are potential benefits from winter cover crops growing: nutrient enhancement, soil nutrient capture, soil moisture retention, erosion protection, improved soil structure, disease control, nematode control, increased soil organic matter, etc. But, there are some risks of winter cover crops: additional management and labour, additional expense for seed cost, interference with primary crop establishment, soil moisture depletion (if cover crop actively growing in spring), cooler soil temperatures in spring because of plants on surface, competition with a primary crop, nutrient depletion by non-legumes, nutrient availability not timely for subsequent crop, allelopathic effects on primary crop, etc. Cover crops help control weeds in spring and fall by out-competing them for resources, by not allowing a niche for them to germinate and through

allelopathic compounds. Be aware that all weeds and all weed species will not be controlled, even under ideal cover crop growth. Season-long weed control cannot be expected; early season control of weeds is more likely. Small seeded annual weeds are controlled more than other weeds by cover crops. Cover crop residue can have allelopathic effects that inhibit the germination of some weed species. However, this effect will be more efficient with high amounts of residue.

Weeds in sweet maize, especially in the initial period of growth, can cause significant reductions in crop growth and can cause a decrease in yields of ear by up to 85% (Williams, 2010). Concern about significant weed growth by not using herbicides has limited the adoption of organic methods, such as cover cropping and mulching (Bond and Grundy, 2001). Cover crops have been utilised to reduce weed management costs, as well as to enhance soil characteristics (Fageria et al., 2005). Some producers of herbicides indicate their phytotoxic influence on the sweet maize plants. In these situations, efficacy of mowed or desiccated mulch to manage weeds seems to depend most on soil coverage and its effect on light interception, rather than on the effects of altered moisture or temperature regimes, allelopathy or mechanical impedance (Liebman and Davis, 2000). Ground cover greater than 50% results in a roughly exponential increase in weed suppression.

Winter cover crops are best adapted to areas with a long enough time period to establish in the fall and without soil moisture deficits in the spring. The first step in selecting a cover crop species is to determine the main goal of the cover crop. Many organic producers select cover crops to add nitrogen, control weeds, protect soil, and/or to increase soil organic matter. There are two main categories to consider cover crops that over-winter and regrow in the spring, and those that do not. In northern climates, many cover crop species will not survive the winter. Winter rye and hairy vetch are cover crops that have the best potential to overwinter. Oat planted in the fall is an example of a cover crop that will winter kill. Producers will need to choose if overwintering is a desirable winter cover crop characteristic. Leguminous cover crops will provide nitrogen to subsequent crops. This nitrogen can increase yield in sweet maize. Red clover and hairy vetch are the best choices.

Boydston and Al-Khatib (2006) reviewed *Brassica* cover crops and weed management. They focused on allelopathy as the mechanism responsible for weed suppression and the hydrolysis products of glucosinolates as the source of allelochemicals involved. Glucosinolates are secondary plant metabolites which have demonstrated a biological activity against weed seeds, pathogens, insects, and nematodes (Chew, 1988).

Paper aimed at comparing the effects of different cover crops systems with those of conventional weed management methods for weed suppression of sweet maize.

Material and Methods

Two-year trials were carried out on chernozem in the experiment field of the Maize Research Institute, Zemun Polje, in the vicinity of Belgrade (44°52'N 20°20'E). The soil was slightly calcareous chernozem with 47% clay and silt, and 53% of sand. The soil properties in layer 0–30-cm depth were fallow: 3.22% organic matter, 0.19% total N, 1.9% organic C, 16.2 and 22.4 mg per 100 g soil of available P_2O_5 and extractable K_2O, respectively, 1.38% total $CaCO_3$ and pH 7.3. The four-replicate plot was set up according to the randomised block design. The elementary plot size amounted to 16.8 m^2 (2.8 m by 6.0 m). The following factors were included into the studies performed under rain fed conditions:

(A) – different species of cover crops

(B) – year investigation.

The experiment included three kinds of *winter cover crops* (common vetch, oat and fodder kale), another variant in which the land was covered with dead organic mulch, and traditional

variant, classical ploughing in the fall and keeping bare land uncovered during the winter. All of the varieties being used as cover crops belong to Novi Sad Field Crops Institute.
Winter wheat was a preceding crop. The experimental plots being ploughed in the autumn have followed one pass of a disk harrow and a field cultivator prior to sowing. Sowing of cover crops was done manually in October 14, 2011 and November 02, 2012. Fallowing nitrogen fixation rates in legume crops, as well recommended fertilization, we came up to the required amount of macronutrients for sweet maize (120 kg ha^{-1} N, 90 kg ha^{-1} P_2O_5 and 60 kg ha^{-1} K_2O). In the fall period, before planting of cover crops, we have entered the entire amount of P and K in the forms of monopotassium phosphate plus additional quantity of nitrogen 50 kg ha^{-1} by ammonium nitrate, and on the two control variants, also all of P_2O_5 i K_2O and 40 kg ha^{-1} N in the form of AN. In the next spring (April 04, 2012 and April 09, 2013), leguminous cover crop had received another 30 kg ha^{-1} N in the form of AN (remaining 40 kg ha^{-1} considered to be provided by nitrogen fixation), oats an fodder kale 70 kg ha^{-1} N, and control plots another 80 kg ha^{-1} N, also in the form of AN.

Mowing the above-ground biomass of winter cover crops was performed 7-10 days before planting or sowing of sweet maize. Sweet maize was sown in density of 65.000 plants ha^{-1}. The inter-row distance was 70 cm, while within-row plant distance was 22 cm. The new Zemun Polje (ZP) sweet maize hybrids ZP 441su (FAO maturity group 400) was sown. Planting of sweet maize seedlings was done on May 21, 2012, and sowing was done on April 25, 2013.

The floristic composition, number of species, number of plants per species, fresh and air dried weed biomass in sweet maize were analysed in this study. All stated parameters in weeds were determined by the one square meter area method. The weed infestation estimation was performed on July 10, 2012 and July 04, 2013. The estimation time was determined on the basis of the actual crop performance that was particularly affected by weather conditions during the years of investigation. Following the estimation, hoeing was done with the aim of suppressing the weeds in cover crops.
Obtained data were statistically processed by the analysis of variance, in which plant cover crops and years of investigation were factors, while LSD test was applied for the individual comparisons (Gomez and Gomez, 1984).

Meteorological conditions

Table 1. Average air temperatures and precipitation sums from April to September at Zemun Polje

Months	Temperature (°C)		Precipitation (mm)	
	2012	2013	2012	2013
April	14.4	14.9	67	22
May	17.9	19.8	128	104
June	24.6	21.7	14	49
July	27.1	24.1	39	3
August	26.2	25.4	4	44
September	22.0	17.3	31	59
Average/Sum	22.0	20.5	283	281

The meteorological conditions during the sweet maize growing season are presented in Table 1. In the growing season of 2012, there was a crop failure because of extreme drought and high temperatures. In the 2013 growing season was the similar in a total cumulative precipitation, but it was better distribution. The second year of study, regarding the meteorological conditions, was similar to the previous one and the difference was in slightly lower air temperatures at the beginning of the growing season of the crop and increased rainfall in July, which had a negative impact on yield, but not on the weediness of maize and soya bean.

However, precipitations in June were very important for sweet maize crop. Most precipitation occurred in May (104 mm), which had a significant influence on the initial growth of investigation crop and increasing competitiveness against weeds.

Results and discussion

Representative conclusions about the effects of different cover crops and meteorological conditions on the floristic composition, number of species, number of plant per species, fresh and air dried weight of weeds in sweet maize are obtained by the insight into the results shown in Tables 2, 3 and 4.

The most abundant weed species in the summer aspect of sweet maize were *Sorghum halepense* L. Pers., *Datura stramonium* L., *Chenopodium album* L., *Amaranthus hybridum* L., and *Solanum nigrum* L. and significant places in weed synusia were taken up by *Amaranthus retroflexus* L., *Amaranthus albus* L., *Convolvulus arvensis* L., and *Hibiscus trionum* L., which was also found in the same crop and locality (Simic et al., 2012).

L.f.-life forms: T-therophytes, G-geophytes; 1-common vetch, 2-oat, 3-fodder kale, 4-dead organic mulch, 5-conventional treatment

Generally, the greater weed infestation can be observed in the first year of the investigation and the reason for the worse weather conditions, especially high air temperatures and unfavourable distribution of precipitation which corresponds to more resistant weed species. Differences in measured parameters of weediness depending on the year investigation were not statistically significant, except for the number of weed species (Table 5). The greatest number of weed species was declared in 2012, and most weed plants and the highest fresh weight of weeds owing to favourable weather conditions in 2013. Thus, favourable meteorological conditions are suitable for growth and development, both endangered, and all other species in agro ecosystems. The dead organic mulch (straw) is justified in sustainable systems of cultivation of sweet maize, primarily in terms of grain yield (Dolijanović et al.,

2012). However, from an infestation, especially perennial species, the advantage is on the side of growing cover crops (dead mulch). The number of species and number of plants per species in this variant is similar to the number in cover crops, but fresh weight mass shows us a strong presence of perennial weeds. In addition, on this plots, after the decomposition of organic matter, there is enough space and light for regular and vigorous weed growth.
If you look at the impact of investigation kinds of cover crop on the infestation of the main crops we notice that in both years the best result given common vetch, in terms of number of species, number of plants per species and especially in respect of fresh weed biomass per unit area (Tables 2 and 3). In all tested parameters, weeds in both investigation year significantly lowest values are obtained if the cover crop was common vetch. The next crop was winter fodder kale, while winter oat showed the weakest effect, especially in terms of the number of weed species and the number of plants per species. In earlier paper, it was emphasized that in terms of reducing the infestation of the main crops, oats gives the poorest results and generally it should be grown in mixtures with legumes (Dolijanović et al., 2013). The differences investigated parameters of weeds in sweet maize cultivated after cover crops, compared to traditional cropping system are generally statistically significant (Table 4).
On the investigated locality, alternative farming systems (intercrops and cover crops) showed efficacy in reducing weed infestation, particularly the number of plants per species and weed fresh weight per unit area (Dolijanović et al., 2007; 2008; 2013).

Values of means followed by the same letter are not significant at the level of 0.05;

Observing the two control variants (dead organic mulch and conventional treatment) in both years, based on data in Table 4, we see a number of weed species, weed plants and especially higher values in the fresh weight of weeds in the conventional system in relation to the dead organic mulch variant. Thus, the mulch system in sweet maize is more favourable in terms of reducing the number of species, number of individuals, especially in terms of fresh weight of weeds. Increasing the biodiversity and number of crops in year per unit area, as in cover cropping, leads to a reduction in the biomass of weeds.

Table 5. Statistical analysis of observed weed parameters in sweet maize (lsd)

lsd	Total number of weed species			Total number of plants per species			Aboveground fresh weight of weeds			Aboveground dry weight of weeds		
	A^{**}	B^{**}	AB^{ns}	A^{ns}	B^{*}	AB^{ns}	A^{ns}	B^{**}	AB^{ns}	A^{ns}	B^{**}	AB^{ns}

Conclusion

Based on results, obtained effects of the cover crops on weed infestation of sweet maize grown on chernozem under rain fed conditions, the following can be concluded:

The weed community was composed of a relatively small number of weed species and number of plants per species–11.6 and 19.5 (2012) and 6.6 and 17.5 (2013). The dominant weed species in the summer aspect of sweet maize were *Sorghum halepense* L. Pers., *Datura stramonium* L., *Chenopodium album* L., *Amaranthus hybridum* L., and *Solanum nigrum* L. and significant places in weed synusia were taken up by *Amaranthus retroflexus* L., *Amaranthus albus* L., *Convolvulus arvensis* L., and *Hibiscus trionum* L.

Differences in the number of weed plants per species, as well as in fresh and air dried weed biomass obtained among observed investigation years were not statistically significant.

The cover crop with common vetch expressed greater efficiency in weed control (number of species, number of plants per species and weed biomass) in comparison to different cropping systems. All differences in the investigations parameter of weeds in comparison with conventional and mulch cropping system was very statistically significant.

The system of cropping cover crops under rain fed conditions before sweet maize expressed a significant advantage in weed control particularly in troublesome perennial species in relation to traditional cropping system of sweet maize.

Abstract

The effectiveness of alcoholic extract of Oak gall and Neem seeds on the integrity of eggplant seeds was examined. Five different seed samples were collected from the northern provinces of Iraq and used in this study. The result of our examination showed presence of various fungi including *Aspergillus, Aurobasedium, Botrytis, Cladosporium, Fusarium, Phoma* and *Rhizoctonia* in the examined seeds and roots samples. Isolation rate of fungi ranged from 1% to 17%. Fungi that were isolated from studied roots included *Alternaria*, *Botrytis, Chaetomium, Cladosporiu, Drechslera, Fusarium, Geotrichum, Macrophomina, Phytophthora, Pythium, Rhizoctonia, Sclerotium* and *Stemphyllium*. Alcoholic extract of Oak gall showed inhibitory effect of 8% and 10% against *F. oxysporum* and *F. semitectum* respectively. Whereas, Alcoholic extract of Neem seeds showed inhibitory effect of 64% and 61.77% against *R. solani* and *F. oxysporum*, respectively. The soil-borne fungus *Trichoderma harzianum* showed an antagonistic activity, and it had antifungal effect against several pathogenic fungi, especially *F. solani*, with antibiosis level of 1.66. *Bacillus subtillis* also showed high inhibitory activity of 100% against *F. semitectum* and 92.66% against *F. solani*.

Key words: *Eggplant, Biological Control, Fungi, Neem, Oak gall*.

Introduction

Biological control is an effective method against diseases transmitted by seeds. It is well known that, this method positively affect the activity of most microorganisms, and it improves soil conditions and sustainability of agriculture (Papavizas and Lewis, 1989). Biological control method is also proven to cause no harm to environment, and it reduces human health risks. It is believed that, Eggplant, *Solanum melongena L*., is originated in China and India. It grows as a wild plant (Chen and Li, 1996), and it usually needs a warm climate for growth. Generally, eggplant is economically important vegetable crop, and it ranks third after potatoes and tomatoes in terms of world production. The plant is cultivated in tropic and subtropics region of Iraq, and the total area of planting is 21,665 ha and production is 24,321.84 kg /ha (anonymous, 2001) .The plant is grown seasonally in open fields in spring, to produce fruit during summer months and autumn. Due to its importance and increased demand in winter and early spring, cultivation of this crop in protected facilities began in 1980s in Iraq to enhance and extend its production capacity (Bozorgi, 2012). The available information on the most producing countries of eggplant in descending order are: China (18 million tons), India (8.4 million tons), Egypt (1.2 million tons), Turkey (813 thousand tons), Indonesia (389 thousand tons), Iraq (380 thousand tons), Japan (371 thousand tons), Italy (321 thousand tons), and Sudan (230 thousand tons) (FAO, 2008). However, eggplant is susceptible to many diseases, particularly fungal infections. Seeds play a vital role in transferring and spreading of these diseases. The damaging effect of diseases to crops, and massive economic loss as a result was indicated in a previous study, where the study stated a substantial economic loss (up to100%) which was related to vascular wilt diseases (Alabouvette *et al*., 1996).

This study aimed to investigate seeds and roots diseases of eggplants that were collected from three Northern provinces in Iraq, and to determine the efficiency of two different biological methods in controlling of such diseases.

Material and methods

Isolation and diagnosis of fungi associated with seeds:

Five samples of eggplant seed lots were collected from several local companies and farmers in three provinces Akrae in Dohuk, Erbil, and Koya in Sulaimani (Iraq).

The samples were kept in polyethylene bags in the refrigerator at 5°C until use. Fungi were isolated from seeds using agar plate method that was described by the International Seed Testing Association (ISTA, 1976). A 200 seeds were surface-sterilized by immersion in 1% sodium hypochlorite (NaOCL) for three minutes. Distilled water was used to wash the seeds thoroughly, and then seeds were dried between two layers of the Whattman filter paper. The treated seeds were distributed in separate dishes. Each ten seeds were placed in a dish containing 15 ml of PDA with streptomycin sulfate (50 mg /L).Plates were kept at 25°C for 12 h under light and 12 h under dark regime for one week. After the incubation period, plates were examined for the presence of fungal growth, and the detected fungal colonies were identified according to (Booth, 1971; Toussaun and Nelson, 1976; Pitt and Hocking, 1997; Leslie and Summerell, 2006). The isolated colonies were purified by using single spore or hyphal tip technique, and preserved on PDA slant at 5°C until used.

Isolation and diagnosis of fungi associated with roots:

Several field-infected plants were transferred to Plant Protection laboratory at the Faculty of Agriculture, University of Salahaldeen. Isolation of fungi from the infected plants was performed according to the method described by Agnihorti, (1971). Following a week of incubation, the colonies were examined and prepared as mentioned in the preceding paragraph and preserved on PDA slant tubes at 5°C.

Pathogenicity of isolated fungi:

Pathogenicity of the isolated fungi from the infected seeds and seedlings was tested. The PDA medium was used for cultivation of fungi, and cultivated plates incubated at 25°C°+2. The grown fungi colonies were used in inoculation of sandy loamy soil. For this experiment 2 kg sandy loamy soil was used. The soil then inoculated with the fungi colonies grown on one half of the PDA plate. The added fungi growth mixed thoroughly with the surface layer of the soil (Saydam *et al.*, 1973). Following mixing, the soil distributed in 1% formalin sterilized 20 cm-diameter pots. The experimental pots were placed in the canopy of wood for three days. Eggplant seeds that had been obtained from Erbil were used for the experiment at rate of 10 seeds per pot. Prior to spreading of seeds on the pots, seeds were sterilized with 1% sodium hypochlorite solution for three minutes. After sterilization, the seeds washed with sterilized distilled water, and spread on contaminated soil.

Biological control: a) Plant extracts:

Two types of forest tree extracts were tested to assess their effectiveness against pathogenic fungi. Oak gall was obtained from Akrae, and Neem seeds were obtained from Sami Abdul Rahman Park in Erbil. Both Oak gall and Neem seeds washed with distilled water, and then placed on a filter paper at room temperature to dry. Each dried plant was kept in a labeled polyethylene bag until use.

A twenty gram of each oak gall powder and Neem seed powder was separately added to 200 ml of 95% ethanol in 400 ml flasks. The mixtures left in shaking condition in water bath (Karlsruhe Company-Germany) for 1 hour, and then kept in refrigerator at 4ºC for 24 hours. The extract was filtered through two layers of gauze, filtrate placed in a petri dish and left to dry at room temperature. The alcoholic plant extracts then collected in glass bottles and stored at -20ºC in deep freezer until use (Alnoman, 1998).

One gram amount of alcoholic extract was added to 5 ml of dimethyl sulfoxide (DMSO) (BioSolve BV, Netherlands). The mixture then filtered using Millipore filters (0.2 micrometer). A 10 mg /ml of the above substance were added to 500 ml sterile PDA medium, and the medium poured into sterile glass petri dishes. The same procedure was followed in preparation the other concentrations (8, 6, 4, and 2 mg /ml). Freshly prepared disc (0.5 cm diameter) of pathogenic fungal colonies was placed over the prepared plates. Each treatment was repeated three times, control containing medium without alcoholic plant extract was also included in the experiments (Riso *et al*, 1987).

b) With fungi and bacteria: Antagonism activity test carried out by using the bio-agent *T. harzianum* against pathogenic fungi that were grown on PDA plates. The plate was divided into two parts, a disk (0.5 cm diam.) containing colonies of *T. harzianum* was placed on the first half of the medium. While another disk (0.5 cm diam.) containing colonies of pathogenic fungi was placed on the second half of the medium. The distance between both microorganisms was almost 4 cm. The experiment repeated three times. Control was also included in the experiment, where, *T. harzianum* was used to inoculate a centre of a medium plate, and a disk containing pathogenic fungi was used to inoculate a different plate. The results obtained after a week of incubation at 25ºC, and evaluated according to Bell *et al.*, (1982).

Antagonism test of *Bacillus subtillis* against fungal pathogens:

Each PDA plate was inoculated with 0.5ml of *B. subtillis* at rate of 2.5×10^8 cfu/ml. The bacterial culture was grown in a nutrient broth at 37 ºC for 24 hours, and 0.1ml of a fresh culture aseptically spread on the surface of the plate. Inoculated disks with fungal cultures were placed at the center of PDA plates, and plates were incubated at 25 ºC. Experiment for each fungi culture was repeated three times. Results of grown fungal colonies on plates were recorded and the ratios of Qatrin perpendicular and the percentage of inhibition were calculated. Generated data was statistically analyzed using the Statistical Analysis System-SAS (Anon, 2005), and validated by Duncan’s multiple range test.

Results and discussion

Isolation and diagnosing of fungi associated with seeds

The testing result of seeds integrity of five eggplant samples that were obtained from Erbil, Dohuk, and Sulaimani is shown in (Table 1).

Table 1. Fungi isolated from the seeds of eggplants

Governorates	Fungi	%Isolation	% Frequency
Erbil	*Aspergillus spp*	3	27.3
	Phoma sp	1	9.1
	Rhizoctonia solani	7	63.6
Sulaimani	*Aspergillus spp.*	5	100
Dohuk	*Aspergillus spp*	4	57.1
	Botrytis cinnerea	3	42.9
Akrah	*Aspergillus spp*	2	20
	Aurobasidium pullulans	1	10
	Cladosporium cladosporioides	1	10
	Fusarium oxysporum	1	10
	Fusarium solani	1	10
	Rhizoctonia solani	4	40
Koya	*Aspergillus spp.*	3	100

The table shows that *R. solani* was found in 7% of examined seeds, with the highest rate (63.6%) of frequency which was recorded in seeds collected from Arbil. This finding is agreed with the findings of (Ismail, 2010), who indicated isolation of fungi from eggplant

seeds. In addition to *R. solani*, *Aspergillus* sp. was also found, and the later fungus presence was recorded in all examined samples at a range between 2-5%. The highest debut (100%) was found in seeds obtained from Sulaimani, and the lowest (20%) was found in seeds obtained from Akrae. A similar result was showed in a previous study by (Al-Kassim and Monawar, 2000), who also stated isolation of these fungi from seeds of eggplant. Moreover on fungal isolation from eggplant seeds, *F. oxysporum* was also isolated from the seeds obtained from Akrae at rate of 10%. A similar result regarding isolation the latter fungi from seeds were also reported by Ismail (2010). However, it is noteworthy to mention that *F. oxysporum* can cause a significant loss in production through causing diseases such as wilt disease. Symptoms of the disease usually occur on mature plants and unilateral gestures. Yellowing may appear on one side of infected plant then extend to all parts followed by wilt (Siva *et al*., 2008).

In a recent study, researchers were able to isolate both *F. oxysporum and F. solani* from seed embryos of eggplant (Habib et al., 2007). The occurrence of *F. solani* in soil is common, and contaminated seeds are the main route of transmission. This fungi can cause root rot diseases and stem ulceration in various plants (Gordon, 1960), and it considered one of the most dangerous pathogenic fungi that can cause wilting (Chakraborty and Chatterjee, 2008).

Isolation of fungi from roots of eggplant:

Our data in Table 2 shows presence of *Fusarium* sp. in all samples that were collected from all studied sites in the regions of Erbil with repetition rate of 66.66%.

Table 2. Fungi isolated from the roots of eggplants in areas of the province of Erbil

- Non-appearance of fungi. Isolation, ** Freq. = Frequency. =Iso. = *

However, information of the conducted field survey demonstrated isolation of *F. solani* from several studied sites especially in Shmamk, Khabat, and Ainkawa at rate of 4.76%, 3.57%, and 1.47% respectively. In addition to what we have explained earlier, as these fungi are commonly found in soil and can be transmitted through seeds, they can also penetrate plants through wounds on lateral roots or through the exposure to undesired conditions. Because its parasitic nature, it can cause root-rot diseases to many plants (Gordon, 1960), and

subsequently the infected plants develop symptoms such as taproot and lateral roots browning. The later description of fungal root infection was also indicated in another study were the researchers stated that, the infection that had been occurred in the root reflected first on the aerial parts then yellowing and drought without discoloration of the vascular vessel (Ahmad and Al-Moussalli, 1987). In addition to *Fusarium* sp., *R. solani* was also isolated from all of the surveyed sites with the highest incidence found in Ainkawa 22.05%, Khabat 17.85%,and Shmamk9.52%. However, its occurrence may due to the contamination of soils in these sites with this fungus, which is considered as one of the most causal agent of rot and seedling death to its wide range host that may exceed 230 plant species. Especially when we conclude that, *R. solani* can remain in the case of vegetative growth in the wet soil for the rest of the year (Parameter,1970).However, during infection process; the fungi affect seeds and seedlings in the soil before and after emergence.At the final stage, the disease attacks the roots and aerial parts of affected pots, fruits, leaves and stems (Anne et.al, 2002).

Pathogenicity of fungi isolated from eggplant:

Seed rot and seedling death of eggplant.

Results regarding seed rot and seedling death of eggplant collected from the region of Erbil are shown in Table 3.

Table 3. Effect of some fungi isolated from seeds and roots of eggplant rot in the Pre-emergence damping-off and seedling death Post-emergence damping-off of seeds obtained from the province of Erbil

Fungi	% Pre- emergence damping–off	%Post- emergence damping–off	% Survival plants
Control	13.3 b	3.3 de	83.3 a
Alternaria alternata	26.7 ab	6.7 cde	66.7 ab
Drechslera spp.	33.3 ab	10.0 bcd	56.7 abcd
Fusarium compactum	43.3 ab	10.0 bcd	46.7 abcd
F. miscanthi	36.7 ab	0.0 e	63.3 abc

Rhizoctonia solani	43.33 ab	36.33 a	20.33 d

Numbers that bear similar letters do not differ significantly at 0.05 probability level using Duncan multiple range test (vertically) .* Each number represents the average of three replicates

F. solani and *F. oxysporum* were the most virulent fungi isolated from seeds at rate of (63.3%) without showing any significant differences between the species of fungi except control treatment. Our result also shows contribution of *F. semitectum*, *F. copactum* and *R. solani* in causing seed rot that reached 53.3% and 43.3 % respectively. However, *A. alternata* caused pre-emergence damping-off at less extent 26.7%. And, *R. solani*, *F. miscanthi*, and *F. solani* caused the post emergence damping-off at rate of 36.3%, 16.7%, and 13.3% respectively. Meanwhile, *F. miscanthi* did not cause death of seedlings and the surviving percentage of the infected plants with *F. miscanth* was 63.3%, which indicates a weak pathogenicity of these fungi. While, surviving percentage the infected plants with *R. solani* reached 20.3%, which refers to high pathogenicity.

Biological Control

Effect of alcoholic extract of Oak galls on fungal growth:

The effect of alcoholic extract of Oak gall in inhibition growth of pathogenic fungi is shown in Table 4.

Table 4. Effect of alcohol extract of oak galls in the growth of *Fusarium* species pathogenic to eggplants

Pathogenic Fungi	Control (Cm)	Concentration				
		2%	%4	6%	8%	10%
		%Inhibition				
F. compactum	7.3 a *	28.4 a	46.7 a	52.3 a	55.7 a	61.4 a
F. miscanthi	6.2 b	35.1 b	50.0 b	60.9 b	62.2 b	64.9 b

Numbers that bear similar letters do not differ significantly at 0.05 probability level using Duncan multiple range test (vertically). * Each number represents the average of three replicates.

The inhibition rate of the extract at 10% concentration against *F. compactum* found to be 61.4% with no significant differences between the treatments and the control plants. On the other hand, testing the impact of alcoholic extract of Oak gall on *F. miscanthi* showed the highest inhibition rate of 10% of the extract was 64.9%, and the lowest inhibition rate of 2% of the extract was 35.1%. When the influence of Oak gall extract was tested against *F. oxysporum*, a significant inhibiting action (100%) of the extract on the fungus was obtained. Although, there were no significant differences among the concentrations used, but a difference was found between control plates and the extract at 2% concentration, where the lowest inhibition rate 76.6% was observed. Moreover, the 10% alcoholic plant extract also had a significant inhibition action (100%) on the growth of *F. semitectum*. Meanwhile, the 2% extract showed the lowest inhibition rate of 62.5% with no significant differences among tested concentrations. The differences were only found with the control. However, *F. solani* was found to be the most susceptible to the plant extract treatment. Similar conclusion was also stated by Yamunarani, *et.al*.,(2005),who indicated inhibition of fungi growth by protein extracted from Oak. Söhreto *et al*., (2007) also mentioned the impact of alcoholic extract of Oak galls on mycelium growth of these pathogenic fungi.

Effect of alcoholic extract of Neem seeds on fungal growth:

The effect of alcoholic extract of Neem seeds in inhibiting growth of pathogenic fungi is shown in Table 5.

Table 5. Effect of alcoholic extract of neem seeds in inhibition the growth of *Fusarium* species pathogenic to eggplants.

Pathogenic Fungi	Control cm	Concentration				
		2%	%4	6%	8%	10%
		% Inhibition				
F. compactum	7.33 a*	14.7 a	27.28 a	30.7 a	46.7 a	53.5 a
F. miscanthi	6.16 b	17.5ab	17.53 a	22.9 ab	44.6 a	58.1 a
F. oxysporum	6.75a b	44.4 b	48.14 b	48.1 b	55.6 a	61.8 a
F. solani	7.33 a*	9.8 ab	27.28 a	26.5 ab	50.0 a	60.1 a

Numbers that bear similar letters do not differ significantly at 0.05 probability level using Duncan multiple range test (vertically).* Each number represents the average of three replicates.

The inhibition level of alcoholic extract of Neem seeds on *F. solani* was found to be 64.0% with no significant differences between treatments. A similar finding was also indicated by other researchers (Carpinella *et al*., 2003). Increasingly, *F. oxysporum* was also negatively impacted by this seed extract; the inhibition level was 61.8%. The highest inhibition level was observed at concentration of 8 and 10%**.** This particular result was in contrast with the result obtained by Hassanein *et al*., (2008) who found the inhibition rate of Neem plant extract at

20% concentration on the growth of *F. oxysporum* and *F.solani* to be 7%. But the inhibition rate of the same concentration on the growth of *F. semitectum* was 60.1%. The impact of 8 and 10 % extract concentration was found to be significantly different from the rest of the treatments. On the impact of the extract on the growth of *F. miscanthi*, the extract's inhibition rate was 58.1% with no significant differences between all treatments. Effectiveness of the alcoholic extract of Neem seeds may be attributed to its content of paraisine, which is one of the alkaline substances that inhibit fungi growth. It may also due to its combination with the dynamic biological processes, including the precipitation of the amino acid in the proteins synthesis (AL-Rawi and Chakravaraty, 1964). Another reason it could be containing materials effective against fungi including Vanillin and 4-hydroxy-3- methoxycinnam aldehyde and Pinoresinol (Carpinella *et al*., 2003).

Biological control using bacteria and fungi:

Efficiency of *Trichoderma harzianum* against pathogenic fungi.

The result presented in Table 6 indicates the high antagonism ability of *T. harzianum* against pathogenic fungi that infected eggplants.

Table 6. The efficiency of biocontrol *Trichoderma harzianum* against fungal pathogens of eggplants

Fungi	Degree of Antagonism *
Alternaria alternata	**2.3
Drechslera spp.	**2.00**
Fusarium compactum	**2.2**
Fusarium miscanthi	**2.0**
Fusarium oxysporum	**2.0**
Fusarium semetictium	**2.0**
Fusarium solani	**1.7**
Rhizoctonia solani	**2.3**

* World peace quintet Bell *et.al*., (1982). ** Each number represents the average of three replicates.

The antagonism level against *F. solani* found to be 1.7 degree, followed by *Drechslera* spp. Our results were in line with the results observed by other researchers, (Küçük and Merih, 2003) emphasized the ability of different bio- control such as *T. harziurum* in inhibiting growth of *Drechslera sorokiniana, F. oxysporum* and *R. solani*. In regard to *F. miscanthi, F. oxysporum* and *F. semitectum* the degree of antagonism level was found to be 2.0, while the degrees of antagonism against *A. alternate , F. compactum* and *R. solani*, were 2.3, 2.2, and 2.3 respectively. These results are consistent with the results reported by Wahgunde and Patil, (2009) in relation to the antagonism ability of the fungi *T. viride* and *T. harziurum* in inhibiting the growth of *A. alternate.* The antagonism ability of bio-control *T. harzianum* can be attributed to the production of B-1-3-glucanase enzyme, which weakens the pathogenic fungi and releasing cellulose enzymes in small quantities. However, this may assist in the penetration process of the bio-controls to pathogenic fungi cells and production of antibiotic, which degrades fungal thread (Benhamon and Chet, 1993).

Proficiency test of bacterial antagonism activity against pathogenic fungi:

The bacterial antagonism activity against pathogenic fungi was tested by using *B. subtillus*. The results show that the inhibitory affect of *B. subtillus* was highest (100%) on *F. miscanthi.* On the other hand, it showed no effect on the growth of *Drechslera sp*. However, in a previous study of Korston and de Jager (1995) the authors found a remarkable antagonism activity of this bacterium on spores growth and mycelia of *Drechslera setariae*. While, the inhibition rate reached up to 92.7% against *F. solani*. In another previous study,

Kim, *et.al*., (1994) have also reported a potential antagonism activity of same bacteria on the growth of *F. solani*. Where the authors concluded the following, treated eggplant seedlings with *B. subtillus* prior to planting in contaminated soil reduced seedling infection rate from 68 % to 76 % by *F. solani*, and 90.8% by *F. oxysporum* within 25 to 30 days after treatment. However, this antagonism activity may be due to the ability of these bacteria in secretion group of antibiotics which include Difficidin, Prydifficidin, Bactracin, and Bacillomyin. It may also attribute to their ability in producing volatile organic compounds. Mahammad and Amusa, (2003) indicated a clear inhibitory impact (43-93%) of a multiple volatile organics that were produced by this bacteria (alkyls alcohols, esters, ketones and acid, oxime, and heterocyclic amine phenols) on the growth of fungal mycelium.

Abstract

The research was conducted in the Agricultural Scientific Research Centre in Sweida-GCSAR (Syria) on two *P. vera* female cultivars (Ashoury and Batoury) using 3 bisexual *P. atlantica* genotypes (PA12, PA35 and PA37) and open pollination as control. Pollen viability was evaluated using IKI (Iodine + Potassium Iodide) and TTC (2,3,5-Triphenly Tetrazolium Chloride) dyes. *In vitro*-germination using hanging drop method was used to evaluate fertility before cross-pollination. In all tests, the bisexual *P.atlantica* genotypes (PA37, PA35) gave high pollen viability and fertility percentages. The ability of these pollinators was evaluated according to the most important economic criteria which used to evaluate the behaviour of *P.vera* verities as set percentages, nut's diameter, spherecity, and split percentage. Genetic relationship among F1 hybrids and their parents was achieved using 20 specific SSRs primer pairs, 16 of them were able to amplify PCR products and revealed 44 alleles, of which 40 were polymorphic (90.91%). Genetic similarity ranged from 0.24 to 0.96. The UPGMA (Unweighted Pair Group Method using Arithmetic Averages) cluster based on Jaccard's coefficient grouped the genotypes into two main clusters. The number of alleles ranged from 1 to 9, with a high level of expected heterozygosity (He) 0.496, and 0.25 of observed heterozygosity (Ho). Marker Index (MI) was 18.94. These results indicated that SSR (Simple Sequence Repeat) marker is an informative technique which played an important role as genetic marker for lineage studies.

Keywords: *Bisexual genotypes, crossing, pollen fertility and viability, SSR marker.*

Introduction

The genus *Pistacia* belongs to *Anacardiaceae* family and comprises eleven species, some of which are of high economic and cultural importance in Mediterranean and Asian countries (Isfendiyaroglu, 2007). All *Pistacia* species are dioecious and their flowers are unisexual except of some individual specimens of *P.atlantica* and *P.terebinthus* species (Kafkas, 2002; Gercheva*et al*, 2008). Two new specific bisexual genotypes of *P.atlantica* were identified in Sweida province; the first genotype showed that all the flowers in the raceme are bisexual with only 1-2% of female flowers, whereas the other genotype has four patterns of racemes (Alhajjar *et al*, 2011). These exceptional transsexual genotypes are of importance in relation with pistachio breeding programs. However, Pistachio breeding program faces a lot of complicated obstacles, since it is dioecious species and therefore the potential of male parents is unknown (Romero *et al*., 2001). Morphological criteria remain unsatisfied, from the fact that one cultivar may express its behavior in different ways according to the ecological conditions, in this prospect; molecular markers could facilitate breeding and allow early seedlings selection, saving time and economic resources (Vendramin *et al.*, 2009). Turkeli and Kafkas (2013) assessed the first linkage map in pistachio using an interspecific cross between *Pistacia vera* L. (siirt cultivar) and bisexual *Pistacia atlantica* Desf. (Pa-18 genotype), using ISSR, SRAP and AFLP markers. SSR markers are multi-allelic, co-dominant genetic markers with a very high repeatability, and so are particularly suitable for

phylogenetic studies because of their high polymorphism and abundance (Gupta *et al*., 1996). In the current work, breeding program was assessed using three bisexual *P. atlantica* genotypes as donators and two Syrian *P. vera* female cultivars (Ashouri and Batouri) as receptors, to evaluate viability and fertility of the pollen grains and thus to demonstrate their potential efficacy, and to determine the genetic relatedness of F1 progenies with their parents (*P. vera* × bisexual *P. atlantica*) using 20 SSR markers.

Material and Methods

This research was conducted at the Agricultural Scientific Research Center in Sweida Province- GCSAR during 2012-2014, and in pistachio fields localized in the rural area.

Plant material

Female cultivars:

Ashouri: It is the Syrian world wild cultivar (red Aleppo), consists about 75% in the mentioned area.

Batouri: It consists about 20% of the cultivated cultivars in the mentioned area.

Bisexual *P. atlantica* genotypes:

PA12: It contains two types of sexual racemes; 50% female and 50% male racemes. Pollen grains are coved with a sticky substance inside the anthers.

PA35: It has bisexual flowers with an anther located over the oval near the stigmata.

PA37: It has bisexual flowers with an anther located on a short base at the bottom of the oval. Also, the flower sometimes consists of two anthers with a stigmata between them. And some branches contain female racemes.

Viability and fertility tests:

Iodine Potassium Iodide (IKI) and 2,3,5- Triphnyle Tetrazolium Chloride (TTC) were used to estimate the viability of pollen grains according to (Dalkilic and Dogru, 2011).

In vitro-germination – hanging drop method was used to estimate pollen grains fertility using sucrose nutritional medium (Acar *et al*., 2010).

Cross pollination:

Pollen grains of the selected genotypes of the bisexual *P.atlantica* Desf. (PA12, PA35, PA37) were used, as well as open pollination as control. It was applied when the stigma of the two cultivars had become receptive. Nuts parameters as nut dimension and sephercity, set nut percentages, and split nut percentages were estimated.

DNA Extraction

It was achieved using CTAB protocol according to (Porebski *et al*, 1997). DNA quantity and quality were estimated using 1% agarose gel electrophoresis by comparing band intensity with 1 Kb ladder of known concentrations.

PCR amplification

Extracted DNA was PCR-amplified using 20 SSR primer pairs according to (Ahmad *et al.*, 2003; Vendramin*et al.*, 2010).

Data analysis

For cytogenetic studies, randomly simple replicates design ($P \leq 0.01$) was used. For cross pollination; one way anova ($P \leq 0.05$) was used. Genetic similarity (GS) was calculated from the alleles across the 20 SSR loci using Jaccard’s similarity coefficients (Jaccard, 1908). A dendrogram was constructed with the unweighted pair group method using arithmetic averages UPGMA (Sneath and Sokal, 1973). Observed heterozygosity (Ho) Wunch and Hormaza, (2007), expected heterozygosity (He) Lorenzo *et al*. (2007), and Marker Index (MI)

according to Powell *et al*. (1996) were also determined to estimate the efficiency of SSR technique. The software used through this study was Gen Stat for cytogenetic studies and nuts parameters, and Microsoft EXCEL, SPSS17, and Past for genetic analysis.

Results and discussion

Pollen grain viability

The results showed that the IKI test, revealed an average of viability percentage ranged from 79.74% to 97.11% (Table, 1). The highest percentage of viable pollen grains was in PA37 genotype (97.11%), followed by the genotype PA35 (96.77%). In TTC test, the viability percentage in all genotypes was nearly higher compared with the IKI test. So, the highest value was 98.17% in the genotype PA37 and 97.06% in PA35 genotype (Table, 1). The present results are in agreement with the previous investigations, Sfendiyaro *et al* .(2006) reported that pollen viability in TTC test ranged between 85.7-98.85% in different mail types.

Pollen grain fertility

Fertility is one of the most important criteria when estimating pollen efficiency in breeding programs. Results in Table (1) indicated to the accordance between viability and the fertility. Pollen germination was estimated as a percentage when the germination tube reached half diameter of the pollen grains. The highest fertility percentage was 88.61% in PA37 genotype, whereas the lowest percentage was 79.22% in PA12 genotype.

Table1. Bisexual *P.atlantica* pollen viability estimated by using IKI and TTC tests and fertility%.

genotype	IKI test			TTC test		Fertility%
	Semi viable	viable	unviable	semi viable	viable	
PA37	1.83	98.17 ^{A}	1.06	1.83	97.11 ^{A}	88.61^{A}
PA35	2.94	97.06 ^{A}	2.01	1.22	96.77 ^{A}	85.49 ^{A}
PA12	5.39	95.36 ^{B}	3.8	2.17	94.03 ^{B}	79.22^{B}
LSD 1%		1.49			1.66	4.57

Nuts set percentage

Table (2) showed that ‘Ashoury’ has got the highest nuts set percentage than ‘Batoury’ in all applied pollinizers. The highest nuts set percentage in ‘Ashoury’ significantly obtained by using PA37 bisexual *P.atlantica* pollen grains (62.60%) and PA 35 (59.90%) in comparison with the other pollinizer and the control. The best pollinizer for ‘Batoury’ was PA35genotype (21.46%) followed by open pollination 21.21%.The present results were disagreement with the previous investigations (Isfendiyaroglu *et al*., 2001; Kardoush *et al*., 2009), and in agreement with (Ozeker *et al*., 2005).

Nuts dimensions and sphericity

Nuts dimension was differed with respect to source of pollen. Within ‘Batoury’ replicates using different pollinizers, the pollinizers PA37 and PA35 significantly gave higher nuts dimensions (2.46 cm and 2.35cm) in comparison with the PA12 and the control (open pollination) (Table,2). Within ‘Ashoury’ replicates, the bisexual *P.atlantica* genotypes (PA37, PA35) were able to increase the nut size 1.92 and 1.90 cm with significant differences in comparison with the control (1.61 cm). Ak (1999) produced nuts of 0.87 cm by using *P.atlantica* pollinizer. The sphericity percentage ranged between 77.47 - 88.81% in ‘Batoury’, and between 64.11 -72.03% In Ashoury. Kardoush *et al*. (2009) reported that the sphericity of ‘Ashoury’ cultivar was 73.9%. And in ‘Batoury’ the nut sphericity was 82.8% when *P.atlantica* pollen grains were used and 68.8% with open pollination. Fares *et al.* (2009) mentioned that the dimension of pistachio nuts ranged from1.63 cm to 2.04 cm.

Split shell percentage

Various split shell values were obtained in both cultivars according to the source of pollinizer. In Ashoury, the genotypes PA35 and PA37 significantly raised the percentage of split nuts (93.75- 90.99%) in comparison with open pollination (83.33%). In ‘Batoury’, the genotypePA37 significantly revealed the highest percentage of split nut (35%), the least split nut percentage (12.00 %)was obtained by using *P.atlantica* PA12 genotype (Table 2).

Table 2. set percentage, loss percentage, dimension/cm, shephrecity%, and split %

Cultivar/ polliniser	**Set %**	**Dim. cm**	**sphericity%**	**split%**
Bat/PA35	21.46 cd	2.46 a	88.81 a	20.00 f

Polymorphism detected by SSR marker

Twenty SSR primer pairs were applied, 16 of them were able to detect polymorphism and revealed 44 alleles across all genotypes, 40 alleles were polymorphic (90.91%). These results were in agreement with Arabnezhad *et al.* (2011), they used 18 SSR primer pairs developed from *P. khinjuk* genome. All primer pairs produced 1-9 putative alleles each with an average 2.75 alleles per locus, and the highest number of putative alleles was revealed in the progeny HB3 (FB×PA35), Table (3). Baghizadeh *et al.* (2010) reported that four SSR primers produced 11 alleles with an average value of 2.75 alleles. However, the primer pairs (Ptms-11, Ptms-33, Ptms-40, and Ptms-42) revealed monomorphic alleles, whereas the other primer pairs revealed polymorphic alleles. The progeny HB3 (FB×PA35) was distinguished by 6 alleles using EPVM021 primer pairs, 3 of them were unique alleles (491, 338 and 307bp, respectively) as shown in (Table, 3). Heterozygosity was detected by EPVM016, EPVF019 and Ptms-7 primer pairs. Allele size ranged between 76 bp in Ptms-11 primer to 690bp in EPVM021 primer.

Table 3: Total number of alleles produced by 14 SSRs primer pairs, number of polymorphic alleles, polymorphism percentage and allele size (bp)

Primer	No. Alleles	olymorphic	Polymorphism %	Allele size (bp)
Ptms-3	3	3	100	129-138-154
Ptms-7	3	3	100	171-182-202
Ptms-9	2	2	100	116-125

SUM	44	40	90.91	
AVE	2.75	2.5		

Genetic similarity

The studied genotypes revealed varied genetic distances ranged from 0.24 between both *P.vrea* female cultivars; Ashouri and Batouri (FA and FB) and PA37 bisexual *P. atlantica* genotype, to 0.96 between two F1 progenies HA1 (FA×PA37) and HA2 (FA×PA12).Genetic similarity between Ashouri cultivar and its hybrids was 0.66, whereas genetic similarity between Batouri cultivar and its hybrids was 0.513, (Table 4). Genetic distances between the hybrids and their parents were closer to their female parents (FA and FB) than to their male parents (PA12, PA37 and PA35) except for the HB3 (FB×PA35) which revealed genetic distances 0.37 with FB and 0.43 with PA35. Pazouki *et al* (2010) reported that genetic similarity within *Pistacia* spp. ranged from 0.03 to 0.8.

Table 4. The genetic similarity among all studied genotypes using Jaccard coefficient

	FA	HA1	PA37	PA35	HA2	HA3	PA12	HB1	FB	HB2	HB3
FA	1										
HA1	0.65	1									
PA37	0.24	0.38	1								
PA35	0.26	0.33	0.63	1							
HA2	0.63	0.96	0.41	0.36	1						
HA3	0.64	0.85	0.36	0.35	0.89	1					
PA12	0.28	0.43	0.68	0.59	0.42	0.37	1				
HB1	0.60	0.75	0.33	0.32	0.72	0.74	0.47	1			
FB	0.79	0.54	0.24	0.26	0.52	0.58	0.28	0.67	1		
HB2	0.68	0.53	0.40	0.36	0.57	0.57	0.26	0.54	0.68	1	
HB3	0.30	0.54	0.39	0.43	0.57	0.53	0.34	0.50	0.37	0.42	1

Cluster analysis

The pattern of cluster analysis based on Jaccard’s coefficient and UPGMA algorithm clustered the genotypes into two main clusters (Figure 1); The first cluster divided into three sub-clusters, the first one branched into two groups, the first group contained all F1 hybrids ‘derived from the hybridization between *P. vera* female Ashouri cultivar and all *P. atlantica* bisexual genotypes’ and the second group contained the hybrid HB1 (FB×PA12). The second sub-cluster divided into two groups; The first one contained *P. vera* female cultivars (FA and FB), and the second one contained only the progeny HB2 (FB×PA37). Whereas the progeny HB3 (FB×PA35) was located in the third sub-cluster. All *P. atlantica* bisexual genotypes were grouped in the second cluster which divided into two sub-clusters, the first one contained both of PA12 and PA37, while PA35 genotype was located independently in the second sub-cluster.

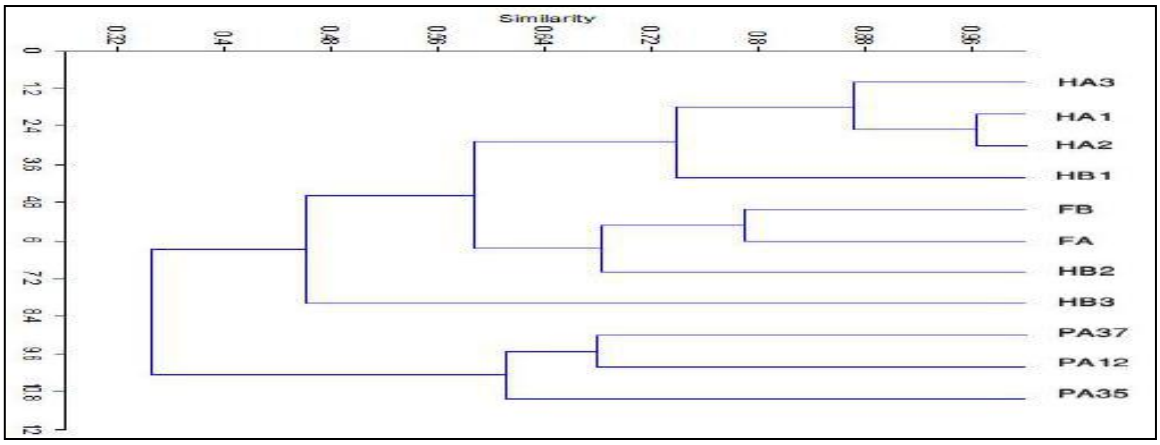

Figure 1. cluster analysis using UPGMA method according to Jaccard's coefficient

To evaluate the efficiency of SSR microsatellite markers for polymorphism detection; Observed and Expected Heterozygosity (Ho and He), and Marker Index (MI) were estimated. Observed heterozygosity (Ho) was appeared in 4 of 16 SSR loci giving an average value 0.25. Expected heterozygosity depending on allele frequency was 0.496 in all polymorphic tested loci. Marker Index (MI) was estimated depending on the effective multiplex ratio which was 19.84. Vendramin *et al.,* (2010) found that Observed Heterozygosity (Ho) was 0.27 while the expected heterozygosity (He) was 0.31 in their study.

Conclusion

The bisexual genotypes PA35 and PA37 were optimized by their high viable and fertile pollen grains ratios, and by giving high nuts set percentage in both cultivars. Our investigation also indicated that SSR marker is an informative technique which revealed high ability to differentiate individuals and played an important role as genetic marker for lineage studies, and may establish a platform to build up an understanding of genetic inheritance in the genus *Pistacia*.

ASSESSMENT OF GENETIC INTEGRITY OF APPLE SEEDLINGS ROOTSTOCKS DERIVED FROM THE LOCAL APPLE CULTIVAR (SUKARI 2) IN SYRIA USING SSR MARKERS

Ola T. AL-HALABI*, Bayan M. MUZHER

General Commission for Scientific Agriculture Research (GCSAR), Sweida, Syria
*Corresponding author: Ola_halabi@msn.com

Abstract

The local applecultivar Sukari 2 is suitable as a source for seeds due to the desirable traits of its seedling rootstocks, this investigation was aimed to study the genetic similarity among seedling rootstocks and their mother plant (Sukari 2) using 16 primer pairs of SSR markers. The results showed that these primers gave 32 alleles, 25 of them were polymorphic with polymorphism percentage 78.1%, and the genetic similarity between the seedlings and their mother plant was above 0.5 except in one seedling, and the highest value reached to 0.818. Likewise, the highest genetic similarity among seedlings with each other was 0.85. On the other hand, the cluster analysis divided the seedlings into 3 groups, the main group contained the most seedlings with the mother, this high genetic similarity with the mother indicated to the possibility of using the cultivar Sukari 2 as a source for seeds. As well,the expected and observed heterosigosity were 0.37 and 0.48 respectively, this illustrated that the SSR marker is an efficient tool in discriminating among individuals in apple rootstocks breeding program.
Key words: *Local apple cultivar (Sukari 2), seedling rootstock, SSR, genetic similarity*

Introduction

Apple growers just in few countries depend on seedling rootstocks, only in the countries which are difficult there to use vegetative rootstocks, or they are not economical (Webster and Wertheim, 2003). However, seedling rootstocks have many advantages over vegetative rootstocks, that they are easy and cheap in propagation, virus free, and free from soil rots which infest roots. Moreover, it is possible to eliminate wide genetic diversity through using defined sources for seeds such the cultivar Red Delicious in America, the cultivars Antonovka and Bittenfilder in Europe, and the wild species in China and Japan (Wertheim and Webster, 2003).In Syria, a group of apple genotypes was selected as a candidate sources for seed production (Al-Halabi et al., 2012a), the local apple cultivar (Sukari2) is one of this group, that the seedling rootstocks derived from it are similar to each other in vigor and diameter, in addition they have the desirable rootstock traits according to Cummins and Aldwinckle (1995). Molecular markers have been proved high efficiency in identifying apple rootstocks in comparison with morphological characters (koc et al.,2009). However, SSR markers which were used to discriminate among genotypes derived from different apple rootstocks (Oraguzie et al., 2005). The genetic similarity among 14 genotypes of apple rootstocks which were produced by the hybridization between the local apple cultivar (Skarji) and MM106 rootstock was achieved using SSR markers (Al- Halabi et al., 2012b). On the other hand, SSR markers were used to study genetic diversity among 41 apple rootstocks from dwarfing, semi dwarfing rootstocks and rootstocks of early flowering*Malus.* Sp (Jin et al.,2012). Our research aimed to evaluate genetic similarity among seedling rootstocks derived from local apple cultivar (Sukari 2) using SSR markers.

Materials and methods

The present investigation was carried out at the agricultural scientific research center – GCSAR- in Sweida province, which is located at 1525m altitude in the south of Syria, during 2010.

Plant material

10 seedling rootstocks derived from the local apple cultivar (Sukari2).

DNA extraction

DNA extraction was achieved using CTAB protocol according to Porebski et al., (1997), by collecting leaves from the seedling rootstocks, in addition to the mother plants (Sukari2).

PCR amplification

PCR amplification was achieved using 17 primer pairs are developed from apple, 10 primer pairs (Hi-SSR) were developed by Silverberg et al. (2006), 6 primer pairs (CH-SSR) by Gianfranschi et al. (1998), and one primer pairs (o2b1) by Guilford et al., (1997).

The reaction was performed with volume (10 µl) consisted of: 1 µl 10 X buffer + 1 µl dNTPs + 1 µl forward primer + 1 µl reverse primer + 3 µl DNA + 0.1 µl taq + 2.9 µl dH_2O. The cycling profile consisted of an initial denaturation step of 3 min at 94º c, followed by 35 cycles of 30 s at 94ºC, 30 s at 55º -58º C (according to primer pairs and its content of CG) and 1min at 72ºC, the amplification process was finished with 5 min at 72ºC.

Visualization of the PCR products

The PCR productswere detected by electrophoresis on 2% agarose gel in 1X TBE buffer, stained with ethidium bromide and visualized by UV light and photographed using gel doc. The molecular weight of the bands was estimated by Bioprofil- Bio- 1D software using 100bp DNA Ladder.

Data analysis

genetic similarity (GS) was estimated according to Jaccard coefficient (Jaccard, 1908), that all bands were recorded and the present band was given 1 and the absent one was given 0.Cluster analysis achieved using UPGMA method (unweighted pair-group method using arithmetic averages) by Past software. Expected Heterozygosity (He) was calculated according to Lorenzo et al, (2007). While the observed Heterozygosity (Ho) was calculated according to Wunsch and Hormaza (2007).

Results and discussion

The polymorphism

16 primer pairs revealed 32 alleles which were 25 ones of them polymorphic, with polymorphism percentage 78.1%, while the primer pair Hi07f01 could not reveal any allele. The number of alleles in different loci was between 1-3 alleles, with an average 2 alleles per locus. This result was in agreement with the result obtained by Farrokhi et al. (2011) in their study of genetic diversity among old Iranian apple cultivars using 16 SSR primer pairs, which revealed 2-5 alleles per locus, indicated that this result is closer to that one obtained from self pollination plants such tomato, cucumber and wheat. However, each of CH01H01, Hi08g06 and Hi08e06 primer pairs gave monomorphic alleles. On the other hand, 13 primer pairs were able to detect the genetic variance among studied seedlings, that the most primer pairs showed two polymorphic alleles (Figure 1) except in CH01E01, CH02B12 and O2b1 which revealed one monomorphic allele and the other was polymorphic. While, Hi04g05, CH01H02 and CH01F02 gave 3 alleles. Likewise, the co-dominant appeared in the mother plant (Sukari2) at the loci CH01F02, CH02B03b, CH01E01 and CH02B12 which indicated that the local apple cultivar (Sukari 2) is a hybrid, this result was in agreement with Al-Halabi et al. (2009). The

size of the obtained alleles was between 86 bp in CH02B03b and 265 bp in Hi07h02, which was in agreement with the predictable size according to Guilford et al., (1997); Gianfranschi et al. (1998) and Silverberg et al. (2006).

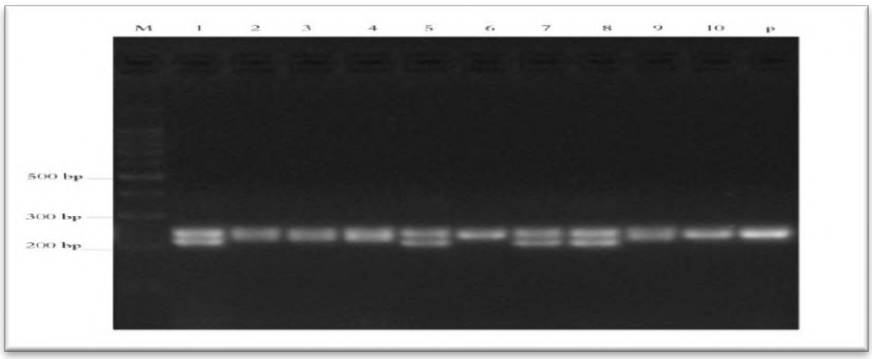

Figure (1): The alleles patterns produced by the primer pair O2b1 in the studied seedlings and the mother plant (Sukari 2). M: Marker 100bp ladder, the numbers from 1 to 10 represents seedlings, and P: the mother plant (Sukari 2).

Genetic similarity

The studied seedlings showed closer genetic distance with the mother plant (Sukari 2), it was above 0.556 except in seedling 4, which was 0.423, while the highest genetic similarity value was 0.818 with seedling 9. On the other hand, the highest genetic similarity value among studied seedlings was 0.85 between seedling 2 and seedling 3, and the lowest one was 0,296 between seedling 4 and seedling 5. Theseresults were in agreement with Al- Halabi et al. (2012b) they found that the highest genetic similarity value among seedlings derived from hybridization between MM106 and local apple cultivar Skarji using SSR markers was 0.84, and the lowest one was 0.29. The seedlings 1, 7 and 9 distinguished by the high genetic similarity in comparison with the other seedlings, which was above 0.5 except seedling 4 (Table 1). These results indicated to the high genetic similarity among the seedlings derived from the local apple cultivar (Sukari 2).

Table 1. Genetic similarity among the studied seedlings and the mother plant (Sukari 2) derived from SSR markers depending on Jaccard coefficient.

	1	2	3	4	5	6	7	8	9	10	Sukari2
1	1.000										
2	.560	1.000									
3	.667	.850	1.000								
4	.407	.400	.333	1.000							
5	.696	.800	.762	.296	1.000						
6	.625	.714	.762	.400	.636	1.000					
7	.640	.727	.696	.423	.652	.727	1.000				
8	.720	.481	.464	.560	.538	.481	.680	1.000			
9	.708	.727	.773	.423	.652	.810	.739	.556	1.000		
10	.577	.652	.625	.609	.520	.583	.600	.500	.667	1.000	
Sukari2	.708	.652	.773	.423	.583	.727	.739	.556	.818	.667	1.000

Cluster analysis

Cluster analysis divided the studied seedlings into three clusters, the first cluster contained 7 seedlings in addition to the mother plant (Sukari 2), this clusterdivided into 3 sub clusters, the first one involved 3 seedlings, the second sub cluster contained 3 seedling with the mother plant, while the third one has only one seedling. The second cluster involved two seedlings, while the third clusterhad only one seedling.However, cluster analysis divide the studied plant populations according to their pedigrees (Hormaza, 2002; Muzher, 2004; Perez et al., 2005; Amirbakhatiar et al., 2006).Genetic diversity in apple is mostly belonging to cross pollination

(Janick et al., 1996), but the local apple cultivar (Sukari 2) has an early flowering stage before all other cultivars (Al-Halabi et al. 2009) , which increases the chance of self pollination, thus lead tohigh genetic similarity with its progeny.

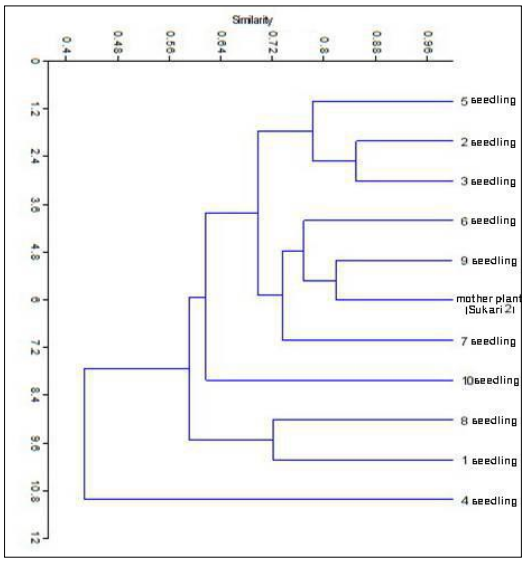

Figure 2. Cluster analysis dendrogramderived from SSR marker , depending on Jacard coefficient using UPGMA method for the seedlings and their mother plant (Sukari 2).

Expected and Observed Heterozygosity

The results showed that the expected heterozygosity (He) derived from SSR markers within the studied seedlings was 0.37, while the observed heterozygosity (Ho) was 0.48. However, He and Ho are useful in determining the genetic variability, that these values were lower than that in the literature reviews, which indicated to the low genetic variability among seedlings derived from the local apple cultivar (Sukari 2), this led to the probability of using Sukari 2 as a source for seed production. The He value in this research was in agreement with the He obtained by Muzher and Sharaf (2014) in theirstudy of genetic variability and relationship among Syrian pears and wild type genotypes using SSR markers which was low0.263. while it was in disagreement with Guarino et al. (2006) that the He was between 0.713 and 0.884 within some of apple cultivars. The characterization of old apple cultivars in comparison with 11 standard cultivars using SSR markers showed that the He and Ho in the old cultivar were 0.82 and 0,84 respectively, while in the standard cultivars were 0.9 and 0.79 respectively which reflected that the cross pollination in apple is high, which consequently lead to the genetic variability (Sikorskaite et al., 2012).

Conclusion

The low polymorphism percentage (78.1%), expected heterosigosity (0.37) and observed heterosigosity (0.44),then the high genetic similarity and the cluster analysis which were obtained using SSR markers indicated to the low genetic variability between the seedlings and their mother plant the local apple cultivar (Sukari 2).Consequently, our results can suggest to use the local apple cultivar (Sukari 2) as a source for seed production, on the other hand SSR markers are a useful tool in apple breeding program.

Abstract

Grains of cereals are a main resource for human nutrition and animal feed throughout the world. At Maize Research Institute programs for improvment quality of protein, and micronutritiens as beta carotine, tocopherols and minerals are conducted. In the case of biofortification nutritional breeding also starts with assembly of parental germplasm for crosses based on the evaluation of a large amount of genetic material. More than 100 inbred lines are screened for concentration of microelements as well as beta carotene and tochopherols. A high amount of variation for micronutrients is present among genotypes and genotypes with high concentration of micronutrients are chosen for further crossing. Maize grains have particularly high concentration of phytate which negatively impact human and animal nutrition. Inorganic phosphorus is forms of P in seeds that generally referred as available P. Therefore, it would be desirable to increase the amount of available P and reduce the amount of phytate in maize grain. Among analyzed maize inbred lines are enough variability for phytate and ionrganic phosphorus that can be used for breeding maize genotypes with low phytate and high inorganic phosphorus content and good agronomic traits. Maize lacks adequate levels of the essential amino acids lysine and tryptophan, thus reducing the overall biological value of its protein. Quality Protein Maize (QPM) is argonomically acceptable and nutritionally improved *opaque2* maize, with increased levels of tryptophan and lysine in the grain. At Maize Research Institute project on conversion of normal maize lines to QPM lines adapted for growing in temperate regions trough MAB is developed.

Key words: *maize, QPM, micronutritiens, biofortification, quality traits*

Introduction

Maize is a high yielding crop that provides a relatively high calorie source of food and feed, but focus on yield has not improved nutritional qualities. Some nutrients that are lacking in maize are beta carotene, iron and essential amino acids. A variety of breeding methods can be used to improve qualities of maize. Conventional approaches include screening of germplasm, mutagenesis, and hybridization. Those traditional methods can be complemented with biotechnology approach such is transgenesis, cisgenesis, overexpression or suppression of gene of interest. The use of molecular biology to isolate, characterize, and modify individual genes followed by classical breeding strategy or plant transformation and trait analysis will introduce new traits and more diversity into maize database. Backcrossing can be used to bring a mutation or transgene into a specific genetic background, while forward breeding can be used to improve characteristics of a line that carries a gene of interest. Biofortification with selective breeding or biotechnology is a way to improve the nutritional qualities of crops. Finding genes which control accumulation of minerals in maize grains is the precondition for biofortified breeding program. Maize and relatives contain many genes that have the potential to improve nutritional quality of maize grain, as maize globin for bioavailable iron and seed storage proteins for protein quality. Few QTL mapping researches have also been conducted on micronutrient content in maize (Qin *et al.* 2012, Šimić *et al.* 2012); however, the results were inconsistent possibly due to the differences in mapping populations, genotypes and

environments used in these studies. Kobayashi and Nishizawa (2012) have shown that the Zn and Fe metabolism is a complex process regulated by many genes. Development of maize with unique grain quality traits, however, has not received the same emphasis in genetics, breeding, and economics as higher yield and agronomic performance. Enhanced grain protein and micronutrient content for both vitamins and minerals is rapidly emerging as the next suite of seed quality traits to be improved.

Improving of maize protein quality

The most well-known experiment that altered total protein content in maize is the Illinois Long Term Selection Experiment. In these studies it was shown that protein content could be increased up to 26.6 percent in the high-protein (HP) genotype after 65 generations of selection. The low-protein genotype contained about 5.2 percent (Moose et al, 2004).

Maize protein is deficient in two essential amino acids, lysine and tryptophan. Therefore, maize is a poor source of protein for both humans and monogastric animals. Lysine, along with methionine and tryptophan, are important targets for improvement of maize protein quality. While there is little variation in amino acid content in modern inbred lines, some mutations such as *opaque2* significantly alter maize amino acid composition. O*paque2* is a transcription factor that controls expression of zeins and of an enzyme that degrades free lysine. Maize with the *opaque2* mutation has decreased zeins and higher free lysine. The *opaque2* (*o2*) mutation which increases lysine and tryptophan content also confers an undesirable phenotype leading to low yields, soft and chalky kernels that renders seeds susceptible to storage pest and ear rots. Using conventional breeding methodologies, research team in CIMMYT, Mexico, created the new, agronomically acceptable and nutritionally improved *opaque2* types by the name of Quality Protein Maize or QPM (Vivek *et al*., 2008).

Research on *opaque2* mutation and high tryptophan was initiated in the 1970-ies in Maize Research Institute Zemun Polje - MRI (Denic *et al*., 1979). Today's MRI breeding program on conversion of normal maize lines to QPM lines adapted for growing in temperate regions trough marker assisted backcross breeding. are relate to: 1) genetic and biochemical variability analysis between one commercial normal maize inbred line and one QPM inbred line in order to be used as parents in marker assisted selection for quality protein maize and 2) efficiency of the three *opaque2* specific SSR markers and the choice of appropriate markers for marker assisted introgression of the *opaque2* gene into the commercial normal inbred line, (Denic *et al.*, 2012; Ignjatovic-Micic *et al*., 2010, 2013). The main goal is to achieve high levels of essential amino acids and high grain yield at the same time. The donor line was CML144, one of the CIMMYT Maize Lines (CMLs) with good general combining ability and a significant number of value-adding traits such as drought tolerance, enhanced levels of the essential amino acids lysine and tryptophan, N use efficiency, acid soil tolerance, resistance to diseases, insects and parasitic weeds. ZPL 5, dent-like commercial MRI inbred lines adapted to the local environmental conditions was selected as the recurrent parent for marker assisted backcross programme to be the recipient of the *o2* allele and to improve the tryptophan content. SSR markers were effectively employed both for selecting *o2* homozygous recessive genotypes and genotypes with the highest proportion of recurrent parent genome. Recipient parent and donor lines were clearly distinguishable with three *opaque2*specific SSR markers (Kostantinović et al, 2014). Therefore, they will be used for marker assisted selection for the *opaque2* gene. Marker analysis will be done using DNA samples extracted from leaf tissue of very young plants. This enables those plants without *o2* alleles be discarded prior to pollination, reducing the size of the breeding population and saving both time and money. Due to the well-established relationship between lysine and tryptophan in the maize protein (4:1 ratio), tryptophan can be used as a single parameter for evaluating the nutritional quality

of the protein. CML 144 had tryptophan content and quality index higher than ZPL 5 and both above threshold set for QPM.

The process of conversion of the standard inbred line in line with improved proteins quality using molecular markers consisted of two cycles of backcross which included three cycles of self-pollination (Figure 1). Molecular analyzes were carried out in the BC1, BC2 and BC2F2 generations for the determination of heterozygosity / homozygosity for opaque2 gene, and BC2, BC2F3 and BC2F4 generations, as well as improved lines for determining the similarity of progeny with the recurrent parent. Phenotypic selection included the biochemical evaluation (determination of tryptophan, protein content and quality index - the percentage of tryptophan in the protein), determining the degree of modification of the grain endosperm and evaluation of important agronomic characteristics. Inbred lines with increased tryptophan content (37-50% compared to the parental line), held genetic similarity to the parental line (93% of the genome of the recurrent parent), increased grain yield (11-31% compared to the parental line) and preserved combining abilities are obtained.

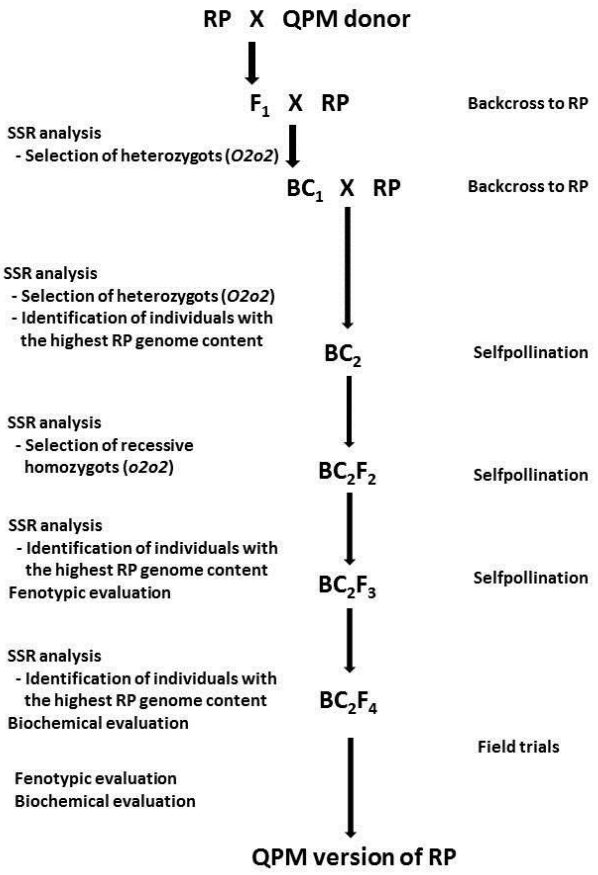

Fig 1. Scheme of standard lines conversion (RP - the recurrent parent) in QPM version.

Improving micronutrients content

Although maize is low in some micronutrients, humans and animals can obtain at least part of their nutritional requirements from maize grain. Biofortification is the use of crop breeding practices and/or modern biotechnology to produce micronutrient-dense staple crops. The conventional approach to mineral biofortification has been to work at three levels. These are to increase the density of the mineral nutrient of interest, to decrease the density of antinutritive compounds (nutrient inhibitors), and to increase the density of compounds that enhance bioavailability of the specific nutrient.

In Maize Research Institute we develop program that aimed to improve micronutrient content and bioavailability. In any breeding program, germplasm screening for a trait of interest is an important first step to genetic improvement. In the case of biofortification, nutritional breeding also starts with assembly of parental germplasm for crosses based on the evaluation of a large amount of genetic material. Drinic et al (2013) studied the variability of microelements in grain of 74 maize inbreed lines. The highest average concentration of Mg, Fe and P had inbred lines from European germplasm while inbred lines from BSSS germplasm had the highest Zn concentration. Lines from BSSS had the lowest average Mg and Fe content as well as lines from Lancester germplasm had the lowest Zn and P content. Some studies have shown that there is sufficient genotypic variation in major cereal crops to breed for higher total iron (Zhao and McGrath 2009), but an evaluation of more than 1000 improved maize genotypes and 400 maize landraces found little variation of total iron in the grain (Ortiz-Monasterio et al. 2007).

The main iinhibitor of absorption of iron (Fe), zinc (Zn), and magnesium (Mg) from cereal grain is phytate (for review,White and Broadley 2009). Dragičević et al (2013) obtained high variability in concentration of Fe, Mn and Zn, as well as phytate (which sustain availability of mineral elements) and β-carotene (which enables better absorption of mineral element and minimize negative effect of phytic acid) in maize inbred lines. Kravic et al (2014) find out that investigated drought tolerant maize local landraces exhibited high variability in concentration of important mineral elements, phytic acid and β-carotene. According to relatively high concentrations of all four factors observed (β-carotene, Fe, Mn and Zn), as well as the lowest ratios between Phy and all examined mineral elements, drought tolerant maize local landrace LL2 is the most promising genotype in further breeding programs for improved nutritional quality, such as enhanced availability of investigated mineral elements. A high amount of variation for micronutrients is present among investigated maize genotypes and genotypes with high concentration of micronutrients are chosen for further crossing. Part of our research is aimed to decrease phytate and increase inorganic phosphorus content. In breeding for increased concentrations of carotenoids and tocopherols, it is also important to know what effect male and female genotypes contribute to kernel content for these compounds when different genotypes are crossed (Drinic et al., 2014).

Acknowlegdement

This research was supported by the Ministry of Education, Science and Technological Development of Republic of Serbia, through the project TR31068.

Abstract

In this study the response of groundnut to salinity over different development periods (blooming, ginofor formation and fruit formation and maturation) was determined in the Eastern Mediterranean Region. The experimental design was split plot in a randomized complete block with three replications and was conducted in a total of 180 pots. In the irrigaton of groundnut, saline water with electrical conductivity (ECw) 0.19 dS m^{-1} ($T_{0.19}$), 3.54 dS m^{-1} ($T_{3.54}$), 7.12 dS m^{-1} ($T_{7.12}$) and 12.86 dS m^{-1} ($T_{12.86}$) were used.

It was determined that Ginofor formation stage was the most sensitive stage to salinity than the other developmental stages. Yield parameters were affected at $p < 0.001$ level from *development stage, irrigation water salinity and the development stage x irrigation water salinity* interaction. Chlorophyll values at different salinity levels of stoma conductivity was show that different. The highest and lowest stomatal conductance were realized in $T_{3.54}$ (356.025 mmol m^2s^{-1}) and $T_{12.86}$ (238.25 mmol m^2s^{-1}) issues. Stomatal conductivity showed differences at different salinity levels. The highest and the lowest stoma conductivity monitored at $T_{3.54}$ (356.025 mmol m^2s^{-1}) and $T_{12.86}$ (238.25 mmol m^2s^{-1}). It was observed that the at the plots where the highest stoma conductivity determined had the higest yield.

Key Words: *Groundnut, salinity, development periods, stomatal conductance, chlorophyll*

Introductıon

Drought problems arising in the arid and semi-arid regions makes almost mandatory to use of marginal quality water in irrigation (brackish, reclaimed, drainage and waste water). Saline water usage causes the salinization to about 830 million hectares of worldwide (Martinez-Beltran and Manzur, 2005). Because of this situation, it has become necessary to determine the salt water-yield function in salty field in detail (especially for the plants that play an active role in human nutrition).

One of plant species rich in oil, protein, carbohydrates, vitamins and mineral substances is groundnut (Arıoğlu et al., 2010). Worldwide about 45.6 million tonnes in 100 countries, groundnut production is realized (FAO, 2013). Yield losses due to drought may vary with time and associates with temperature and high stress factors, such as region-specific irradiance. About 2/3 in arid regions, crop production potential is limited , to the seasonal rainfall. In these areas, productivity changes between 0.7 - 0.8 Mg ha^{-1}. But, even with that limited water efficiency in commercial areas are level of 2.0-4.0 Mg ha^{-1} (Smartt, 1994). Lack of soil moisture in groundnut farming and irrigation water quality are considered to be the most important factors limiting the yield. Growth period changes from about 120 to 150 days. precipitation of 500-700 mm is sufficient for the cultivation of groundnuts during the growth. But this fall should be distributed to the growing period. Groundnut maximum daily water consumption occurs in flowering, pod-linking and maturation. The highest water consumption is in July-August, In August-September, it was measured as about 6.0-8.5 mm day^{-1}. In starting period (germination) when the groundnut needs adequate soil moisture, small degree of water stress should be applied a during the vegetative period. Flowering period is the the

most sensitive stage to water shortages. In general, extreme water shortages in the vegetative period causes delay of flowering and the formation, development and harvesting of fruit. Water shortages of the flowering period lead to loss of flowering and poor flower pollination. Studies conducted in response to the saltwater applications of groundnuts is almost negligible. To our best knowledge, revealing different stages of plant development functions of salt-yield research does not exist in literature.

In this research, the response of groundnut during three different development to different irrigation water salinity effects of yield, vegetative and physiological parameters were determined.

Material and method

Research was conducted in greenhouses and sheltered from rain, between May and October 2012, using NC-7 variety of the Virginia group (leaning early). The plants were grown in 43 cm diameter and 47 cm high plastic pots. Each pot filled with sandy-clay loam soil (42.0% sand, 35.3% clay, 22.7% loam) which has a volume weight of 1.38 gr cm^{-3}, salinity C_1S_1.

The experiment was conducted according to the split plot in a randomized complete block design in three different growth period (Blooming, Ginofor formation, The formation and maturation of fruits periods), 4 different salinity in irrigation water (ECw) (0.19 dS m^{-1} (T_0), 3.54 dS m^{-1} ($T_{3.5}$), 7.12 dS m^{-1} (T_7) ve 12.86 dS m^{-1} (T_{13})). The experiment was repeated three times and total number of pots were 180. NaCl salt and pure $CaSO_4$ salt sources were used in the experiment. Na and Ca values in the irrigation water were kept between 0.1 and 0.7 (Grattan ve Grive, 1999). Prior to each irrigation, extra 3 post were used in the determination of the amount of irrigation water. 20% of leaching water was applied at each irrigation treatment to issues except for T_0. Irrigation water salinity (dS m^{-1}) was measured by portable EC meter (Orion 3 Star, USA), soil moisture content (cm^3 cm^{-3}) and soil salinity was measured by ΔT marka HH-2 moisture meter. Before the experiment, calibration equation was determined for the soil salinity y= 0.0127x + 0.91, (r^2=0.96**). In order to determine the evapotranspiration, , 3 pots were weighed prior to each irrigation. The weighed differences between the pots at each irrigations were summed and the seasonal evapotranspiration were calculated. During harvest, the plants were removed from the pots and the soil was removed and then the groundnut yield was determined. The physical characteristics of grains were measured as width (mm), length (mm), the average grain weight (gr) and numeral (number m^{-2}). Plant height were measured to determine the vegetative response before each irrigation.

In this research, stomatal conductance and chlorophyll content were read a total of 6 times in 2 pots out of every replication before irrigation in order to determine the effects of irrigation water salinity on plant physiology. Stomatal conductance was measured by porometer (Model SC-1. LPS0881) and chlorophyll content was measured by Minolta SPAD 502. Stomatal conductance and chlorophyll content were measured in the middle of parcel, the full-blown fresh leaf which see the sun, In outdoor conditions between 12:00-14:00 o'clock, once a week and before irrigation.

Result and dıscussion

Soil Moisture Content, Soil Salinity and Evapotranspiration: In this research, the plants were irrigated 4 times in blooming and ginofor period and 3 times in the fruit ripening period. Unsalted water for irrigation has been applied to all treatments from planting to exit from to soil period. Salt water applications have started blooming period and continued until the harvest period. Soil salinity has increased significantly depending on irrigation practices (except forT_0). 0.19 dS m^{-1} irrigation water even did not cause a significant reduction in salinity level in the next period of saltwater applications in blooming and ginofor formation periods. This situation is due to the presence of Na ions in the soil being heavily complex and

the high hydration diameter do not impede the full realization of the leaching process (Frenkel ve ark. 1978). Evapotranspiration (Et) decreased overall by increasing salinity (Table 1). The highest Et was measured in control treatment in blooming and ginofor formation periods and it also was measured in $T_{3.54}$ issue in during fruit ripening period. Significant relationship was found (y=-14.307x+799.15 r^2=0.95**) in blooming period between Et and average ECe, and also in ginofor formation periods (y=-10.081x+754.35, r^2=0.93**) and insignificant relationship was found (y=-12.357x+745.34 r^2=0.74ns) during fruit ripening. Increased salinity in 1 unit of dS m^{-1} of 1 causes a decrease 14.3 mm of Et in blooming period and also in ginofor formation period it causes a decrease 12.35 mm.

Table 1. The average values of evapotranspiration and soil salinity in the growth period

Treatment	Blooming Period		Ginofor Formation Period		Fruit Formation and Maturation Period		Seasonal Average	
	Et (mm)	ECe (dS m^{-1})	Et (mm)	ECe (dS m^{-1})	Et (mm)	ECe (dS m^{-1})	Et (mm)	ECe (dS m^{-1})
$T_{0.19}$	813.00	1.15	744.00	1.62	714.33	0.62	757.11 a	1.13
$T_{3.54}$	738.00	3.36	716.67	2.45	757.33	1.67	737.33 a	2.48
$T_{7.12}$	677.67	6.88	704.33	4.38	630.00	2.88	670.67 b	4.69
$T_{12.86}$	628.67	12.61	613.33	8.25	586.67	4.57	609.56 c	8.42

Stomatal conductance, Chlorophyll Fluorescence: Increase in irrigation water salinity decreased the stomatal conductance (Figure 2). Average of stomatal conductance was measured respectively in T_0, $T_{3.5}$, T_7 and T_{13} as 307.476, 356.025, 268.187, 223.056 mmol m^{-2} s^{-1} .According to Duncan analysis, stomatal conductance values of $T_{3.5}$ and T_{13} were took place separate groups and also T_0 ve T_7 were same. The stomatal conductance of $T_{3.5}$ was determined higher than the T0 (control). This was evaluated as the final effort of the plant to recover from the salt stress. The regression coefficient between stomatal conductance and soil salinity showed different linear relationships in the blooming period (y=-2.43x+340.l63 r^2=0.12 ns), in ginofor formation period (*y=-34.484x+418.56 r^2 = 0.96***), also in fruit formation and maturation period (y =-18.417x+310.3 r^2 = 0.37ns) As seen, the effect of soil salinity on stomatal conductance during ginofor formation more important than the other periods. The highest and lowest stomatal conductance in growth period were measured in blooming (326.053 mmol m^{-2} s^{-1}) and fruit formation periods (265.440 mmol m^{-2} s^{-1}).

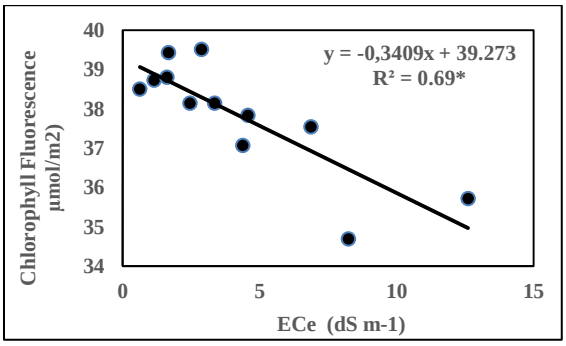

Figure 2. The relationship between chlorophyll content and soil salinity

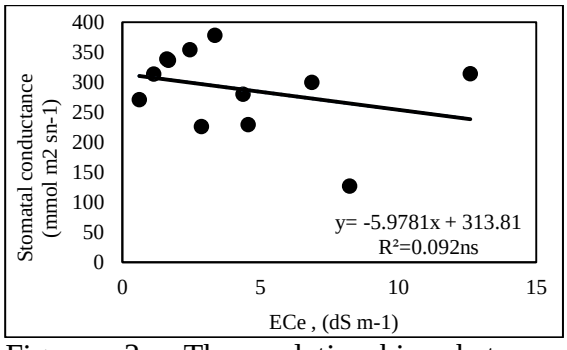

Figure 3. The relationship between stomatal conductance and soil salinity

Average values of ECe were measured between 5.99 dS m^{-1} and 2.43 dS m^{-1} in the same period. Despite the increased stomatal conductance reduction of soil salinity may be a result of cause aging of salinity stress in plants during the growth period. The effects of soil salinity on stomata conductance ($p<0.01$) was the more efficient than growth periods has been

determined in statistical analysis (Table 2.). The highest regression coefficients were determined in the ginofor formation period regression analysis between stomatal conductance and ECw ($p<0.05$).

Corrected Total	344					

Gs: Growth stages, ECe: electrical conductivity of soil paste (dS m^{-1}), Sd:Degree of freedom

Chlorophyll Fluorescence: Chlorophyll values decreased due to the increase in salt concentration (Figure 3). However, this reduction was not statistically significant (r^2=0.89ns, $p<0.05$). Chlorophyll values of control treatment ($T_{0.19}$) was measured 38.674 µmol m^{-2}, and also in $T_{13.86}$ 36.080 µmol m^{-2}. Chlorophyll values of $T_{3.5}$, T_7 were determined respectively, 38.569 µmol m^{-2} and 38.038 µmol m^{-2}. $T_{0.19,}$ $T_{3.5}$, T_7 issues were included in the same group, $T_{12.86}$ was icluded in the different group. The lowest chlorophyll value during the period was measured in $T_{12.86}$ by 35.193 µmol m^{-2} and also the highest value was measured in $T_{0.19}$ by 39.491 µmol m^{-2}. The effect of soil salinity on chlorophyll value at each development cycle were different. In regression analysis between soil salinity and chlorophyll content was obtained as y=-0.2588x+39.084 R^2=0.99** in blooming period, y=-0.61x+39.721 R^2 = 0.99** in ginofor formation period and y=-0.1948x+39.29 R^2=0.17ns in fruit formation and maturation period. As it is seen from the equations, closing to the harvest time, chlorophyll values of the plants became more erratic than the other periods. In addition, to the weakening synthesis of chlorophyll towards the end of the the plant's life cycle and entering senescence salinity stress is a major cause of this condition. Statistically, chlorophyll value was significantly affected by developments periods and soil salinity (*$p<0.01$*, Table 2). While chlorophyll values in blooming an ginofor formation periods located in the same group (37.531 µmol m^{-2} and 37.174 µmol m^{-2}), fruit formation and maturation period were located in a different group (38.815 µmol m^{-2}).

The Relationship Between Physiological Characteristics and Yield: The response of physiological parametres of Groundnut to the irrigation water salinity was shown with analysis of variance in Table 3. The analysis of variance shows that yield parameters were affected at the level of *$p<0.001$* in *their growth period, irrigation water salinity and interaction of growth period x irrigation water salinity.* When the average value of the yield parameter in the development period analyzed, highest values were obtained from fruit formation and maturation periods. This situation shows that if the saline water implemented closer to harvest in the growth period, it would be relatively lower average yield reduction. Stomatal conductance and chlorophyll values at each growth period were not effective at the same level. When regression relationships are examined, both physiological properties were determined to be most effective in ginofor formation (Table 3).

** Blo: Blooming stage, GNF: Ginofor Formation Stage, FFM: Fruit Formation and Maturation Stage

Chlorophyll values were effective on a greater number of yield parameters according to the stomatal conductance. In particular, grain weight, grain width, grain size were an important relationship with stomatal conductance and chlorophyll levels as both of poynomial and linear regression. stomatal conductance had a greater influence on plant height than the values of chlorophyll did. The effect of stomatal conductance on fruit formation and maturation period had an important relationships with the plant height. It has been shown that this influence had more impact than the chlorophyll values did.

Conclusion

It is crucial to detect accurately plant water sentitivity period and their water tolerant period . The information obtained from the previous researches show that determining the above-mentioned periods for many plants is important. As in drought stress, salinity stress is also caused the low yield by the approximately same mechanism in plant. In areas where water is scarce, the use of saline water for irrigation could cause serious problems in plant physiology. The previous findings indicated that drought-salinity stress could cause the similar physiological responses in their sensitive growth period.

It is important to know the pysiological response of plant during periods of stress in order to estimate the yield. The findings from this study indicates that the most sensitive period to salinity is ginofor formation period among the blooming, ginofor formation and fruit formation periods. Increased salinity stress caused a decrease in evapotranspiration. It was determined that the stomatal conductance significantly reduced depending on the salinity and chlorophyll content. The yield on the changes in chlorophyll content rather than changes in stomatal conductance plays a more important role. As the plant get older, impact of changes in stomatal conductance yield became insignificant. However, the chlorophyll content was determined to be more significant impact on the plant's final stage.

Abstract

This study was conducted at rained conditions in Diyarbakır during 2013-2014 grown seasons. The trial was conducted as a randomized complete block design with four replications. In the study, physiological parameters were investigated to determine their effect on the grain yield and quality parameters. 20 bread wheat advanced line originated from CIMMYT and 5 cultivars were used in this study. Genotypes was evaluated in terms of wet gluten value and sedimentation, protein content, test weight(TW), thousand grain weight(TGW), canopy temperature, chlorophyll content (SPAD), leaf area index, normalized vejatasyon index (NDVI), heading day, grain yield. As a result of analysis of variance, significant differences were determined in terms of TW, SPAD, heading day at level of 1% and 5%. Correlation analyses showed negative correlation between grain yield and canopy temperature, SPAD, protein, sedimentation value, wet gluten content; whereas positive correlation between grain yield and TGW, TW, NDVI.

As a result of this study; G7, G21, G22 and G24 had better performance in terms of TW, G11 and G16 for heading time, G1, G17, G19 and Pehlivan for chlorophyll content respectively. Because of heat stress early types of the genotypes must be used the breeding programs. Also, relationships between grain yield and physiological parameters should be investigated as comprehensively for breeding programs.

Keywords: Wheat, physiology, grain yield, quality.

Introduction

Wheat is an important crop being a staple food in Turkey (Yildirim et al., 2008). In Turkey, per person wheat consumption is 228.7 kg. Wheat production is 20.1 million tons under cultivated areas in Turkey (TSI, 2012). High grain yield in wheat has been the main aim in wheat, breeding studies was focused on attempts to improve the yield potential by new genotypes (Kusaksiz & Dere, 2010). Breeding programs are traditionally empirical, that is, the selection is based on the yield per se as a final integrator of all the processes occurring during the life of the plant. Selection efficiency could be increased if specific physiological and/or morphological attributes related to yield under specific environments could be identified and used as selection criteria for complementing traditional plant breeding (Acevedo, 1991). Total chlorophyll content per leaf area may be evaluated in a fast, single and nondestructive way using a portable chlorophyll meter like SPAD-502 (Soil-Plant Analysis Development Section, Minolta Camera Co., Ltd., Osaka, Japan). SPAD indirectly measures leaf chlorophyll and nitrogen (N) content. The linear or non-linear relationship between real leaf chlorophyll content and chlorophyll meter (SPAD) readings were reported in more than twenty published studies for different plants (Mulholland et al., 1997; Yamamoto et al., 2002; Uddling et al., 2007). Bread wheat (Triticum aestivum) is an important crop in Southeastern Anatolia of Turkey, where high temperatures and water stress often reduce plant growth and crop yields. Therefore, wheat yield is lowered. The ability of a cultivar to produce high and satisfactory yield over a wide range of stress and non-stress

environments is very important (Rashid *at al*, 2003). Some morphologic, physiologic or ecologic factors such as irradiance, leaf water status and measurement time (i.e., morning vs. afternoon), crop growth stage, heat stress, mineral status of the soil and irrigation may affect SPAD readings. Also year, location and cultivar differences may have an effect on leaf greenness and SPAD readings (Bavec and Bavec, 2001; Rharrabti et al., 2001).

The aim of this study was to determine of the effects on grain yield and quality of physiological characteristics in bread wheat in Turkey and to evaluate whether the physiological characteristics could be used as selection criteria to obtain stable and bread wheat genotypes.

Materials and methods

The experiment is conducted in randomized complete block design with four replications in GAP International Agriculture research and Traning Center field. Studies were conducted under the rainfall condition with 20 advenced bread wheat lines and 5 cultivarsb(Table-1). Each of the five commercial wheat varieties and a 20 adventes lines were grown in 6 rows where each row length was kept 5 meter by maintaining a row to row distance of 20 cm. A seedling rate of 450 seed/m^2 was used in each planting. The trials were managed with optimum nutrient application (60 N: 60 F: 0 K) while the weeds were controlled with of herbicides. The data was statistically computed by JMP 5.0.1 program as well as for correlation.

Results and discussion

As shown in Table-1, in 2013-2014 growing season, grain yield has been low due to the frost on March 31, temperature and drought stress. Also, significant differences were determined in terms of TW, SPAD, heading day at level of 1% and 5%

Table 2. The correlation between the parameters

C.Temp.= Canopy temperature, **YAI**: Leaf area index, **NDVI**: Normalized vegetation index, **TGW**: Thousand grain weight, **PRT**: Protein, **SDM**: Sedimentation, **W.GLT**: Wet gluten, **G.Yield**: Grain yield,

Correlation analyses showed negative corelation between grain yield and canopy temprature, SPAD, protein, sedimantation value, wet gluten content; whereas pozitive corelation between grain yield and TGW, TW, NDVI. Several studies, Although a positive correlation was determined beetwen grain yield with SPAD(Yildirim et al 2009). According to results of this study, a negative correlation was determined beetwen grain yield with SPAD. This situation, It is believed to be caused by frost. Because, genotype is delayed 15-20 days as the vegetation.

Conclusion

Grain yield has been low due to the frost on March 31, temperature and drought stress. As a result of this study; G7, G21, G22 and G24 had better performance in terms of TW, G11 and G16 for heading time, G1, G17, G19 and Pehlivan for chlorophyll content respectlively. These genotypes must be used the breeding programs. Also, Because of escape than the heat stress, early heading genotypes(G11 and G16) should be evaluated. Relationships between physiological parameters and grain yield, quality should be investigated as comprehensively for breeding programs.

Abstract

Flaxseed is a valuable product, containing 34-35% fat, 23% protein, 22% nitrogen-free extract, 9% fiber, 3% ash and 8% water. It is widely used in chemical, food and pharmaceutical industry. Health promoting activity of flaxseed oil is mainly connected with the presence of essential fatty acids (EFA). On average, it consist of 50–58% α-linolenic acid (ω3), 15% linoleic (ω6) and 17% oleic acid (ω9) glycerides. However, the beneficial for health ω3/ω6 ratio may vary depending on the cultivar type. To achieve both the high yields and the highest possible quality of raw material, new flax cultivars are introduced to agricultural production, as genetic factor can significantly affect flax ontogeny, including fat content and composition.

The research aimed at selection of flax cultivars best for the production of the highest quality oil (the most desired set of EFA), as well as the cultivars whose seeds accumulate the lowest number of nutritional values. Namely, 28 flax cultivars were subjected to analysis, all registered in such countries as France, Netherlands, Austria, UK, Estonia, Canada, Romania, Czech Republic, Germany, Belgium and Poland. The analysis included comparison of such parameters as: crop yield, calorific value of flax seed, content of mineral and organic components, fat and protein yields, and also fatty acids chemical composition. The results showed that for different cultivars the crop yield may vary from 1.09 to 2.88Mg·ha^{-1} with corresponding calorific values from 121 to 325 MJ·ha^{-1}. At the same time fat and protein yield averages respectively 420-1162kg·ha^{-1} and 302-764 kg·ha^{-1}.

Key words: *flaxseed, mineral and organic composition, mono-unsaturated fatty acids (MUFA), poly-unsaturated fatty acids (PUFA), saturated fatty acids (SFA)*

Introduction

Oil flax is a raw material used in different industries, including chemical, pharmaceutical, food, fodder, paper, textile as well as medicine. Its seeds, in comparison to other oil plants, are the most effective, stabile and cheap source of linoleic acid from *n-3* family (Rumińska 1990, Tokarz 1994). The obtained esters of linseed oil, produced from cold – pressed oil, can be used for supplementation of different food products which are important in diet – related diseases in humans (Jelińska et al. 2003, Obiedzińska and Waszkiewicz-Robak 2012).

The application of 10% addition of ground brown and yellow flax seeds to wheat or mixed wheat and rye bread baking, results in significant increase in total protein, two – fold increase in dietary fibers and three – fold growth of crude fat content as compared to standard bread. Similar tendency, namely the considerable increase, was recorded with regard to Ca content– by 70%, Cu – by 150% and Mg – up to 200%. Five – fold increase in the quantity of linolenic acid was reported in fatty acids profile of bread Jelińska et al. (2003). Usually, the

content of this acid in flax seeds amounts from 52 to 58 % of total fatty acids (Ajuyah et al. 1991). The presence of polyunsaturated fatty acids influences decreased risk of the occurrence of cancer and the bread with the addition of linseed flouris recommended in glutene – free diet (Gambuś et al. 2009). Linseed oil is rich in indispensible polyunsaturated fatty acids (PUFA), overrunning, in this respect, all more important oil plants, as well as fish fat (Jelińska et al. 2003, Zając et al. 2010).

The fact that flax seeds are rich in fibre, slime, phenolic compounds, as well as indispensible unsaturated fatty acids, mainly from *n-3* family. From these reasons they are used in animal feeding.The basic aim of flax seeds or linseed oil application in animal feeding dose is the increase in polysaturated fatty acids (PUFA) content in animal products, as well as the decrease in mutual ratio of fatty acids from *n-6* and *n-3* families, which should reach a ratio of 4-5:1. Higher amount of PUFA from family in the human diet reduces the overall cholesterol level in blood, and through the increase in HDL lipoproteins concentration decrease LDL lipoprotein concentration in blood serum (Tuberoso et al. 2007).

Full meeting of the increasing demands for linseed oil production for consumption purposes can be obtained through the increase in oil flax and fiber flax cultivation area, accompanied by increased yielding and appropriate choice of flax cultivars. At the same time, reduction in flax seed originating from cultivation of fiber flax as a byproduct should be introduced Zając (2004). The level of flax yielding in the different countries is low, especially as compared to basic crops, as well as highly variable according to the years (Diepenbrock et al. 1995, Arslan et al. 2011). This fact points to the need of a proper selection of flax cultivars, as well as the answer to the question if agro –meteorological conditions significantly effect on genetically determined composition of fatty acids. The aim of this work was a comparison of available, registered flax cultivars and selection of flax cultivars best for the production of the highest quality oil, as well as the cultivars whose seeds accumulate the lowest number of nutritional values.

Materials and methods

In the years 2009-2011, in Experimental Station belonging to the Department of Plant Cultivation in Pawłowice in Poland (eastern longitude 17°12´ and northern latitude 51°31) the field experiment was conducted, according to the method of subblocks in correlated system, in four replications. The research involved 30 cultivars of oil and fiber flax and old varieties originating from different countries. Winter wheat was a forecrop for the oilseed flax. The pre-sowing fertilization involved: 46% triple superphosphate, in the amount of 40 kg $P_2O_5 \cdot ha^{-1}$, 60% potassium salt, in the amount of 70 kg $K_2O \cdot ha^{-1}$ and 46% urea - 20 kg $N \cdot ha^{-1}$ .Thirty four coma four percent ammonium nitrate was introduced in a growth stage of flax plant (so – called herring – bone phase), in the amount of 20 kg $N \cdot ha^{-1}$, in the form of top – dressing fertilization.

The soil in Pawłowice is classified as autogenic, brown soil, originating from light loam on medium loam, assigned to agriculturally usable good wheat complex, of soil class III b. In the years of investigation the phosphorus content in the soil ranged from a medium to a very high level, potassium content was between a low and a very high range, magnesium – high to very high content, while pH range was slightly acidic.

The Experimental Station is situated in the hottest region of Lower Silesia, which is the hottest region of Poland. The climate in the region of Wrocław possesses the features typical for tepid climate of the temperate zone. In order to characterize in the experimental years the weather conditions during the vegetation period of the flax, the indicator developed by Sielianinov was used (Molga 1986, Radomski 1987). According to Sielianinov, during the summer months, when there is the greatest water demand by plants, the sum of the temperatures divided by 10 gives the approximate numerical result of evaporation sum, resulting from the measurement with Wild's balance-evaporimeter. On this basis, Sielianinov developed an index, which he called the coefficient of water security or the conventional moisture balance (hydrothermic coefficient): $K = 10P / \Sigma t$.

In this work, in order to determine the moisture conditions during the growing season of plants, eleven different ranges were taken adopted: for Sielianinov's hydrothermic coefficient K below 0.3 - extremely dry; between 0.31 and 0.5 - very dry; 0.51 ÷ 0.7 – dry; 0 71 ÷ 0.9 - quite dry; 0.91 ÷ 1.0 - moderately dry; 1.01 ÷ 1.2 – average; from 1.21 to 1.5 – optimal; 1.51 ÷ 1.9 - quite humid; 1.91 ÷ 2.4 – humid; 2.41 to 3.0 - very humid; and above 3.1 -extremely humid. Moreover, the agroclimatic conditions were described using indexes proposed by Kaczorowska (1962).

Precipitation was expressed as percentage of long-term average of each month, assuming the scale: less than 25 - a period of extremely dry; 26-49 - very dry; 50-74 – dry; 75-124 – normal; 125-149 - humid, 150-174 - very humid; and above 175 – extremely humid period.

The temperature course during the experimental period was evaluated by their deviation from the mean value for the multi-year period. Expressed in degrees it was: above 2.0 - very warm period; from 2.0 to 0.6 – worm; between + 0.5 and - 0.5 – normal period; from - 0.6 to - 2.0 – cold; and below - 2.0 - very cool period.

The course of weather conditions in the years of investigation, *i.e.* distribution of the temperature and rainfall were presented in table 1.

Fatty acids profile was determined using gas chromatograph equipped with the flame ionization detector (FID) and capillary column ZB-WAX (30 m × 0,25 mm i.d., 0,25 µm film thickness). Helium with a velocity flow-rate of 20 m s^{-1} was used as a carrier gas, the temperature of injector was 250°C, and the detector temperature was equal 270°C. The column oven was working under the programmable temperature regime: 80°C maintained for 1 min, first temperature ramp to 140°C at the rate of 20°C min^{-1}, than rise to 200°C at the rate of 10°C min^{-1}, and further rise to 250 °C at the speed of 30°C min^{-1}. The maximum temperature of 250°C was kept for 6 min. Total time of analysis was 18 min. Qualitative and quantitative analysis of chromatograms was performed on the basis of comparison respectively the retention times and the peaks areas of fatty acids methyl esters in the examined sample with the methyl esters standards (Supelco 37 Component FAME Mix).

Results and discussion

Oil flax shows very high variability of yield in which mainly depends on the course of metheorological conditions, as well as environmental conditions. The research conducted by a number of authors proved considerable fluctuation of yield size data according to the years, ranging from 0.31 t/ha to over 3.0 $t \cdot ha^{-1}$, while within a single year the difference between maximum yield could reach a value of 1.95 $t \cdot ha^{-1}$ (Diepenbrock et al. 1995).

In this study, no significant differences in flax fielding, resulting from the course of weather conditions, was obtained, and the mean value of seed yield was equal 2.3$t \cdot ha^{-1}$ (tab. 2). However, significant differences in yielding between particular cultivars were observed.

In the three – year experiment, the highest – yielding cultivar proved to be Floriana, the Romanian fiber cultivar featuring the yield of 2.88 $t \cdot ha^{-1}$, while the poorest yield size characterized Opal, the oil cultivar whose yield amounted 2.68 $t \cdot ha^{-1}$. The differences in cultivars yielding were also reported in the research Mohammadi et al. (2010). The author proved that the course of the weather conditions did not affect the percentage of protein, ash, fiber, N, P, K, Mg and Ca contents in flax seeds, and also the yield of fat, protein and energy efficiency from the area unit. In the three – year experiment, climatic conditions did significantly influence on percentage of fat content in seeds and their average values were equal respectively 37.9% and 30 $mg \cdot 1000\ g^{-1}$.

Significant differences between particular cultivars were recorded for the content of fat, protein, fiber, P and K in flax seeds and for the first two of the difference ranged approximately 5.5%. The mean content of fat and protein in seeds equalled respectively 37.9% and 26.7%, which corresponds with the results reported by Diederichsen, Raney (2010) and Laza, Pop (2012). A genetic factor did not affect the content of Mg, Ca and Na, which was also confirmed in the research by Laza and Pop (2012). Different findings were reported by Kiralan et al. (20109, who indicated significant effect of a cultivar factor on the content of mineral components Ca, Mg, Na, K, P at simultaneous considerable differentiation of some their values.

The yield size and the content of organic components in the seeds correspond with the yield of protein (Dordas 2011), fat (Khourang et al. 2012) and energy efficiency from 1 hectare. Mean yield of fat in the experiment was about 870 kg from 1ha. As far as the field of fat was concerned, the best cultivars proved to be: Floriana, Raulinus, Athlanta, Linda and Opal and the results obtained for these cultivars were higher from the mean ones by 290, 172, 144, 132 and 126 $kg \cdot ha^{-1}$ respectively. Considering the yield size of protein, the highest values characterized flax cultivars: Venica – 764.3kg, Electra – 758.4kg, Opal- 730,1kg, Florinda- 708.0kg and Hermes – 702.4kg. The most energy – efficient were cultivars: Venica, Floriana, Raulinus, Royal and Athlanta, with field size values ranging from 325.4 to 288.9 MJ, at mean value for the experiment amounting 253.6 MJ z 1 ha. Energetic value in the experiment by Poiša and Adamovičs (2011) obtained the level higher by nearly 30%.

Warm year 2012 affected on the content of the following acids $C_{8:0}$, $C_{14:1}$, $C_{18:1n9c}$, $C_{22:1n9}$, $C_{24:1}$, MUFA and OFA. Similar findings were reported in the research of Gambuś et al.(2009). The year 2010, with the lowest 24 – hour – temperature and the highest precipitation during flax growing period, favored higher contents of $C_{14:0}$, $C_{18:0}$ and $C_{22:6n3}$. On the other hand, the year 2011, described according to Sielianinov coefficient as quite wet, featuring the highest mean air temperature during plants growing period, provided for higher contents of $C_{18:3n3}$, $C_{20:2}$, $C_{20:3n6}$, $C_{22:2}$, $C_{24:0}$ and PUFA. Different results were obtained by Zając et al. (2001), who proved that only the content of $C_{14:0}$ was modified by agro-meteorological factors.

Many authors, regardless of the investigated factors, reported the differences in fatty acids composition in flax cultivars (Herchi et al. 2011, Klimek-Kopyra et al. 2012). Usually, the analysis includes the use of the mutual proportions and the relations of particular acids or their groups, like: MUFA, PUFA, SFA, UFA, DFA, OFA, ∑P.M.L ODR, LDR, as well as COX coefficient (Zając et al. 2001, Piłat, Zadernowski 2010, Herchi et al. 2015, Maknatjou et al 2015).

The highest relations between PUFA and MUFA took place in 2011 and amounted 1:2.77. No significant differences in the proportion of PUFA/MUFA and of UFA/SFA in cultivar were found, although these values fluctuated from 2.23 to 3.12 for PUFA/MUFA and from 4.96 to 6.15 for UFA/SFA. According to the research by Zając et al. (2001), the years and cultivars did not influence on MUFA, PUFA, SFA and UFA, as well as, there mutual proportions, nevertheless, the value of obtained were comparable.

Table 3

Selected fatty acids content of oil flax seeds (*Linum usitatissimum* L.), % of total fatty acid.

[1)](PUFA = Essential Fatty Acids - EFA); [2)] DFA – index of desirable fatty acids (sum of unsaturated fatty acids and stearic acid, i.e. neutral and hypocholesterolemic acids, (C18:0+UFA); [3)] OFA - sum hypocholesterolemic fatty acids (C l4:0 + C 16:0); [4)] COX (Calculated oxidizability value) = [1 (18: 1%) + 10.3 (18: 2%) + 21.6(18: 3%)]/100 ; [5)] ODR (Oleic desaturation ratio) = [% C18: 2 + % C18: 3 / % C18: 1 + % C18: 2 + % C18: 3] × 100; [6)] LDR ((Linoleic desaturation ratio) = [% C18: 3 / % C18: 2 + % C18: 3] × 100; [7)] Athero – sum of C12:0, C14:0 and 16:0 acids. The difference between sum of presented in table fatty acids and 100% reflect the sum of FA with uneven number of carbons in the molecule..

Conclusion

- The weather conditions did not modified the percentage of fat and protein content in flax seeds, as well as, they did not influence on the yield of fat, protein and energy efficiency from 1 ha.
- The obtained seed yield within the range from 1.09 to 2.88 $t \cdot ha^{-1}$, fat content 421.0÷1161.8 $kg \cdot ha^{-1}$and protein content – 302.5÷764.3 $kg \cdot ha^{-1}$resulted from the cultivar factor. Among the compered fibre cultivars, the highest seed yield were found out for Floriana, Venica, Hermes, Electra, Marylin, while in oil cultivars the highest yield values characterised Opal, Raulinus, Athlanta, Oliwin, Flanders.
- Genetic factor determined the content of $C_{16:0}$, $C_{18:0}$, $C_{18:2}$, and $C_{20:1}$ acids.
- The years of research significantly affected the fatty acids profile of flax oil, namely: $C_{8:0}$, $C_{14:0}$, $C_{14:1}$, $C_{18:0}$, $C_{18:1n9c}$, $C_{18:3n3}$, $C_{20:2}$ and $C_{20:3n6}$ (given as sum), unsaturated C_{22} acids (namely $C_{22:1n9}$, $C_{22:2}$, $C_{22:6n3}$), $C_{24:0}$, $C_{24:1}$, MUFA, PUFA, OFA and their mutual proportion PUFA/ MUFA.

A COMPARATIVE STUDY OF HAIRY ROOT INDUCTION EFFICIENCY IN TWO MEDICINALLY IMPORTANT PLANTS USING AGROBACTERIUM RHIZOGENES

Bahman HOSSEINI, Elnaz NOROZY

Faculty of Agriculture, Urmia University, Iran
*Corresponding author: b.hosseini@urmia.ac.ir

Abstract

Medicinal plants have been used from ancient times to attempt cures for diseases and their importance has become increasingly apparent. Despite advancements in the chemical synthesis of secondary metabolites, extracted from plant sources is the only way to achieve many valuable secondary metabolites. Recent advances in plant genetics and recombinant DNA technology, contributed to improve and strengthen research on the biosynthesis of secondary metabolites. Hairy Root Culture is the new route for large scale secondary metabolite production because of their fast and plagiotropic growth, genetic and biochemical stability. Using recombinant DNA technology allowed to changes in gene expression that are involved in the biosynthesis of secondary metabolites. High potential of hairy roots to produce valuable metabolites and commercialization it's by using bioreactor system, have been attracted by private companies. Different explants of two medicinally important plants *Agastache foeniculum* and *Dracocephalum kotschyi* were used for induction of hairy root cultures using the *Agrobacterium rhizogenes* strain A4, by immersion and injection inoculation methods. Furthermore, the effect of different elicitors (colchicines, chitosan and UV-B) on hairy root growth and secondary metabolites were evaluated. Rosmarinic acid production as one of the main active substances of these plants was quantified by HPLC. We were able to induce hairy roots in both plants by immersion method with high transformation frequency (30-50%). Copious growth of hairy roots and secondary metabolites (total flavonoid, total phenolic and antioxidant) production was observed in all of applied elicitors except salicylic acid. Rosmarinic acid production in transformed roots was higher than the amount in non-transformed roots. In the near future, hairy roots will become powerful tools for biotechnologists with which to reach the precious underground resources of the plant kingdom. This review creates a paradigm for future scale up of hairy roots in bioreactors for large scale production of secondary metabolites and its increasing use as model system in metabolic engineering.

Keywords: *Agastache foeniculum*, *Dracocephalum kotschyi*, Elicitor, Hairy root, Secondary metabolaits

Introduction

Agastache foeniculum and *Dracocephalum kotschyi* are important sources of products that people use, including food, cosmetics – sanitary and medicines. Anise hyssop (*Agastache foeniculum*) is a perennial herbaceous plant, belonging to the Lamiaceae family. The origin of this plant has been reported in South America. The essential oil of *A. foeniculum* is used in food, pharmacy, cosmetics – sanitary and ice cream industries. Anise hyssop is also used in traditional medicine for treating lung diseases and cough (Omidbaigi 2007). *A. foeniculum* has many useful constituents including monoterpenes and phenyl propanoids. Rosmarinic acid, chlorogenic acid, rutin, apigenin and galangin, are among the constituents of anise hyssop essential oil, with many pharmacological properties. The antioxidant activity of essential oils depends on the content of total polyphenols, which is measured 98.6 mg/g in *Agastache*

foeniculum (Matei 2012). *Dracocephalum kotschyi* Boiss (Labiateae) is an herbaceous, perennial and endemic plant known in Iran as Zarrin-Giah. Recent pharmacological studies have confirmed some of the methoxylated flavonoids in plant's parts having anti-cancer properties. *Agrobacterium rhizogenes* mediated hairy root production is a valuable tool for studies on the biosynthesis of secondary metabolites and for exploitation in metabolic engineering. For this reason, hairy roots have been induced in several medicinal and aromatic plants and cultured for the production of secondary compounds (Bonhomme et al, 2000). Several factors affect the rate of *A. rhizogenes* mediated transformation (Cao et al, 2009). Many studies have shown that various plant tissues have different responses to transformation with different strains of *A. rhizogenes* (Sharafi et al, 2013; Samadi et al, 2013). The use of biotic and abiotic elicitors is a common strategy that is used to increase the growth rate and production of secondary metabolite in hairy root systems (Soleimani et al, 2012). Rosmarinic acid (RA) is a phenolic compound and is produced in the roots of *Agastache foeniculum* and *Dracocephalum kotschyi* that has shown antioxidant, anti-virus, antimicrobial, anti-allergic, anti- inflammatory and anticancer activities. In the present study two medicinal plants namely *Agastache foeniculum* and *Dracocephalum kotschyi* were chosen to induce the hairy root cultures, as these have medicinal properties residing in the roots. The objective of the study was to find the induction efficiency of hairy roots by *Agrobacterium rhizogenes* in all the two plants. The growth dynamics and secondary metabolites of cultured transformed root were investigated.

Materials and Methods

Explants Preparation

Seeds were obtained from the plants grown in research field of horticultural department, Urmia University, Iran. Seeds were surface sterilized and sterile seeds were cultured on MS (Murashige & Skoog 1962) media containing 7 g L−1 agar. Hypocotyls, cotyledons, internode, one-month old and five-month-old leaves were prepared as explants for transformation.

Bacterial Culture Preparation and plant transformation

Agrobacterium rhizogenes strain A4 (provided by the bank of microbes at the National Institute of Genetic Engineering and Biotechnology (NIGEB),Tehran, Iran) was cultured on LB solid medium for activation of the strain and sub cultured three times on the same medium.The explants were infected with bacteria using two different methods, a) by immersion the leaves in a suspension of bacteria, and b) by injection of bacteria in different parts of explants by 0.5 ml insulin syringes (Exel – America). After infection explants were cultured in MS solid medium supplemented with 3% sucrose in dark regime at 25ºC for 48 hrs. Elimination of bacteria was then done by transferring the stabbed explants to MS solid medium with antibiotic cefotaxime (500 mg/l) at 25ºC in dark. Hairy Roots that developed were transferred to antibiotic and hormone free ½ MS liquid medium at 25ºC at 100 rpm on orbital shaker under dark and sub-cultured in fresh medium every 15 days.

Treatment of hairy roots in liquid media

In separate experiment, the effects of different concentrations of Chitosan (50, 100 and 150 mg L−1), colchicines (0/01, 0/03 and 0/05 %) and UV-B radiation (3, 6 and 9 min) at a week in the hairy roots formation and elicitation of total flavonoid, total phenolic and antioxidant production were investigated. Approximately 1 g of hairy roots were incubated in 250 mL Erlenmeyer flasks containing 50 mL liquid ½ MS medium for 3 months on the rotary shaker (100 rpm) at 25◦C. Liquid ½ MS medium was used in all treatments as control sample.

Preparation of extracts

Lyophilized and powdered plant materials (0/1 g) were separately extracted with 80 % methanol (5 mL). The extraction procedure was the same as that described above. Total

phenolics were determined colorimetrically by the Folin-Ciocalteu method. The prepared extracts (1 ml) were mixed with 5 ml of Folin-Ciocalteu reagent (previously diluted tenfold with distilled water) and allowed to stand at room temperature for 10 min. A 4 ml sodium bicarbonate solution (75 $g.l^{-1}$) was added to the mixture. After 30 min at room temperature, absorbance was measured at 765 nm using a UV spectrophotometer (Pharmacia Biotech).

Determination of total flavonoid content

Total flavonoid content was determined using aluminium chloride (AlCl3) according to a known method, 15 using quercetin as a standard. The plant extract (0.1 ml) was added to 0.3 ml distilled water followed by 5% NaNO2 (0.03 ml). After 5 min at 25°C, AlCl3 (0.03 ml, 10%) was added. After further 5 min, the reaction mixture was treated with 0.2 ml of 1 mM NaOH. Finally, the reaction mixture was diluted to 1 ml with water and the absorbance was measured at 380 nm.

Estimation of total antioxidant capacity

The antioxidant activity of extracts were measured by the DPPH (2, 2′-diphenyl-1-picrylhydrazyl) free radical scavenging method. Sample solutions (50µl) in methanol were added to DPPH methanol solution (2 ml, 40 $\mu g.ml^{-1}$). The mixtures were incubated at room temperature for 30 min and the absorbance was measured at 517 nm.

Determining the amount of Rosmarinic acid

High performance liquid chromatography (HPLC) was used for determination of Rosmarinic acid content. Rosmarinic acid was detected at 254 nm. Retention time of Rosmarinic acid was 5.34 min. Chromatographic peaks were confirmed by retention time and UV spectra that are related to the reference standard. The retention time of the peak obtained with standard of Rosmarinic acid was used to identify the corresponding peaks of root extracts.

Results and discussion

Effect of Explants types

Hairy roots were induced at the wound site of explants after 3–4 weeks of culture. There were no hairy roots formed from control explants. In *Agastache foeniculum*, the highest rate of hairy root induction (51.1 %) was obtained for one-month-old leaf explants by A4 strain. The hypocotyl explants showed necrosis with a low rate of hairy root induction. Moreover, hairy roots were not observed in control explants. In *Dracocephalum kotschyi* the one-week-old leaf explants (36/66 %) were highly and significantly susceptible to infection by A4 strain of *A. rhizogenes* and internode explants (1/66 %) showed low rate of hairy root induction. Many studies have shown that *A. rhizogenes* strains and explants types have significant impacts on the induction of hairy roots (Sharafi et al.2013; Soleimani et al. 2012).

Effect of inoculation method on hairy roots induction

Effects of the inoculated methods in hairy roots induction in two plants were different. In *A. foeniculum* ANOVA results indicated no statistically significant differences between the two inoculated methods, but immersion was the best method to inoculation of *D.kotschyi*. Contact between bacteria and plant cells can be increased by direct injection of bacterial suspensions into the explants or by immersion (Tomilov et al., 2007).

Effect of elicitation on hairy root growth and total flavonoid, total phenolic and antioxidant

Investigation the effects of UV-B on the growth rate of hairy roots showed that Fresh weight of hairy roots (1/3 g) declined sharply in 9 min and UV- B treatments were no significant effect on dry weight of roots (fig. 1). Also the highest increase in metabolites was observed at 6 min (fig. 2, 3, 4)

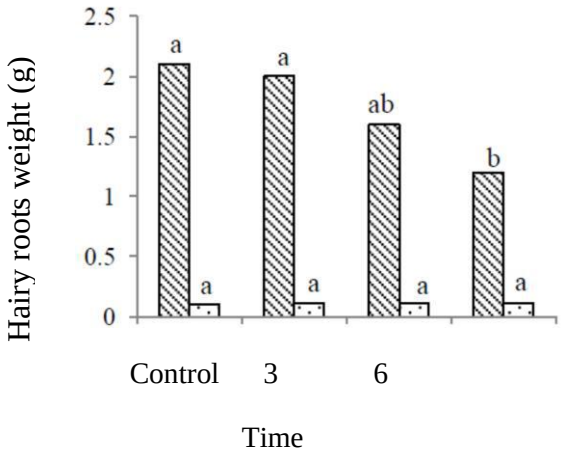

Fig. 1: Effects of UV-B treatments on hairy roots growth. The different letters denote a statistically significant difference at $P \leq 0.05$, as determined by Duncan's multiple

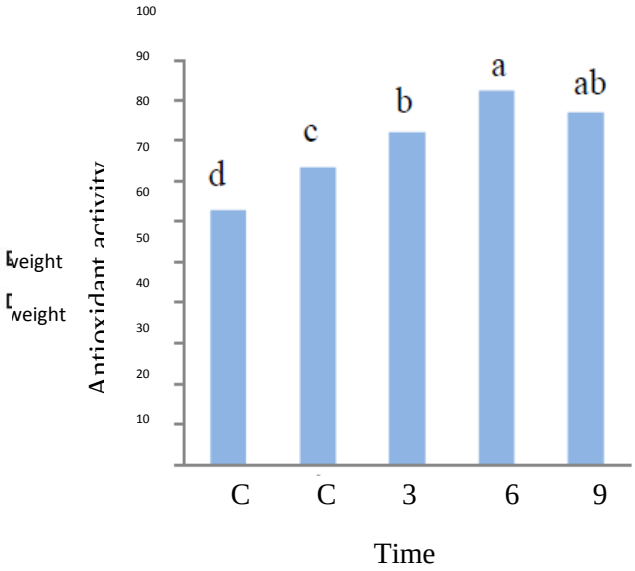

Fig 2: Effects of UV-B treatments on antioxidant activity. The different letters denote a statistically significant difference at $P \leq 0.05$, as determined by Duncan's multiple range test.

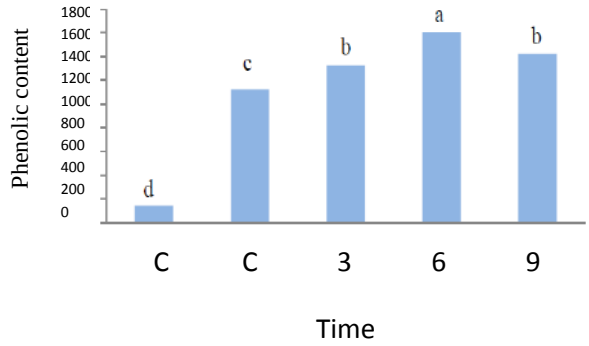

Fig 3: Effects of UV-B treatments on phenolic content. The different letters denote a statistically significant difference at P ≤ 0.05, as determined by Duncan's multiple range test.

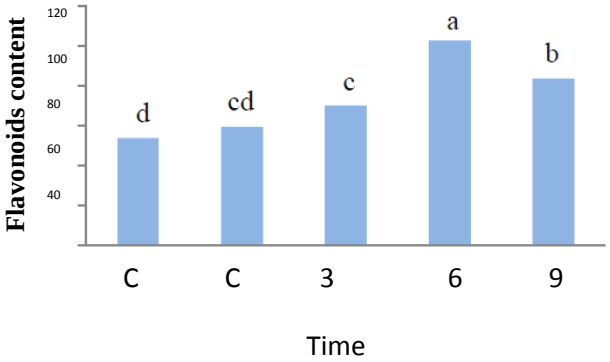

Fig 4: Effects of UV-B treatments on flavonoids content. The different letters denote a statistically significant difference at P ≤ 0.05, as determined by Duncan's multiple range test.

Amongst the various concentrations of colchicine, the 0/05% concentration increased the antioxidant activity (90/33 %), phenolic content (1632/61 µg/g DW) and flavonoid content (143/50 □g/g DW) of the hairy roots (Fig. 5, 6, 7).

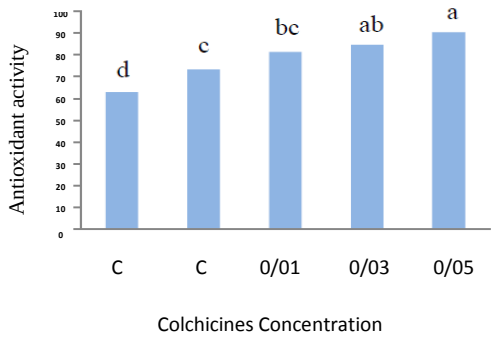

Fig 5: Effects of colchicines treatments on antioxidant activity. The different letters denote a statistically significant difference at P ≤ 0.05, as determined by Duncan's multiple range test.

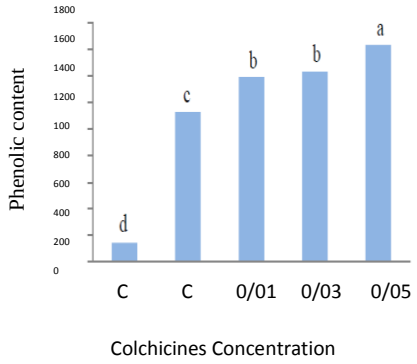

Fig 6: Effects of colchicine treatments on phenolic content. The different letters denote a statistically significant difference at P ≤ 0.05, as

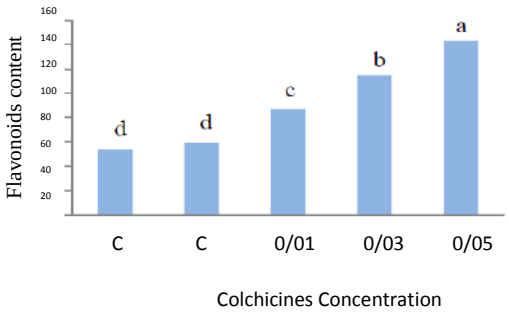

Fig 7: Effects of colchicine treatments on flavonoids content. The different letters denote a statistically significant difference at P ≤ 0.05, as determined by Duncan's multiple test.

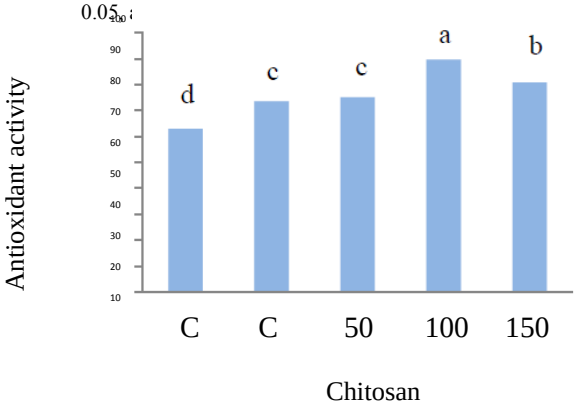

Fig 8: Effects of chitosan treatments on antioxidant activity. The different letters denote a statistically significant difference at P ≤ 0.05, as determined by Duncan's multiple range test.

Chitosan 100 mg/l increased the fresh weight of the hairy roots (fig. 12). The 100 mg/l concentration increased the antioxidant activity (89/66 %), phenolic content (1617/85 µg/g

DW) and flavonoid content (96/33 µg/g DW) of the hairy roots (Fig. 8, 9, 10). Effect of elicitation depends on the elicitor type, environmental conditions, the concentration of elicitor and the interaction between the elicitor and plant cells (Smetanska 2008).

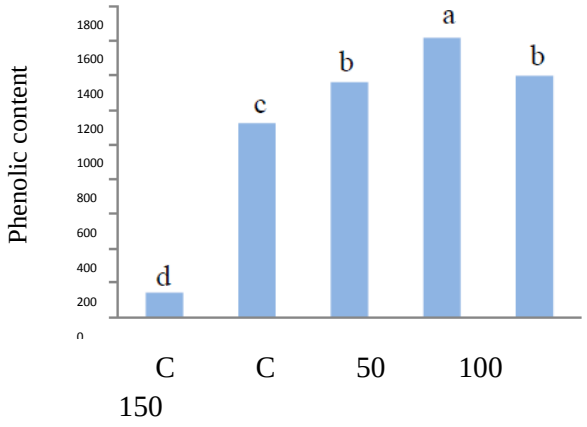

Fig 9: Effects of chitosan treatments on phenolic content. The different letters denote a statistically significant difference at $P \leq 0.05$, as determined by Duncan's multiple range test.

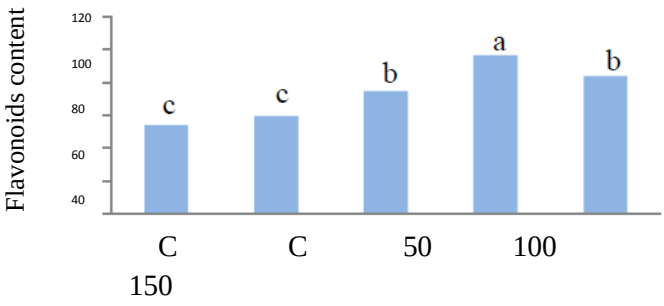

Fig 10: Effects of chitosan treatments on flavonoids content. The different letters denote a statistically significant difference at $P \leq 0.05$, as determined by Duncan's multiple test.

Rosmarinic acid production in hairy roots

The HPLC analysis confirmed the presence of RA in tested samples according to the same retention time of 5.34 min as standard (fig. 11). The highest amount of RA (213.42 µg g−1 dry weight) was produced in transformed roots; the level was almost 4-fold higher than RA content of non-transformed roots (52.28 µg g−1 dry weight) under the same conditions. Many studies have pointed out that hairy root growth and metabolite production depend on '*rol*' gene expression, the *rol* genes could activate expression of defense genes and thus the production of secondary metabolites (phytoalexin production) in plant cells (Sherafi et al. 2013).

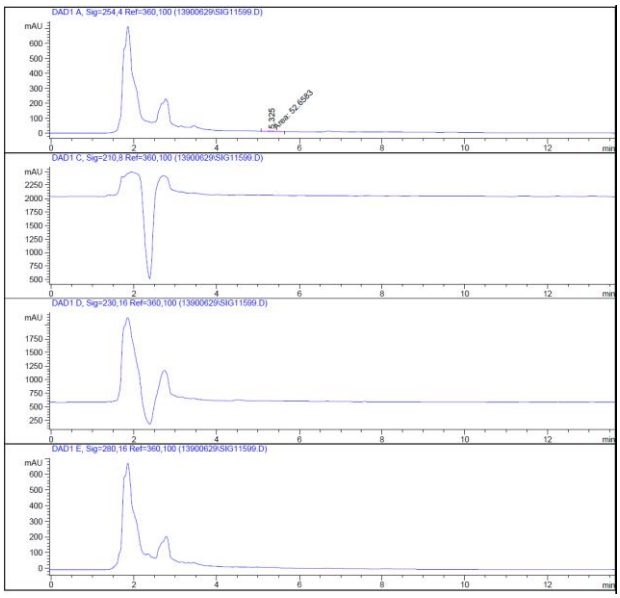

Fig. 11: Rosmarinic acid content of hairy root cultures, grown in 1/2 MS media. Values represent the mean ± SD of three independent measurements.

STUDY OF OCHRATOXIN A' AND ZEARALENONE' CONTAMINATION IN WHEAT AND MAIZE FROM ALBANIA

Afërdita SHTËMBARI[1*], Dritan TOPI[2]

[1]University of Tirana, Faculty of Natural Sciences, Department of Industrial Chemistry, Tirana, Albania
[2]University of Tirana, Faculty of Natural Sciences, Department of Chemistry, Tirana, Albania
*Corresponding author: aferditashtembari@live.com

Abstract

Ochratoxin A (OTA) and Zearalenone (ZON) are mycotoxins, natural contaminants, produced by molds. OTA is produced by *Aspergillus ochraceus* and *Penicillium verrucosum* species, while ZON is produced by *Fusarium* species. Exposure to OTA has been associated with distinct renal diseases in humans endemic in the Balkans, referred to Balkan Endemic Nephropathy (BEN) and Urinary Tract Tumors (UTT). The critical effects of ZON result from its potent oestrogenic activity, considered as a possible causative agent in the outbreaks of precocious pubertal changes in young children. The objective of this study was to assess the presence of OTA and ZON in cereal commodities harvested during 2014 in different regions of Albania and to assess risk of mycotoxin exposure posed to humans and animals. Random flour samples (n = 21): winter wheat (14 samples) and maize (7 samples) were collected in Lushnja - Fieri region (n = 14) and Korça region (n = 7), according to their production distribution in the country. The samples were analyzed, by High Pressure Liquid Chromatography (HPLC), coupled with fluorescence detector. Analytical results indicate that OTA levels in two maize samples (139.15 and 8.575 μg/kg), was above the Maximum Residue Level (MRL) established by Commission Regulation 165/2010 amending EU Regulation 1881/2006, for maize (5 μg/kg) with destination for human consumption, while ZON levels detected was under MRL (200 μg/kg), established on wheat for human consumption. Our findings indicate that OTA and ZON presence in cereals harvested in Albania is established, and may indicate health implications to consumers.

Key words: *Ochratoxin A*, *Zearalenone*, *Wheat*, *Maize*, *Albania*.

Introduction

Mycotoxins are secondary metabolites of fungi. Due to the widespread distribution of fungi in the environment, mycotoxins are considered to be one of the most important contaminants in foods and feeds. According to the Food and Agriculture Organization (FAO), more than 25% of the world's agricultural production is contaminated with mycotoxins, resulting in economic losses in the grain industry (Cazzaniga *et al*., 2001). *Aspergillus*, *Fusarium*, and *Penicillium*, all known field fungi, are the natural fungal flora associated with foods. The most common mycotoxins are aflatoxins, deoxynivalenol (DON), zearalenone (ZON), ochratoxin A (OTA), fumonisin, and patulin (Gaag *et al*., 2003).

Ochratoxins are a group of mycotoxins produced by several fungi of the *Aspergillus* or *Penicillium* families and are weak organic acids consisting of a derivative of an isocoumarin. The family of Ochratoxins consists of three members, A, B, and C, which differ slightly from each other in chemical structures. These differences, however, have marked effects on their respective toxic potentials. Ochratoxin A is the most abundant and hence the most commonly detected member but is also the most toxic of the three members (Van der Merwe et al., 1965). OTA is produced by *Aspergillus ochraceus* and *Penicillium verrucosum* species. Exposure to OTA has been associated with distinct renal diseases in humans endemic in the Balkans (in Bulgaria and ex-Yugoslavia), referred to as Balkan Endemic Nephropathy (BEN) and Urinary Tract Tumors (UTT) (Stoev et al., 1989). Ochratoxin A (OTA) is a nephrotoxin,

affecting all tested animal species, though effects in man have been difficult to establish unequivocally. It is listed as a probable human carcinogen (Class 2B) (Olsen et al., 2006).
Zearalenone was discovered as the cause of a reproductive disorder in pigs known as vulvovaginitis (Moss, 2002). ZON is a oestrogenic mycotoxin that can be produced by several field fungi including *Fusarium graminearum* (*Gibberella zeae*), F. *culmorum*, F. *cerealis*, F. *equiseti* and F. *semitectum* (Bennett and Klich, 2003). ZON is one of the most common *Fusarium* mycotoxins in the temperate regions of America, Europe and Asia. It is most frequently encountered on corn, but also contaminates other cereals and plant products (Krska *et al*., 2003). The critical effects of ZON result from its potent oestrogenic activity, considered as a possible causative agent in the outbreaks of precocious pubertal changes in the young children. The International Agency for Research on Cancer (IARC) has categorized ZON as a class 2A carcinogen (IARC, 1993).
In this study we have analyzed the ochratoxin A and zearalenone contamination in cereals harvested during 2014 in different regions of Albania. Random samples (n = 21): winter wheat (14 samples) and maize (7 samples) were collected according to EU regulation 401/2006. The wheat and maize samples collected directly after their harvesting season avoided the post-harvest contamination stage, which indicate that OTA and ZON origin of contamination in cereals is of pre-harvest stage.
The wheat and maize samples were collected in Lushnja - Fieri region (n = 14) and Korça region (n = 7), according to their production distribution in the country. The objective of this study was to assess the risk of mycotoxin exposure posed to humans and animals. The samples were analyzed, separately for OTA and ZON contamination by High Pressure Liquid Chromatography (HPLC) (LOD = 0.2 μg/kg).

Materials and methods

Sample characterization

Flour samples of winter wheat and maize were collected during 2014 in mill factories from three different regions of Albania: Korça (wheat and maize), Lushnja and Fieri (only wheat). Selection of these regions was based on the statistics for agriculture production in country (INSTAT, 2014). As the distribution of mycotoxins is not uniform throughout the matrix, the sampling procedure was carried out according to Commission Regulation (EC) No 401/2006 (European Commission, 2006).

Mycotoxins analysis

Apparatus

Linear shaker IKA HS 501 digital (IKA Labortechnik, Germany) was used for the extraction. For liquid chromatography, the system Waters Alliance 2690 with the fluorescence detector Waters 474 (Waters, MA, USA) equipped with columns Prodigy 5μ ODS(2) was used for OTA and ZON detection.

Chemicals and reagents

Standard solutions of OTA and ZON were purchased from Biopure (Tulln, Austria). For sample clean-up, immunoaffinity columns (R-Biopharm Rhône) were used. Reagents purchased at Merck (Darmstadt, Germany) and Supelco (PA, USA) were of analytical or chromatography grade purity.

Analytical procedure

OTA and ZON mycotoxins were determined separately in a single HPLC method following the instruction for use enclosed to respective immunoaffinity columns and standards (R-Biopharm Rhône, 2003). Mycotoxins were extracted from samples with appropriate solvents.

After sample clean-up, mycotoxins were determined by liquid chromatography. The limit of detection (LOD) and the limit of quantification (LOQ) for OTA and ZON was 0.2µg/kg. The results of were calculated according to sample moisture content of 12%.

Results and discussion

Two cereal grains, wheat and maize, are the most important cereal crop in terms of cultivated area, production, and consumption in the world as well in Albania. Owing to the abundant production and the main role of wheat and its flour products in the diet of humans and animals, they can play a very important role in endangering human health in case of contamination with health-threatening factors. In the farm and the warehouse, wheat can be invaded by different microorganisms, especially fungi (Saari *et al*., 1968).

6	Lushnjë	<LOD	<LOD
7	Lushnjë	<LOD	37.806
Mean value/positive samples		**73.8625**	**37.806**
Min Value		**8.575**	**37.806**
Max Value		**139.15**	**37.806**
Incidence of positive samples		**28.6 %** (2/7)	**14.3 %** (1/7)
Above MRL (%)		**14.3 %** (1/7)	**0.0 %** (0/7)

OTA was detected in two out of six maize samples varying 8.575-139.15 µg/kg, while in wheat was only one out of 14 samples in concentration 2.816 µg/kg. ZON was detected only in one maize sample (37.806 µg/kg). Analytical results indicate that OTA levels in two maize samples was above the Maximum Residue Level (MRL) established by Commission Regulation 165/2010 amending EU Regulation 1881/2006, for maize (5 µg/kg) with destination for human consumption, while ZON levels detected was under MRL (200 µg/kg), established on wheat for human consumption. Our findings indicate the OTA and ZON presence in cereals harvested in Albania is established, and may indicate health implications to consumers.

Conclusion

After analysis performed by HPLC, some of the wheat and maize samples resulted being contaminated with Ochratoxin A and Zearalenone. It is noticed that the incidence of positive samples in maize samples were bigger than in wheat samples. It is worth noting that in maize samples, we found samples containing higher OTA values than maximum limits as defined by national and European legislations. From this experimental work, we conclude that the risk of the preharvest contamination of OTA and ZON in cereals, in Albania, is present, especially for the maize produced during 2014.

Considering all the problems that cause contaminated cereals with mycotoxins (OTA and ZON) in human and animal health, it is recommended to make systematic analyses, because cereals are the basic food of population in Albania. Being the basic food of the population, increases the possibility of exceeding the daily limits that everybody (human and animals) should consume.

Acknowledgements

This analysis of mycotoxins was conducted in cooperation between Department of Chemistry, Faculty of Natural Sciences; University of Tirana, Albania; and Faculty of Veterinary Medicine; University of Skopje, Republic of Macedonia.

Abstract

Cereals and cereal products are significant and important human food resources and livestock feeds worldwide. Cereal grains are food staples in many countries. They are the raw materials of many our foods and certain beverages. Because of their extensive use as human foods and livestock feeds, the microbiology and safety of cereal grains and cereal products is a very important area. The aim of this study is the identification of mold developed in wheat's germ. The samples were obtained in sterile condition from 5 different industrial mill companies in south-east of Albania during March- June period 2014. The wheat was treated with 90ml neutral detergent 0.1 %. Then it was washed four times with 90ml of sterile water. The kernels were dried in Petri dishes with filter paper which were sterilized before. The identification of mold was determined by the method of placing the wheat's germ on solid medium Czapek and Potato dox agar. It was cultivated a total of 10 plates with 5 kernels for each medium. The Petri dishes was incubated in 25^0C. The identification of mold was based on colony growth, cultural and phenotypic characteristics. Mold's species present in wheat were determined by direct microscopic observation. By identification of moulds and classification in species and genus there was noticed mainly Ascomycete classes especially Aspergillus and Penicillium species. Ascomycetes class mold are characteristic of stored grains. This shows that wheat used in industrial mill companies are not young, but are stored wheat for a while. In general wheat samples which have been analyzed were within standards.
Keywords: *microbiological characteristics, wheat, mold, Aspergillus, Penicillium, species.*

Introduction

Wheat is probably the most common cereal available all over the world and is in even higher demand in recent years due to its abundant health benefits. Over the years, wheat has shown itself to be one of the most successful and sustainable cereals crops in the world.

Because of their extensive use as human foods and livestock feeds, the microbiology and safety of cereal grains and cereal products is a very important area. The sources of microbial contamination of cereals are many, but all are traceable to the environment in which grains are grown, handled, and processed.

Microorganisms that contaminate cereal grains may come from air, dust, soil, water, insects, rodents, birds, animals, humans, storage and shipping containers, and handling and processing equipment. Many factors that are a part of the environment influence microbial contamination of cereals, including rainfall, drought, humidity, temperature, sunlight, frost, soil conditions, wind, insect, bird and rodent activity, harvesting equipment, use of chemicals in production versus organic production, storage and handling, and moisture control. The microflora of cereals and cereal products is varied and includes mold, yeast and bacteria.

This study was based on fungus present in wheat's germ. Total numbers of fungi was determined by dilution techniques (Pitt, J. et al, 2009). The samples were obtained in strictly sterile conditions in order to avoid the impact of environmental and air microorganisms. They were taken in different parts of silos for a better presentation. This was done because microorganisms are different in the upper and inner layer of silos (King, A.D. et al, 2003).

The total numbers of molds were determined by the method of placing the suspensions on solid medium (Czapek dox agar, Potato dox agar, Malt extract agar, Plate count agar). It was prepared three dilutions with 3 parallels. After incubation at 26°C the colonies were counted. The calculation of total number of microorganisms was done by assuming that each colony grew from a single cell (Prifti, D. et al, 1980).
A very important point of this study was the identification of molds that were grown in all media. The identification of mold was based on colony growth, cultural and phenotypic characteristics. Some of them were determined by direct microscopic observation. They were classified in 5 species: *Rhizopus spp.* and *Mucor spp*. (Pitt, J. et al 2009), *Aspergillus spp*. (Adolf, J. et al, 1970), *Penicillium spp*. (Raper, B.K. et al, 1992), *Fungi imperfecti spp*. (Barnet, H.L. et al, 1972).

Materials and methods

The aim of this study is the identification of mold developed in wheat's germ. The samples were obtained in sterile condition from 5 different industrial mill companies in south-east of Albania during March-June period 2014. Experimental work has been developed in the laboratory of microbiology at the Faculty of Natural Sciences of Tirana, Albania.
Experimental work was based on :
1kg of wheat was taken for each sample in order to prepare the sample average with diagonal division. It was analyzed 5 samples. The wheat kernels were treated with 90ml neutral detergent 0.1 %. They were washed four times with 90ml of sterile water. Then they were shaken for 1 minute. The kernels were dried in Petri dishes with filter paper which were sterilized before. The identification of mold was determined by the method of placing the wheat's germ on solid medium Potato dox agar and Czapek dox agar This was done by using a forcep. It was cultivated a total of 10 plates with 5 kernels for each medium. The Petri dishes was incubated in 25^0C. The identification of mold was based on colony growth, cultural and phenotypic characteristics. Mold's species present in wheat were determined by direct microscopic observation.

Results and discussion

As mentioned in the methodology, 5 samples were analyzes and total of 10 plates were cultivated with 5 kernels for each medium. It was determined the number of kernels with mold, their percentage and the total number of mold developed in each Petri dishes.
The results are presented in Table 1 for cultivated kernels in Potato dox agar and Czapek dox agar medium. These results are presented graphically for a clearer result (Figure 1). Sample which represented the highest percentage of kernels with mold was sample 1 for both media. This rezult is too high for this sample (72% in PDA dox agar and 82% in Czapek dox agar) and this shows that the wheat's germ is a sutable plase for mold's development.

Table 1 : Cultivated kernels in Potato dox agar and Czapek dox agar medium

Samples	Nr. of kernels with mold		% of kernels with mold		Total nr. of Mold	
	PDA	Czapek	PDA	Czapek	PDA	Czapek
Sample 1	36	41	72%	82%	41	50
Sample 2	18	24	36%	48%	24	30
Sample 3	29	35	58%	70%	31	38
Sample 4	34	18	68%	36%	36	20
Sample 5	31	34	62%	68%	40	46

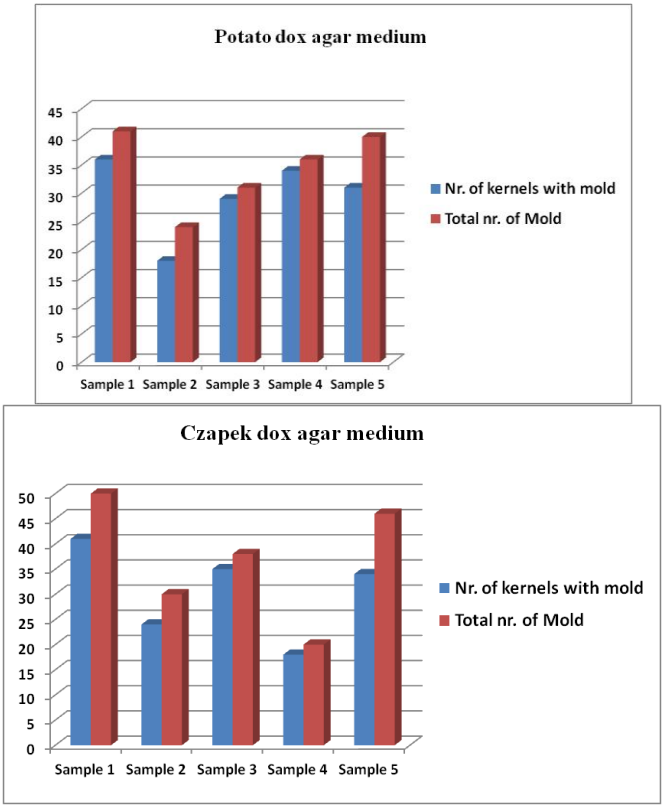

Figure 1 : Number of kernels with mold and Total number of mold cultivated in Potato dox agar and Czapek dox agar.

A very important point of this study was identifying the molds that were grown in all media. The identification of mold was based on colony growth, cultural and phenotypic characteristics. Some of them were determined by direct microscopic observation.

By identification of mold and classification in species and genius there was noticed mainly Ascomycete class especially Aspergillus and Penicillium species. Ascomycetes class mold are characteristic of stored grains. This shows that wheat used in industrial mill companies are not young, but are stored wheat for a while.

In general wheat samples which have been analyzed were within standards. The results are presented in, Figure 2, Table 2 and 3. The sample with the highest number of mold, especially *Aspergillus spp*. was sample 1.

Conclusion

By identification of mold and classification in species and genius there was noticed mainly Ascomycete class especially Aspergillus and Penicillium species. Ascomycetes class mold are characteristic of stored grains. This shows that wheat used in industrial mill companies are not young, but are stored wheat for a while. In general wheat samples which have been analyzed were within standards. From all the experimental work, we may recommend that the industrial mill companies should pay attention to preparation for milling processes, such as : cleaning, sorting, conditioning of the wheat because wheat is the basic food in our life.

Abstract

Olive oil, one of the oldest manmade agricultural products, has retained its status of importance in modern area. The authenticity of the Olive Oil is of great importance both on economic and health aspect. Evaluation of quality is focused in the group of quality indicators such as: Acidity, Absorbance (K_{270}); Stability index, Peroxide value (PV), etc. Unsaturated fatty acids, naturally, are present in *cis* isomers, while under thermal stress during technological processes such as: extraction, refining and bleaching the trans- isomers are formed. Exceeding the minor content levels of 0.05 % per trans-isomers of oleic acid and 0.05% as the sum of the trans-isomers of linoleic and linolenic acid, indicates the authenticity of the product. The *trans*-fatty acids play a key role in development of cardiovascular diseases by increasing the risk of heart diseases and many other diseases.

The Olive oil samples were collected from regions where is assumed main production of Olive oil by Kalinjoti *cv*, and the quality of olive oil were characterized for trans-fatty acids by gas chromatographyapplied for extraction in Olive Mill factories. Fatty acid profiles revealed the presence of 17 FA, including the *trans*-isomers. Trans fatty acids in olive oil samples resulted on values range from 0.01 % to 0.02 %, while in the sum of trans-linoleic acid isomers in maximum value of 0,03 % to 0.05. The sum of *trans*-FA resulted under or equal to 0.05%, indicating the geniunity of the product produced by local Olive Mills.

Keywords*: Extra Virgin Olive Oil, Virgin Olive Oil, fatty acid, trans-isomers, Albania.*

Introduction

Olive Oil (OO), extracted from olive fruits, has been a traditional product of ancient Mediterranean populations. It has been a staple food of the Mediterranean region in the past, while in last decades it has gained popularity, particularly in Western developed countries. The Mediterranean Diet has been connected with low incidence of Cardiovascular Diseases, found in population groups of Cretans (Greece) and Sardinians (Italy), aiming mainly to the use of diet with high levels of polyphenols, originating from Olive oil and Red wine (Patumi *et al*, 2002).

Based on a set of chemical and sensory evaluation analysis, definition and perception of defects, olive oils are classified into three categories; extra virgin olive oil (EVOO), virgin olive oil (VOO) or lampante virgin oil (LVO) (Topi *et al*. 2012). The authenticity of the various Olive oils according to their category is of great importance on economic and health aspect. Evaluation of quality is focused in the group of quality indicators: Acidity (Free Fatty Acids - FFA), Absorption Coefficient (K_{270}); Stability index, Peroxide value (PV), etc. The trans- isomers of oleic, linoleic and linolenic acid are formed by thermal stress as it occurs during refining, bleaching and related processes in different oils. They are a proof for such treatments in case that they exceed the detectable amount of 0.05 % for trans-isomers of oleic acid and 0.05% as the sum of the trans-isomers of linoleic and linolenic acid, indicating for authenticity of Olive Oil (OO). *Trans*-fatty acid play key role in development of cardiovascular diseases by increasing the risk of heart diseases and many other diseases.

Cultivation of olive tree and production of the olive oil in Albania is present mainly in regions of Western part, along the Adriatic and Ionian Sea while is present in the inland river valleys of Shkumbini, Osumi and Vjosa rivers (Shundi *et al*, 2006). Such diversity of regions of Albania, impose production of OO with distinctive characteristics and tastes, mainly due to different olive cultivars, local environment conditions (soil, climate, altitude) and agricultural applied practices.

According to International Olive Oil Council and European Community, the determination of Fatty Acids (FA) is an important quality parameter for Vegetable oils. The International Olive Oil Council (IOOC, 2001) and the EEC (EC, 1991) have defined the quality of olive oil (Table 1), based on parameters that include free fatty acid (FFA) content, peroxide value (PV), Absorption Coefficient (K_{232} and K_{270}), Stability index and sensory score (Bouskou *et al*. 2006; EC, 2003; IOOC, 2003; Vossen *et al*. 2007) .

In particular, the quantity of FFA is an important factor for classifying olive oil into commercial grades. The hydrocarbon chain of fatty acids in OO vary between 12 and 24 carbons (Mailer *et al*. 2006). The hydrocarbon chain is saturated or with one, two or three double bonds :

In the case that a double bond occurs on the chain, it can orient itself in two ways (Figure 1), the *trans* and *cis* configuration, where the second cause the chain to bend or curve making it to lose the straight structure [Mailer *et al*. 2006]. OO is obtained by different extraction technologies: cold pressing, two-phase, three-phase and recently two and half-phase. According to the extraction technology, the hydrophilic polar compounds may be present in final product in different amounts. Application of lower temperatures during the extraction increase the content rates of, biologically active substances (tocochromanols, phytosterols, carotenoids, phenolic compounds) (Matthaus *et al.* 2003; Schwartz *et al.* 2008; Siger & Nogala-Kałucka 2008; Rusinek et al. 2012).
The cold-pressed oils do not contain any of the isomers of *trans*-FA which are formed in refined oils as a result of the drastic process parameters (Beckingham *et al*. 2006). When oils are exposed to elevated temperatures or pressure they can change from the "cis" (natural isomer) to the "trans" isomer (IOOC, 2003). The separation of the FA especially for *trans*-FA can be achieved on gas-chromatography (GC-FID). Lower grade olive oils and refined olive oil allow wider limits for *trans*-isomers. *Trans* isomers show different physical properties compared to the natural cis isomers and are readily separated with gas chromatography. This method can also detect if oil has been exposed to color removal substances (Wroniak *et al*. 2008).
Nowadays determining the level of *trans*-FA in food is a requirement of the governmental health agencies, since it is necessary to give people information about lipid composition in the food they are eating, especially for those who have health problems like heart disease, obesity and hypertension (Serran *et al*. 2009).
The latest research shows that the main concern is the effect of trans-FA on cardiovascular diseases. *Trans*–FA have been shown to negatively increase the risk for cardiovascular diseases. Consumption of trans-FA: has been shown to increase "bad" LDL cholesterol levels, while decrease "good" HDL cholesterol levels, as well as have adverse effects on the inner lining of blood vessels, and raises the risk of diabetes (Serran et al. 2009).

Materials and Methods

Materials

Twelve samples of mono cultivar olive oils were collected (December 2014) by the same cultivar but from different region (Vlora and Mallakastra region and Kavaja-Vora region), aiming to give indication of the origin of product through studying fatty acid (FA) profiles and trans fatty acids. The samples were characterized for their trans fatty acids by a lot of methods and limits, which were introduced into the International Olive Oil Council (IOOC) trade standards (IOOC, 2001), into EC Regulation 2568/91 (EC, 2003) and into the Codex Alimentarius Standard (Codex Alimentarius, 1981) for controlling product authenticity and quality (Bianchi *et al*,.).
The conditions for the analysis were: solvent: acetone/acetonitrile 50:50 v/v, flow rate 1.2 mL/min., oven temperature 42^0C.

Methods-Determination of Trans-Fatty Acid (TFA)

Fatty acid methyl esters (FAME) were prepared through direct alkaline transesterification, according to the method proposed by IOOC, using pentadecanoic acid (C 15:0) as internal standard.
The mixture FAME prepared was analyzed by a model of gas – chromatography, with flame ionization detector (FID) using a capillary fused silica column containing a cyanopropylsilicone stationary phase (50 m × 0.25 - 0.32 mm × 0.1 - 0.30 μm). The

chromatographic conditions were optimized, including for *trans*-fatty acids analysis, with a programmed column temperature: 150 – 200 °C. The temperature of injector and detector was set at 250 °C and 260 – 280 °C, the carrier gas was hydrogen or helium (1.2 ml/minute) and quantity of substance injected: 1µl of solution at 2% in hexane (IOOC, 2001; Karn *et al*. 2013).
Calculations were performed according to AOCS Official Method Ce 1b-89 (AOCS, 1994), and by the computer program according the EC Regulation 2568/91 method (EC, 2003). According to this method, the trans fatty acid content of olive oil is given by the sum of the following acid contents relative of the total fatty acids (IOOC, 2001):
trans – octadecenoic (T 18:1)
trans, trans – octadecadienoic (TT 18:2)
cis – trans and trans – cis octadecadienoic [(CT + TC) 18:2]
trans – cis – trans , cis – cis – trans, cis – trans – cis and trans – cis – cis octadecatrienoic [(TCT + CCT + CTC + TCC) 18:3].

Results and Discussion

This study indicates that there is a relationship between olive cultivars and their fatty acid profiles. Fatty acid composition of all the analyzed monovariety oils meets the limits set for extra virgin olive oil (EC Regulation, 2003), because fatty acid composition is used only for the evaluation of oil purity, which is guaranteed by establishing the maximum content of some minor fatty acids. Thirteen different fatty acids (FA) were found for both OO. In order of abundance, the most important ones were: palmitic acid (16:1), oleic acid (18:1), linoleic acid (18:2), linolenic acid (18:3). Results of analysis of oil from cultivar's of Vlora's and Mallakastra's are shown in the table below (Table 2), indicating the variation in the four most prominent fatty acids in olive oil.

Table 4: Fatty acid profile (in% of total FA) of the Kalinjoti Cultivar

Chemical formula	Kalinjoti (Mallakastra)	Kalinjoti (Vlora)	CODEX STAN 33-1981
C16:0	8.82	11.09	7.5 - 20.0
C16:1	0.45	0.72	0.3 - 3.5
C18:0	2.92	2.57	0.5 - 5.0
C18:1	76.15	75.51	55.0 - 83.0
C18:2	9.31	8.15	3.5 - 21.0
C18:3	0.86	0.75	-

Table reports the percentage of fatty acids in monovariety oils from cultivar Kalinjoti in region of Vlora and Mallakastra and confirm their similar. These results show that there is no big difference between the same cultivar although it is cultivated in different regions of Albania. The difference between the two oils is very small, maybe as a result of the climatic, geographic, genetic and other factors. All the values of fatty acids are almost in conformity to those of International Olive Oil Council's regulation (IOOC, 2001) and Codex Alimentarius (1981).
The fatty acid composition is a quality parameter and authenticity indicator of virgin olive oils (Zambiazi et al. 2007). As shown in Table 3, numerous cis–trans isomers of fatty acids were detected in the both oil samples produced from important olive varieties. The total trans-fatty acid in both oils ranged almost in the limits set for extra virgin olive oil (Table 3). The sum of *trans*-FA resulted under 0.05% in the both oils. This study is a comparison of the *trans* – FA content of the same cultivar but in different region of Albania. The *trans* – FA C18:1T content was: 0.016% (Kalinjoti of Mallakastra) and 0.016% (Kalinjoti of Vlora); *trans* – FA

C18:2T content was: 0.012% for Kalinjoti of Mallakastra and 0.013% for Kalinjoti of Vlora; trans – FA C18:3CTC content was: 0.023% for Kalinjoti of Mallakastra and 0.019% for Kalinjot of Vlora.

Table 3: Trans-Fatty acid content in monocultivar Olive oils of the Kalinjoti Cultivar

Trans fatty acid	Kalinjoti (Mallakastra)	Kalinjoti (Vlora)	CODEX STAN 33-1981
C18:1T	0.016	0.016	0.0 - 0.05
C18:2CT	0.012	0.013	-
C18:3CTC	0.023	0.019	-
C 18:2 CT + C 18:3 CTC	0.035	0.032	0.0 - 0.05
∑TSF	0.051	0.048	0.0 - 0.05

Elaidic acid and total trans-isomers of linoleic and linolenic acids in early harvest groups ranged from 0.00 to 0.02%, respectively. The oils contained small amounts (0.05 %) of total trans-FA. The total amount of trans-fatty acids in virgin olive oils should be not exceed 0.1%. The all trans-FA acid isomers C18:1T and C18:2T + C18:3T were generally within acceptable limits of the IOOC's regulation (IOOC, 2001), the EU (EC, 2003).

The *trans*-isomer fatty acid in an olive oil from the both region is similar with a little difference, result a value from 0.01% to 0.02% and in the sum of trans-linoleic acid isomers in the same maximum value of 0.01% to 0.02.

Analysis the value for the three families of fatty acids Saturated Fatty Acids (SFA), Mono unsaturated Fatty Acids (MUFA), and Polyunsaturated Fatty Acids (PUFA), results that olive oil from the Mallakastra Kalinjoti cultivar has high levels of MUFA (77.23) and PUFA (10.17) while Kalinjoti olive oil from Vlora has higher levels of SFA (14.4).

Table 4. Fatty acid composition of selected oil

Fatty acid	Kalinjoti (Mallakastra)	Kalinjoti (Vlora)
∑-TFA	0.051	0.048
∑-SFA*	12.58	14.4
∑-MUFA*	77.23	76.7
∑-PUFA*	10.17	8.9
MUFA/SFA	6.139	5.326
MUFA/PUFA	7.594	8.618
PUFA/SFA (P/S)	0.808	0.618
MUFA/SFA	6.139	5.326

The MUFAs are of great importance because of their high nutritional value and positive effect on oxidative stability of oils. Oleic acid (18:1), the predominant fatty acid in virgin olive oil, was between 73.65% and 76.15%. The oil from cultivar of Vlora had the lowest oleic acid and MUFAs levels compared to the other oil from cultivar of Mallakastra. Linoleic acid, which is much more susceptible to oxidation than MUFAs ranged from 8.15% to 9.31%. The linolenic acid level of Albania virgin olive oil samples was below the maximum value fixed by the IOOC (1.0%) and by the EU (0.9%) [IOOC, 2001; EC, 2003]. These findings are in agreement with the results found in various olive oil producing countries of the Mediterranean basin [Codex Alimentarius, 1981; Diraman et al. 2009; Ersoy *et al*. 2001; Gutierrez *et al*. 1999; Gurdeniz *et al*. 2006; Kamoun *et al*. 2007; Ollivier *et al*. 2003; Opoku – Boahen *et al*. 2012; Romero *et al*. 2003; Zengin *et al*. 2006].

The relationship between the saturated and polyunsaturated fatty acid content is expressed as P/S index. In the diet, it is important the index value be higher than 1, due to the essential character of the linoleic fatty acid (ω-6) (WHO, 1982). Several studies indicate that the P/S relation influences in the level of nutrient metabolization in the body, and as the proportion increases a smaller deposition of lipids (LAWTON et al., 2000). The values of the P/S indexes of the oil studied are shown in Table 4. As the result show the index P/S is lower than 1 in the both oils, because in olive oil consist small amounts of PUFA (Zambiazi et al. 2007).
The fatty acid composition of both olive oil groups from different locations of Albania has been shown to be similiar with regard to the ratios of oleic to linoleic acid and MUFAs to PUFAs which are an important indicator of oxidative stability (Table 3). The variations in fatty acid profiles of both olive oils differ depending on the zone of olive production. Primary factors affecting fatty acid composition, especially oleic acid content, in virgin olive oils may originate from latitude, climate, olive cultivar and/or stage of fruit maturity during harvest (Skevin *et al*.2003). Also, these values were similar to those reported for foreign olive oil varieties. All the values of fatty acids that were analysed, were in conformity to those of the IOOC's regulation (IOOC, 2001), the EU (EC, 2003). The level of palmitic acid (16:0), the major fraction of SFA in olive oil, ranged from 8.82% to 11.09% and the range of stearic acid levels (18:0) in samples were 1.61–4.25%. The little differentiation between structural isomers of these two fatty acids from the bothoils would bring a better knowledge of the chemical composition of olive oil and can be of great interest in their nutritional impact.
Fatty acid profiles played a role in the characterization of extra virgin olive oil from different geographical locations of Albania.

Conclusion

Basing on the results of the study, cultivar of Kalinjot presents qualitative and balanced profile of fatty acids, and trans – isomers, which the levels of the trans fatty acids are almost in conformity to those of International Olive Oil Council's regulation (IOOC, 2001) and Codex Alimentarius (1981), so we may conclude that production of the mono variety olive oil from Kalinjoti cultivar is in accordance with quality characteristics drawn by EU Regulation 1989/2003.

The fatty acid composition and the determination of trans fatty acid in the oil is a very important factor in the stability determination and main application definition. This factor is also associated to the harmful impact in the human health.

It represents an interest in producing a quality olive oil. Basing in the comparison with results from literature, it can be concluded that the levels of trans-fatty acids in the oils of Kalinjoti cultivar are almost similar to those in neighboring countries: Italy, Greece, and Spain.

According to the FFA and trans-isomers results, we conclude that the Mono cultivar Olive Oil, are classified as extra virgin olive oil (EVOO).

Abstract

This work is devoted for the first time to the study of the dynamics of predatory activity of the whiteflies populations *Aleurothrixus floccosus*Mask. and citrus whitefly *Dialeurodes citri* Ash. on clementine (var. clementine single) and orange (var. Thomson Navel) at the citrus region Chlef-Oued Sly (western north of Algeria). Populations sampling on the foliage at the young shoots bearing branches were conducted from the end of July 2012 to early July of the following year 2013. Predators as *Clitosthetus arcuatus Rossi*, *Semidalis aleyrodiformis Stephens* and *Chrysoperla carnea Stephens* were well represented, participating in the largest contribution differences in composition between the communities of seasonal beneficials. The temporal distributions of the adult abundances of *C. Arcuatus* were considered during the entire monitoring period for the cardinal directions (north, west, south and east), respectively. Adult abundances were characterized by 3 pics, a first one in early October, one second pic in mid-November and the 3rd largest in june with more than 300 individuals per yellow sticky trap per fortnight. During autumn period, the canopy foliage exposed to South and East is particularly sought after by adult lacewings *Chrysoperla carnea* with percentages of 42% and 33% respectively.

Key words: *citrus whiteflies, predatory populations, Chlef region, Clithostetus arcuatus, beneficial communities.*

Introduction

Whiteflies (Hemiptera: Homoptera: Aleyrodidae) are some of the most potentially detrimental pests for agricultural crops and ornamental plantings, (Byrne et *al.*, 1990; Martin 2004). Generally, aleyrodid populations are kept in check by natural beneficials. But, in agriculture crops where farmers have upset the natural balance, often substancial damaging populations may occur on the leaf undersides, due to producing waxy filaments and honeydew on which black sooty moulds grew. This interfered with the normal physiological activity of the host plant. The citrus whitefly *Dialeurodes citri* (Ashmead) and the woolly whitefly *Aleurothrixus floccosus* (Maskell) are one of the key pests affecting citrus in Algeria (Berkani, 1985; Benmessaoud-Boukhalfa,1987; EPPO, 2012).

However, their control is nowadays mostly chemical. Lots of predatory species, represented mainly by neuroptera and beetles help to control whitefly species. Natural biological control by lacewings is also among the most important integrated pest management (IPM) tactics for population regulation of the homoptera pests such as they have a high biotic potential, feeding on aphids, mealybugs, eggs, larvae and pupae of whiteflies occurring naturally on Clementine and orange citrus (Biche, 2012).

Because citriculture has a great economic importance in Algeria, more sustainable means of successful controlling Aleyrodid populations is needed. The tendency in biological control is to neglect the vast potential of indigenous predators, not only to reduce populations before they exceed the economical threshold but also to anticipate these beneficial arrivals in the

citrus groves (Mignon et *al.*, 2003; Gomez-Marco et *al*., 2015). Different inventories of predatory insects of citrus whiteflies and mostly of Homoptera pests affecting citrus has been realized in several citrus producing areas around the Mitidja region. Specifically, systematic and ecological studies on Coccinellidae predatory species found on citrus orchards have been published by Saharaoui and collaborators (2009, 2015). However, few works have addressed attention on these beneficial predatory families concerning their seasonal composition on citrus. Thus, our investigations have covered the producting zone of citrus in the chlef region, where studies on the biodiversity of natural enemies are globally poor documented in relation with populations of whiteflies trends and how they could be influenced by phytosanitary management, the host plant and climate.

Material and methods

The study was carried out between the end of July 2012 to early July 2013 on two conventional citrus orchards situated in the Chlef region (Algeria). The Chlef plain is the second extensive sublittoral plain of citrus plantings after the Mitidja plain with more than 5 709,50 ha of superficy. The 4 ha (a *Citrus sinensis* old orchard) and 2.34 Ha (a *Citrus clementina* old orchard) studied sites are located respectively at Oued Sly at a distance of 12 km from Chlef with a latitude of 36°05'53.15"N, Longitude of 1°13'02.11"E, and at 4 km from Chlef with a latitude of 36°10'04.56"N ; Longitude of 1°17'18.09"E.

The Aleyrodidae populations and associated predatory beneficial were determined on the foliage at the young shoots bearing branches and from yellow sticky plastic vertical traps. In each orchard, three traps were randomly and monthly sampled in the winter season. Every fortnight at the other seasons, we carefully examined one twig with leaves from cardinal directions through the canopy of ten randomly sampled trees. The significance of the differences in beneficial diversity between two seasons in one considered orchard was calculated by a resampling procedure (bootstrap) (Poole, 1974).

We tested the total similarities between seasonal beneficials by an ANOSIM (Analysis Of SIMilarity) using the index of Bray-Curtis as a measure of similarity and the P-values Bonferroni corrected given by 10 000 permutations. To assess which taxa are primarily responsible for an observed difference between groups (Clarke 1993), we used the program SIMPER (SIMilarity PERcentage) to calculate the contribution (in percentage) of each insect species to the differences observed between seasonal communities. We have pooled all samples to perform one overall multi-group SIMPER. All the multivariate analyses were conducted with PAST 1.98.

Results and discussion

Abundance variations in *A. floccosus* and *D. citri* populations with associated predatory species in the studied sites

Variations in abundances of the two whiteflies studies species on twigs with infested leaves and on traps, are shown in figure 1 and figure 2. The main predatory fluctuations species are different from an orchard to another. The seasonal trend along the studied period was similar for the both sampling types according to the two white flies species (figure 1 et 2).

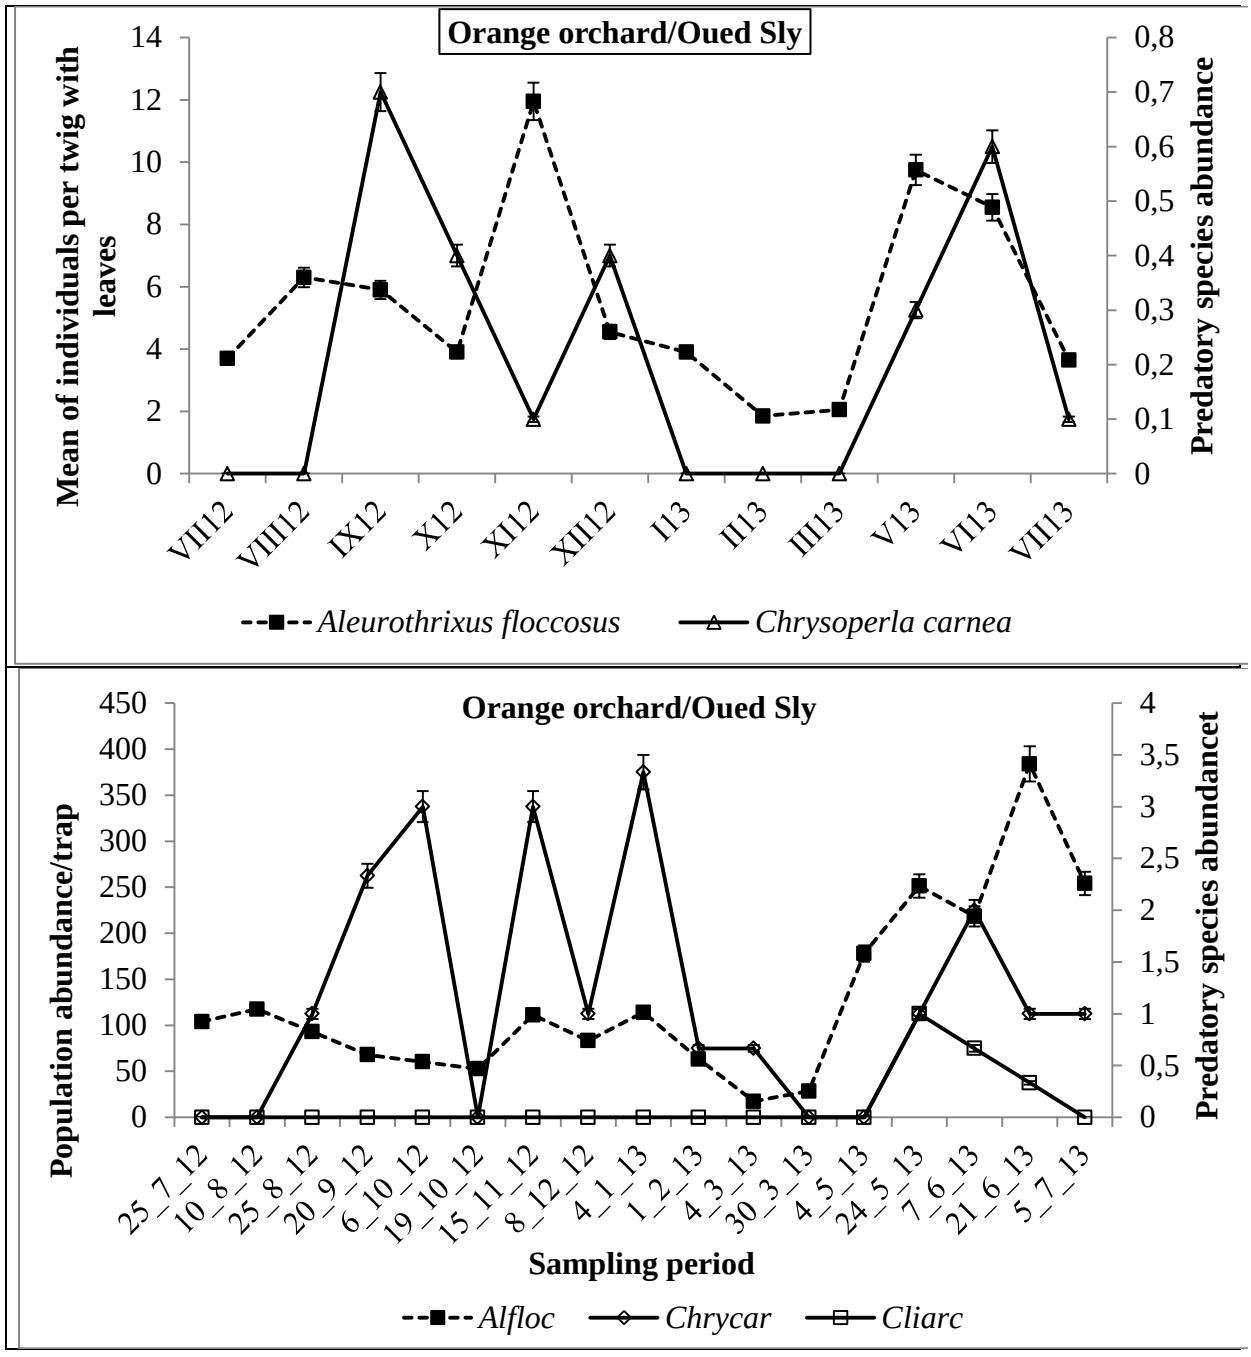

Figure 1: Seasonal abundances of *A. floccosus* and associated predators in orange orchard at Oued Sly (Chlef region)

Predators were well represented in this case *Clitosthetus arcuatus Rossi*, *Semidalis aleyrodiformis Stephens* and *Chrysoperla carnea Stephens* participating in the largest contribution differences in composition between the communities of seasonal beneficials.
Adult abundances of *C. arcuatus* were characterized by 3 pics, a first one in early October, one second pic in mid-November and the 3rd largest in june with more than 300 individuals per yellow sticky trap per fortnight. During autumn period, the canopy foliage exposed to the South and East direction is particularly sought after by adult lacewings *Chrysoperla carnea* with percentages of 42% and 33% respectively.

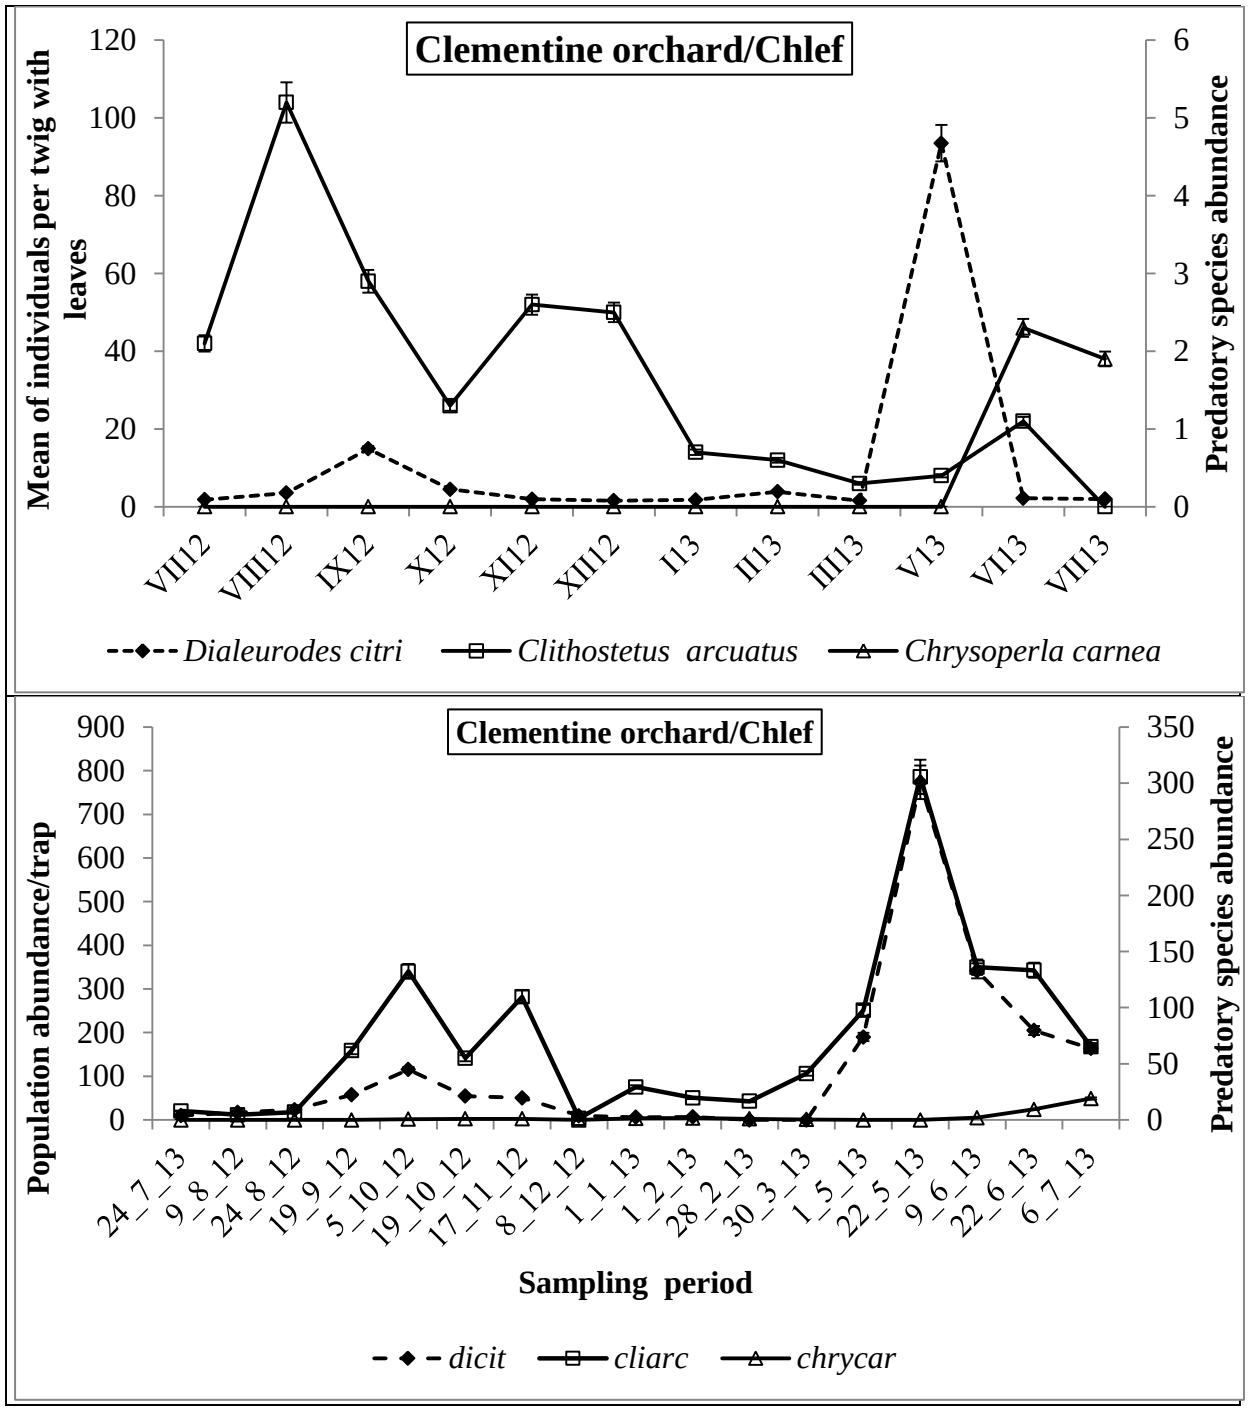

Figure 2: Seasonal abundances of *D. citri* and associated predators in clementine orchard at Chlef.

These observed results reflect possibly the abundance of preferred prey. Differences in incidence could be influenced by host preys and microclimate of the vegetation cover in the orchards wich could explain the coincidence and temporal arrival in relation with white flies populations.

Associated assemblages tendency

Semidalis aleurodiformis (Neuroptera, Coniopterygidae) was by far the most common species found among the identified predatory insects (table 1). These insects are very common on the citrus canopy. It is known moreover that coniopterygids are specially attracted to yellow sticky traps (Bru and Garcia Mari, 2003). *Clitostethus arcuatus* seems to be the most important predator of *D. citri*, showing a high voracity on the immature stages.

Table 1: SIMPER analysis of the seasonal assemblages of beneficials associated with *Dialeurodes citri* populations in orange orchard (2012-2013). (Numbers in bold characters correspond to the characteristic species of each community, LS12: late summer, AT12 : autumn, SP13 : spring, ES : early summer13).

The dustywings Coniopterygidae belong to the order of net-winged insects Neuroptera with some 6010 species. The family Coniopterygidae alone comprises about 450 species gathered in 23 genera (Aspöck et *al.*, 2001). The family is distributed in Europe, Africa, the Canary Islands, Asia, the Orient, and Australia, and also reaches North and Central America. Due to their very small size, many dustywing species may still remain undetected in Algerian citrus orchards. Among the aphid enemies, the parasitoïds (Hymenoptera) are often the first to establish themselves, followed by ladybirds then Anthocoridae, Chrysopidae intervene once the populations of aphids are in decline, (Saharaoui et *al.*, 2015).

The most important contributions to controlling *A. floccosus* have been through biological control programmes. In several Mediterranean countries where the pest was introduced, *Cales noacki* was better able than *Amitus spiniferus*, two Hymenoptera parasitoïd species, to reach high parasitization levels on the whitefly nymphs everywhere (Berkani, 1985). In citrus groves where chemical control was not applied, *C. noacki* was found to parasitize 99% of *A. floccosus* young stages, thus depressing the whitefly populations to very low levels throughout the year, in such a way that high infestations of the whitefly may occur towards late summer-early autumn because *C. noacki* development may slow down with the high temperatures and low relative humilities of summer.

Conclusion

The results obtained in this study highlight a seasonal variation of beneficial communities on citrus orchards in Chlef region. *Clithostethus arcuatus* was the most represented as the only specific aleurodiphagous species on white flies populations. Generalist predators seem to have a better activity during the hole occurring of the aleurodids prey populations especially *Semidalis aleyrodiformis* and *Chrysoperla carnea.*

Aknowledgments

The authors are grateful to Professor F. Garcia Mari from the polytechnical university of Valencia (Spain) who has provided facilities to identification of the collected beneficials. This work received financial support via the program PCI/AECID AP/038550/11.

THE APHIDS INFESTING CITRUS ORCHARDS AND THEIR NATURAL ENEMIES IN THE NORTHWESTERN ALGERIA

Zine-Eddine LABDAOUI, Yamina GUENAOUI*

Department of Agronomy, University Ibn Badis of Mostaganem, Algeria
*Corresponding author: guenaouiy@yahoo.com

Abstract

During the last decade, especially in the Northwest part of Algeria, the citrus orchards showed fluctuations in production with a reduction of citrus growing areas in comparison with others growing areas. The decline of quality and quantity of production is a result of several problems occurring in the same time: aging of orchards, water stress, inadequate methods of control, emergence of new pests and diseases. The objective of this study was to determine the main aphid species causing serious damages directly and indirectly on *Citrus sinensis* and *Citrus clementina* and to identify their main natural enemies including parasitoids and predators. After two years of investigations the main aphid species recorded on both citrus orchards were: *Aphis gossypii* Glover, *Aphis spiraecola* Patch and *Toxoptera aurantii* Boyer de Fonscolombe (Hemiptera: Aphididae), *Aphis craccivora* Koch.The primary parasitoids recorded were mainly: *Lysiphlebus fabarum* (Marshall), *Lysiphlebus confusus* (Trembley and Eady), *Lysiphlebus testaceipes* Cresson, *Aphidius colemani* Viereck, *Aphidius matricariae* Haliday an *Binodoxys angelica*e Haliday (Hymenoptera: Braconidae : Aphidiinae).We also recorded an important activity of predators mainly *Propylea 14- punctata* (L.), *Coccinella septempunctata* (L.), *Scymnus* species (Coleoptera: Coccinellidae) , *Aphidoletes aphidimyza* Rondani (Diptera: Cecidomyiidae) and 2 Syrphidae species but their presence happened too late. This study was conducted for a better knowledge on the health status of citrus orchards because the complex of aphid antagonists is poorly investigated in our region. This work could help citrus growers in understanding the situation for taking the best measures to preserve activity of natural enemies by reducing chemical control.

Key words: *Citrus, aphids, natural enemies, integrated control, Northwestern Algeria*

Introduction

Algerian citrus orchards harbour an important diversity of native and alien species of pests that attack trees in the same time and also a wide range of native and exotic natural enemies. Among the main pests damaging citrus groves, aphids are particularly noxious because high aphid population is regularly seen during spring season (during flushes) leading to reduction in vigor of the host plant and causing great damage both directly and indirectly (leaf deformation, malformation of flowers, underdeveloped shoots, virus transmission and consequently damage on fruits). In all citrus growing areas in Mediterranean Basin several aphids are considered harmful pests, (Barbagallo et al., 1986; Marroquin et al., 2004). In Algeria, studies conducted on aphids were concentrated in the Mitidja region (the north-center of Algeria).The number of species is depending on region, season, variety and period of investigation (Aroun, 1985; Mostafaoui et al., 2014; at least 08 species were recorded on *Citrus sinensis* var.Thomson (Benoufella-Kitous et al., 2014). In Greece 09 aphid species were reported on citrus (Kavallieratos et al., 2002) and in Turkey 07 species were determined (Satar et al., 2014). At least 25 aphid species have been reported infesting citrus in the world but only 3 or 4 species are considered damaging in Italy (Barbagallo et Patti, 1986) or in Spain (Hermoso de Mendoza et al., 1997) where *Aphis spiraecola* and *Aphis gossypii* are found to be the most abundant (Tena et Garcia-Mari, 2011). In the north-western Algeria

studies on aphids are very limited and the complex of their natural enemies very poorly investigated. The present work is a first step of a wide study undertaken by the first author within the framework of a thesis with several objectives in order to found appropriate measures for integrated pest Management. This paper lists the aphid species found infesting tender shoots during spring of 2014-2015 and makes inventory of natural enemies (parasitoids and predators) found feeding on aphids infesting new shoots at flush periods.

Material and Methods

Sampling method:

Aphids: During early spring aphid populations were monitored weekly on 10 trees, using only leaf count method. Samples were taken in a more 30 years old orchard with mixed varieties (*Citrus sinensis*, *Citrus clementina*). Three infested leaves were taken on young shoots from different levels of the canopy of each sampled tree and transferred to laboratory at (25°C, RH 60±10%, DL: 16H/24). In the laboratory live aphids are observed under stereo-microscope at adult stage (wingless and winged specimen) to identify the species according to several keys (when needed French or Italian specialists are asked for confirmation).

Natural enemies:

Parasitoids: In the laboratory, full mummies were taken from leaf with precaution and each one was put in individual small transparent box until emergence of wasps; empty mummies were counted as primary parasitoids when emerging hole is smooth or as hyper-parasitoids when the margin of emerging hole is irregular and added to total parasitism with identification of parasitized aphid species. Leaves bearing aphid colonies were placed with watered mesh in small boxes and left at least a week period at laboratory conditions to obtain new mummies from parasitized aphids. Total parasitism was estimated by counting emerged and none emerged aphid mummies.

Predators: Predators were separated according to their mobility using a smooth brush or mouth aspirator and put in small box with additional colonies of aphids until reaching adulthood stage. Specimens were conserved for later identification.

Results and Discussion

Aphids: In the first step of study only six aphid species were recorded. Aphid diversity showed 3 most important species found in all samples: *Aphis gossypii* (Glover) (fig.1 a,b), *Aphis spiraecola* (Patch.) (Fig.2) and *Toxoptera aurantii* (Boyer de Fonscolombe) (fig.3). Three other species: *Aphis craccivora* (Koch), *Myzus persicae* (Sulzer) and *Aphis fabae* (Scopoli) were found in limited colonies.

A. gossypii is a cosmopolitan, polyphagous species widely distributed in the world. It is one of the most pests of citrus in many Mediterranean countries (Kavallieratos et al. 2002; Satar et al., 2014). According to Vanlerberche-Massuti and Chavigny (1998) there is a genetic structuring within the species *A.gossypii* according to host plant type. This species cause direct damage by feeding on tender shoots and on flowers (fig.1b) and indirect damage by transmitting the Citrus tristeza Virus in citrus (Marroquín et al., 2004; Compra et al., 2000).

A. spiraecola is a polyphaous species found on *Citrus* species but it can infest other fruit trees of *Prunus* species in many Mediterranean countries (Ben Halima-Kamel et Ben-Hamouda , 2005). It is a key pest on *C. clementina* in Spain (Gomez Marco, 2015), in Algeria

(Mostefaoui et al., 2014) were compared to *A. gossypii*, its abundance on Clementine variety could be explained by a better tolerance to high proline contents in the foliage.

Toxoptera aurantii named Black Citrus Aphid is a pan- tropical species common on citrus trees. II is also found on tea and on other plants as *Pittosporum tobira* in the Mediterranean areas (Sahraoui and Sourreau, 2000). The parasitoid complex of *T. aurantii* in the Mediterranean area was reported in Italy (Tremblay, 1984) .The most important of its parasitoids are species of the genus *Aphidius* Nees, *Lysiphlebus* Förster.

Fig.1: *A. gossypii* on bud (a) and flower (b)

Fig.2: *A. spiraecola*

Fig.3: *T. aurantii*

N.B.: The aphid *Toxoptera citricidus* that was expected to be present in Algeria was not found in our samples. This species was recorded in almost all Mediterranean countries in Spain (Hermenzo de Mendoza et al., 2008), in Italy (Coccusa and Barbagallo, 2011).

Natural enemies

Predators: The most important families were Coccinellidae and Cecidomyiidae.

Fig.4: *Aphidoletes aphidimyza*

Fig.5: *Scymnus* spp. larva

Fig.6: *Coccinella algerica*

Fig.7: *Propylea 14punctata*

Coccinellidae: Although aphid-feeding coccinellids rarely play a role in the long-term regulation of population dynamics of aphid species within agro-ecosystems, they are effective predators reducing within-season densities of selected species of aphis pests (Obrycki et al., 2009).The Coccinellidae found to feed on aphids were *Coccinella algerica* Kovar, *Propylea 14 punctata* L., *Symnus* spp.

Cecidomyiidae: *Aphidoletes aphidimyza* Rondani (Diptera: Cecidomyiidae) (fig.4) is a worldwide predator used with success in biological control. It was found throughout Mediterranean citrus (Hermoso de Mendoza et al., 2012; Vacante et al., 2012; Urbaneja et al., 2014). Based on direct observations, larvae were first found in spring in all dense colonies of aphids killing more aphids than needed for their development. Similar observations were reported in Spain by Hermoso de Mendoza et al. (2012) with additional information concerning the number of potential generations per year.

Parasitoids: Primary parasitoids recorded belong to Aphidiinae subfamily.
The main parasitoids were: *Lysiphlebus testaceipes* (Cresson) (Fig.9), *Lysiphlebus fabarum* (Marshall) (Fig.10), *Aphidius colemani* (Viereck) (Fig.11)

Fig.8: Emerging parasitoid Fig.9: *L. testaceipes* Fig.10: *L. fabarum* Fig.11: *A.colemani*

L. testaceipes was recorded on *A. gossypii*, *T.aurantii* and *A.spiraecola.* According to Stary et al., (1988) this species was introduced from Cuba to Europe in 1973 in the Mediterranean part of France to control *T. aurantii* and *A. spiraecola.* It had established itself over the whole Mediterranean area where it was recorded not only in Europe but also in Africa; it was reported in 2010 in the South-eastern Algeria (Laamari and Coeur d'Acier, 2010) but its first record in Algeria dates from 1990 (Guenaoui,1990). Because this species is very invasive (the reason why it was removed from the positive list of biological control of EPPO) it is invading the continental part of Europe with a first detection in Serbia (Zikic et al., 2015).

L. fabarum was also recorded on *A. gossypii*, *A. spiraecola* and *T. aurantii*. Only bisexual strain was found in this study but an asexual strain was reported on *A. gossypii* for the first time in Algeria in 1993 at Mostaganem, (Guenaoui et Mahiout, 1993).This parasitoid is a koinobiont endoparasitoid associated with a wide range of aphid hosts in the world (Stary, 1988). In Algeria the sexual strain was found on 9 aphid species associated to 18 host plant species (Laamari et al., 2011). In Iran 47 aphid species were reported to be parasitized by this species (Rakhshani et al., 2013). *L. fabarum* plays a dominant role in several orchards. Parasitoid wasps belonging to the genus *Lysiphlebu*s (Foerter) are composed of over 20 species exploiting over one hundred species of aphids. In a recent study on genetic and morphological variation in sexual and asexual parasitoids of the *Lysiphlebu*s genus two groups were determined: the *fabarum* group and the *testaceipes* group with variation in morphs and reproductive mode, (Petrovic et al., 2015). In the *L. fabarum* species there is difference in trait life between sexual and asexual strains (Ameri et al., 2015).

A. colemani was recorded only on *A.gossypii.* This species was already recorded in Mostaganem (Algeria) on *Melanaphis donacis* on *M. persicae* and *A. gossypii* (Guenaoui, 1991) and on *Hyalopterus pruni* (Geoffroy) on pomegranate trees (Guenaoui, 1998). In the South-East Algeria this species was recorded on 47 aphid species infesting 85 host-plant species (Laamari et al., 2011).

Binodoxys angelicae (Haliday): Only one specimen of was found on *A. spiraecola.*

The richness of natural enemies is depending on the resources in the environment of citrus tree. For instance, in Italy as in Spain the role of weeds in the Integrated Pest Management of citrus was demonstrated (Ali-Arous, 2008; Urbaneja et al., 2014). In Spain the two first species were also found being the most abundant in citrus with 82% of *A. spiraecola* on *C. clementina.*

Conclusion

In the first step of study, the most abundant aphid species are *A. gossypii* and *A.spiraecola* followed by *T.aurantii*. Natural enemies were composed at least of 6 primary parasitoids with 2 main species (*L. fabarum, L. testaceipes*).The parasitism rate was low (below 5%) at the beginning with an increasing rate to15% by counting mummies. The mortality due to the parasitism before mummification was not evaluated. The activity of predators occurred too late with predominance of Coccinellidae (*P.14 punctata*, *C. algerica*) and Cecidomyiidae. The midge *A. Aphidimiza* showed a great efficacy in dense colonies but its action occurs too late

with a specific behavior called over-killing. In a future research, we need to conduct investigations to record more species and determine factors affecting colonization and abundance of aphids with evaluation of the incidence of intensive control of spontaneous vegetation, on aphids and on their natural enemies because growers are in the habit to destroy all growing weeds around trees.

DENSITY INFESTATIONS OF PARLATORIA ZIZIPHII (LUCAS) (HEMIPTERA: DIASPIDIDAE) ON CITRUS IN THE NORTHWESTERN ALGERIA.

Imad BOUAZZA, Yamina GUENAOUI*

Department of Agronomy, Faculty of Nature and Life, University Ibn Badis of Mostaganem, Algeria
*Corresponding author: guenaouiy@yahoo.com

Abstract

In Mostaganem area (Northwestern Algeria), a study on scales infesting citrus conducted during three years (1996-98) showed a predominance of *Parlatoria ziziphii* (Lucas) (Hemiptera: Diaspididae) with the hypothesis of destruction of its natural enemies by overuse of pesticides. In recent years, populations of this species increased dramatically leading to heavy damage on fruits that become unmarketable. The main objective of the present work was to analyze the role of different biotic and abiotic factors on seasonal abundance of scales infesting fruits. The present results refer only on the first year period of a wide study conducted in two sites on two varieties (*Citrus sinensis* var. Thomson and *Citrus clementina* var. Clementina). One hundred fruits per variety were observed *in situ* from July to the beginning of harvest. The density of scales on fruits had increased, reaching a mean of 6 scales per fruit before harvest. The importance of infestations was depending on the position of fruit on tree. The fruits located in the center were significantly higher infested. We also recorded natural enemies associated with *P. ziziphii*. The parasitism was very low (about 0, 25%) in September and October, increasing to about 10% in November. Through a field investigation we tried to identify real factors limiting effectiveness of natural enemies.

Key words: *Parlatoria ziziphii, fruit, Citrus, density infestations, natural enemies.*

Introduction

In Algeria, citrus orchards are attacked by several native and invasive pests with predominance of the diaspididae family named armoured scale insects. The black scale *Parlatoria ziziphii* (Lucas) (Hemiptera: Diaspididae) is an important pest of *Citrus*, widely distributed, throughout the Mediterranean basin. The pest was recorded on several hosts, mostly on *Citrus* (Rutaceae) (Stathas et al. 2007). It attacks all aerial parts of citrus trees (shoots, branches, leaves and fruits) and the main impact of damaged fruits is responsible in reject from national and international markets. Causes leading to diaspidid problems in citrus include salinity, heat stress, pesticide use, fertilization and pruning. Heavy infestations lead crawlers (neonate larvae) to migrate from leaves to fruit in summer. *P.ziziphii* causes pronounced discoloration with attached insect, even if the fruits are cleaned at the packing station (Benassy, 1985). Trees over ten years old are particularly prone to attack.

In Algeria, this pest is covering a vast extension of citrus orchards in the center (Mitidja region, le most important citrus area with more 40% of total cultivation (Benguendouz et al., 2011). In the northwestern Algeria a study showed that almost *Citrus* species were heavily infested with a rate of scales varying from 80% to 99% (Alouach, 1998). *P. ziziphii* is considered as a hard pest to kill because it is very difficult to set up efficient control strategies (Praloran, 1971). Citrus growers use only pesticides that lead to recurrent infestations in a short time with use more pesticides because farmers rarely consider resistance of pest as part of problem. In Mediterranean basin the scale develops 3-4 overlapping generations/year (in Tunisia (Benassy, 1975); in Egypt (Salama et al., 1985). The present work is a part of a study undertaken in a framework of a thesis conducted by the first author, on the most noxious diaspididae species in the northwestern Algeria including dynamics of scales on leaves and

fruits with estimation of impact of natural enemies with/ without integration of wild vegetation and with / without pesticides treatment). The main objective of this paper was focused on estimation of density populations of *P.ziziphii* on fruits by following the populations from the first contamination of young fruits by crawler larvae until the harvest period in order to detect the best period for insecticide application. This could reduce the number of applications during the vegetative period. The trials were conducted in unsprayed orchards in order to evaluate the parasitism and record the main predators feeding on the diaspidid.

Material and methods

Presentation of the site of study

The present study was conducted in 2014 and 2015 in two private citrus orchards located in Misserghin province in the northwestern Algeria (Fig.1). In the past, this region had been one of the most important growing citrus areas especially of *C.clementina* variety; this hybrid variety was born in a farm located in the Misserghine vicinity.
The sampled trees are more 30 years old.

Fig.1: Algeria map: Site of study ◯

Fig.2: Location of the citrus orchards (Google map, 2014)

The observations were done on two varieties (*Citrus sinensis* and *Citrus clementina*) (Fig.2).

Sampling method: The 2 experimental orchards were sampled during the fruit season. On each sampling date, 10 fruits per tree (2 fruits from each cardinal position and 2 fruits inside the center) were marked and observed weekly. 10 trees per variety were sampled. Observations (*in situ*) with a magnifying glass were realized in order to count all scales infesting fruit from the first infestation by mobile larvae (crawlers) until harvest. A total of 200 fruits were weekly followed. Natural enemies feeding on scales were recorded. The global parasitism rate was evaluated.

Results and discussion

1- Percentage of fruits infested by *P.ziziphii* in both varieties

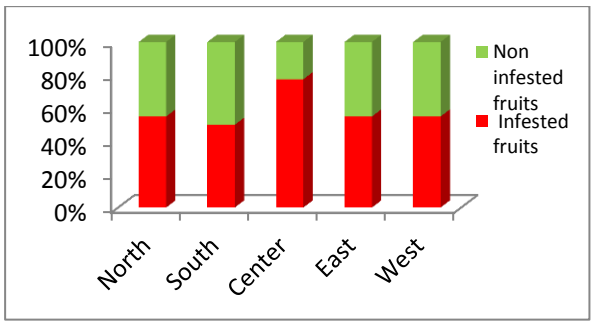

Fig.3: % of infested Clementina fruit (ICF)

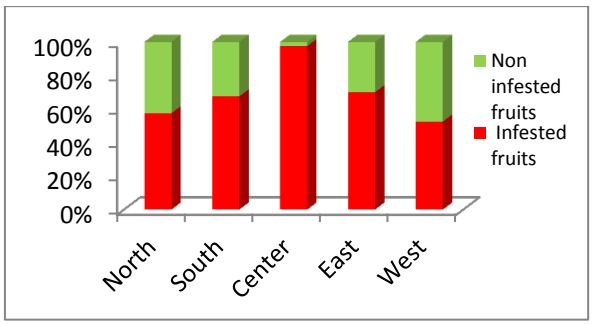

Fig.4: % of infested Thomson fruit (ITF)

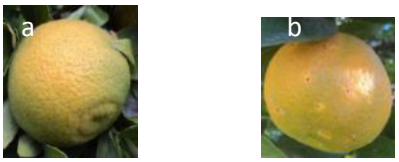

Fig.5: Non ICF (a); ICF (b)

Fig.6: Non ITF (a); ITF (b) (c)

2- Mean of scales per fruit:

To compare mean scale populations associated with each variety and orientation for each location means ANOVA test (Statbox 6,4) was used and means were separated using Newman–Keuls test (5%). The mean number of scales/fruit (Fig.7) increased from about 02 scales at the beginning (mid August) to 6 scales / fruit in late November on Clementina variety and from 1,6 scale to 5, 6 individuals on Thomson variety. There is no significant difference between varieties the ($p > 0, 05$). Regarding the position of fruit on the tree (Fig 12), the density population of scales per fruit is significantly higher in the center with 14,75 scales (Clementina) and 13,35 scales (Thomson).

Statistic analysis showed a significant difference of populations on fruit located in the center because there the diaspid *P.ziziiphii* is protected from wind and sun.

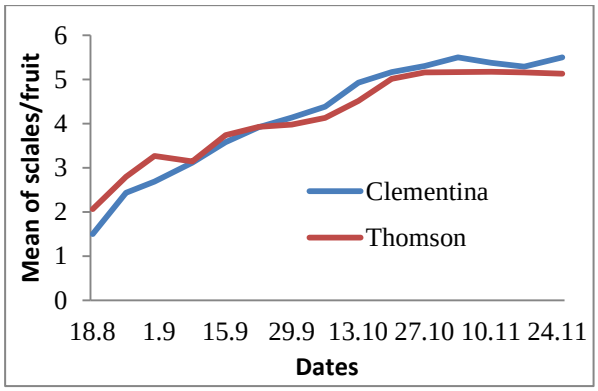

Fig.7: Mean of scales/ fruit

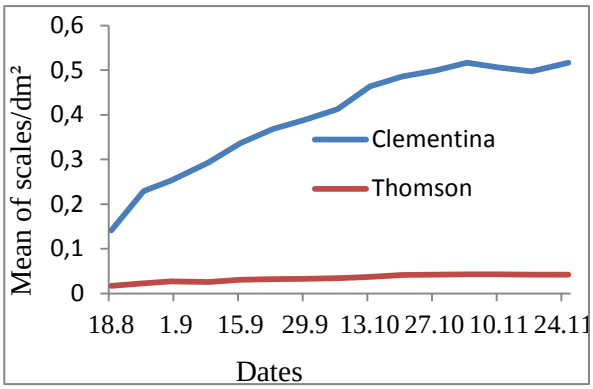

Fig. 8 : Mean of scale/dm² of fruit

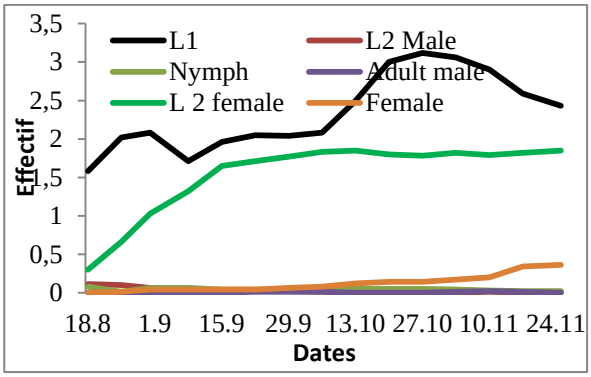

Fig.10: Number of scales/fruit/ instar on Thomson variety

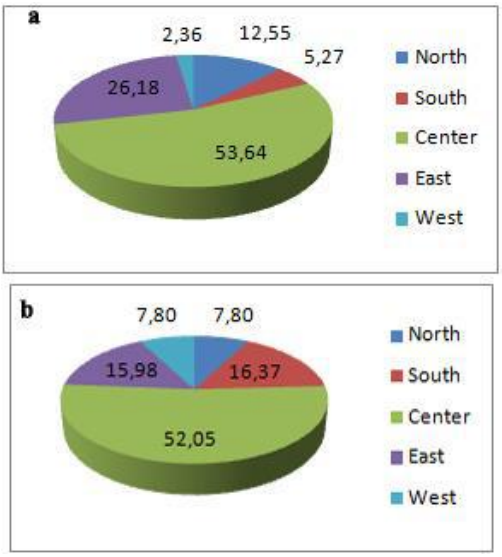
Fig. 9 and Fig.10 show the distribution of young larvae and females + males adults.



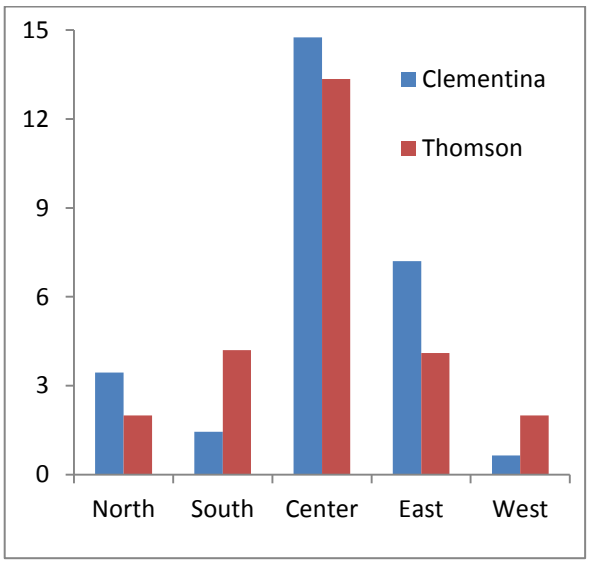


Fig.11: Rate of scales/ fruit on Clementina (a) and Thomson (b)

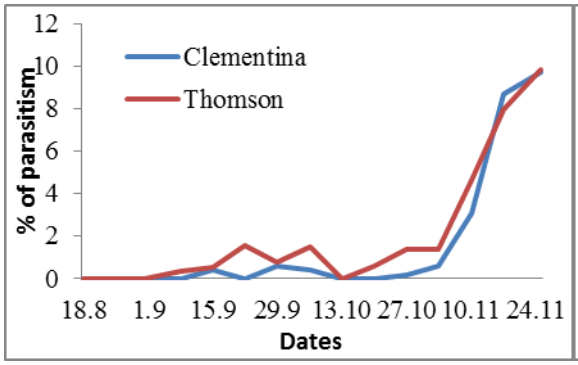
Fig.12: Mean of scales/fruit/orientation

The density populations of the diaspid on fruits are depending on variety, position of fruit and activity of natural enemies.



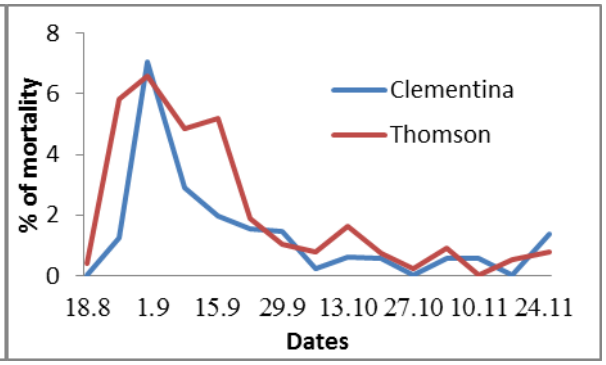


Fig.12: % of parasitism

Fig.13: % of mortality without parasitism

The total parasitism rate (primary parasitoids and hyper-parasitoids) is shown (Fig.12). It was below 5% until early October on both varieties and it increased to 10%. Use of chemicals could have a negative impact on the efficiency of natural enemies. The % of mortality was high in August and early September on the 2 varieties reaching 6-7% probably due to high temperatures and action of predators (Fig.14). In several cases, divergences between the thermal preferences of the host and those of the parasitoid lead to a disruption of the temporal or geographical synchronization increasing the risk of host outbreaks (Hance et al., 2007).

Fig.14: adult of *Chilochorus bipustulatus* (Coleoptera: Coccinellidae) on fruit.

Conclusion

Our field results showed that *P.ziziphii* is present throughout the year in all citrus trees. The leaves were heavily infested .The young larvae (crawlers) that are mobile moved from leaves to fruit. They insert their mouths and left their legs becoming fixed on fruits until death. The infestation density on fruit is depending on position of fruits on the tree. In the center the density was significantly higher because the scale is protected from sun and wind. In the center, pruning is not used in most of orchards. To control *P.ziziphii* on citrus we have to apply a strategy combining several measures using agronomic tactics such as pruning, in the center to prevent high infestations.lt will be important to spray (if needed) with efficient products when young larvae are settling on fruits.

Two *Aphytis* species were the main parasitoid of *P.ziziphii* but their efficacy is low. The most frequent predator feeding on fruit was *C. bipustulatus.*

In the current social context, the reduction of pesticides is strongly needed with the development of alternative solutions including biological control, agronomic measures.

SEVEN YEARS OF STUDIES ON TUTA ABSOLUTA (MEYRICK) (LEPIDOPTERA: GELECHIIDAE) IN ALGERIA: WHAT HAVE WE LEARNED ABOUT?

Yamina GUENAOUI*, Abderahmene DEHLIZ, Raouf BENSAAD, Zine-Eddine LABDAOUI, Kacem HAMOU

Department of Agronomy, University Ibn Badis of Mostaganem, Algeria
*Corresponding author:guenaouiy@yahoo.com

Abstract

This paper presents summarized a part of works conducted on *Tuta absoluta* since its first record in 2008 in Algeria. This invasive pest is always the most devastating tomato crop in the most important growing areas but main pests as aphids, whiteflies and mites are becoming problematic. Several studies on biological and ecological parameters, distribution, phytosanitary measures about *T.absoluta* were carried out during the last years. The main native antagonists (predators and parasitoids) were inventoried in different tomato growing areas in two far regions: In the vicinity of Mostaganem (Northwestern Algeria) and at The Oued- Righ Valley, a Saharian area located in the Southeastern Algeria. Natural enemies were sometimes misidentified. The effectiveness of some species is controversial. Tomato culture under unheated greenhouses is generally more confronted to attacks of *T.absoluta* than in open fields. Usually, farmers adopt chemical control and it is not easy to break them of this habit. To our great surprise, a prospection in more fifty small farms in the South part of Algeria revealed interesting findings: when tomato is cultivated in intercropping with aromatics plants or vegetables in association with date palm trees, attacks of *T. absoluta* were often very limited leading to suppression of chemical control. By these farming practices agricultural measures providing a good level of preservation of biodiversity are suggested. This study revealed a lack of knowledge about pest management practices, depending on season, on region and level of knowledge or standard of living of farmers. This paper explores and analyses the current limiting factors in the use of alternative measures such as biological control.

Keywords: *Tomato, Tuta absoluta, biological control, biological parameters, farming practices.*

Introduction

The invasive leaf-miner *T. absoluta* (Meyrick) (Lepidoptera: Gelechiidae) originated from South America has become one of the most devastating pests of tomato crops over the world. Since its first record in Spain in 2006 (Urbaneja et al., 2007; Garcia-Mari et Vercher, 2010) the pest spread quickly over all the Mediterranean countries because it found there all suitable conditions. Year after year, new territories became invaded and the pest is continuing to spread throughout three continents (Europe, Africa and Asia). Recently, it has been reported for the first time in Maharashtra (India) in November 2014 (Sridhar et al., 2014).This biological invasion may be defined as a natural disaster because it is causing a rapid and damaging socioeconomic impact with unwanted consequences in many countries (Riccardi et al., 2011). In Algeria, the first damaged tomato crops by were observed in spring 2008 in Mostaganem province (North-western Algeria) (Guenaoui, 2008). The pest spread to all tomato growing areas reaching Biskra (South Algeria) the most important greenhouse area (Allache, 2012) with environmental conditions highly favorable. Its control is still very difficult due to several well known factors (high reproduction potential, easy selection of resistant strains to applied insecticides) but difficulties are particularly due to a low knowledge level of many tomato growers who aren’t initiated to talk about the new

approaches associating food security, economic growth and social stability well known in developed countries.

After seven years of studies on different aspects of the problem, what have we learned about this pest? Are-we capable to control it by applying the same methods used in developed countries? Are-we ready to apply ecological measures and safety tactics by changing deeply our behavior? We try to comment some controversial information on biology, behavior, and suitable host-plants. The relationships between the tomato leaf-miner and its new environment through the factors interacting in the agro-ecosystem should be taken into count in development of IPM program for control of *T.absoluta* in Algerian conditions.

1-Biology, Ecology and behavioral activity of *T.absoluta*

Material and Methods

Insects and host- plants

A population of old larvae were recorded on infested tomato plants grown under plastic house at the farm of the university of Mostaganem and transferred to young caged tomato plants for having young adults that could assure rearing at different temperatures to perform experiments on development time, fecundity, longevity… (for more details see Guenaoui et Ghelamallah, (2008); Dehliz and Guenaoui (2015**).** Seedlings were regularly potted and kept healthy for experiments. To determine the reproduction type, virgin females were introduced in caged tomato plants under optimal conditions. The experiments were repeated many times during three consecutive years.

Results and discussion

The larvae attack all parts above the ground starting from seedling till fruiting stages causing serious damage when an adequate control is not operated. Determining biological parameters is critical regarding various habitat conditions. The development time and survival of each larva and the fecundity of females were noted daily. The development time is depending on the climatic conditions; for instance a generation (egg-adult) took about 3 weeks at 27 ° C and 27 days at 25°C (Guenaoui et Ghelamallah, 2008). Under optimal laboratory conditions (25°C±1 and RH= 70 ± 10% with a photoperiod of 16/8 h (L/D). Net reproductive rate (R_0), intrinsic rate of increase (R_m) mean generation time (T) and mean generation doubling time (DT) were respectively 22 females/female/generation, 0,05female/female/day, 27,7 days, and 06,3 days. In the northwestern part of Algeria, at least 10 overlapping generations per year were obtained. When females are mated and fed with rich food (solution of honey) they can lay eggs on any substratum such as inner surface of bottle. Mean fecundity was estimated to be 72, 5 ± 55 varying from 02 eggs to more 200 egg. Longevity of adults was estimated to be 11days (female) and 04days (male) without additional food. Biological parameters showed differences regarding other published data but cultivar may be considered as the main reason for these difference .In spite of repeated works in the world, the biology of this species is not yet known well, seeing recently that the pest will be able to reproduce by parthenogenesis in a few cases (Abbes and Chermiti, 2012; Capparros Medigo, et al., 2012). In all experiments the reproduction of *T. absoluta* necessitated mating of female. The possible parthenogenesis in *T. absoluta* mentioned by Capparos et al (2012) lead to ask two questions: Why and how the pest reproduce by parthenogenesis? Why in its origin area (according to our knowledge) never this mode of reproduction had been cited in the past? In a study on parthenogenesis, calling behavior and insect-released volatiles of a leaf-miner moth belonging to *Phyllonorycter* genius, the asexual reproduction was observed by Mozuratis et al., (2002), but in despite a

complete absence of males, the authors observed that reproducing females diurnally demonstrated the calling posture normally used for releasing signaling compounds.

2-Is sweet pepper a suitable host plant for *T.absoluta* ?

T.absoluta can attack several plant species belonging to Solanaceous family including weeds, vegetables. We tested only the most important vegetables (tomato, potato, egg-plant and sweet pepper) with the main objective to test the suitability of *Capsicum annuum* (sweet pepper) for *T. absoluta* because it is often listed among attacked plants.

Material and methods

Potted and caged sweet pepper plants were offered to ten freshly mated and fed females during three successive days. In a series of experiments we operated by comparing 2 combinations: (1) sweet pepper + tomato, (2) only sweet pepper.

Results and discussion

The best suitable host plant for *T. absoluta* was tomato. On sweet pepper we observed eggs without hatching; few hatched larvae burrowed leaves but died before reaching adulthood stage. This can explain the attractiveness of tomato for *T.absoluta.* Sweet pepper is not a suitable host plant for *T.absoluta*. This question had been well documented by Potting et al. (2013) especially in the erratum 6 because import restriction for both fresh tomatoes and sweet peppers from areas invaded by *T.absoluta* was applied in many countries. This observation is a useful indication on the suitability of the tomato plant through its volatile compounds which are used to identify the host plant. In many cases olfactory orientation by pests is guided by specific volatile blends released from their hosts (Dahlin et al. 2015).This information could make possible use of volatile interactions between neighboring plants which can lead to change in their volatile emissions. Tomato plant that coexist with other plants not attacked by *T.absoluta* may be less attractive for *T. absoluta* due to volatile interactions. These changes in host plant volatile profiles induced by interactions between undamaged plants could be used to manage *T. absoluta* populations in crops.

3-IPM Strategies of control: Biotechnical tactics; Biological control, chemical control

Several strategies are used to control *T.absoluta*: pest monitoring, agricultural practices, chemical control, management by using sex pheromones for mating disruption, or mass trapping and at a less extent biological control (Gabbara et Arno, 2010; Al- Jboory et al., 2012; Savino et al., 2012; Biondy, 2013; Zappala et al., (2013); Chailleux et al., 2014; Ghoneim, 2014; INPV, 2014). Chemical control is the most used method.

Material and methods

We have tested the role of both insect proof nets and sex pheromones trapping in unheated plastic houses, bio pesticides and inventoried natural enemies of *T.absoluta* from 2010 to 2014, (for more details see Guenaoui et al., (2011a); Guenaoui et al., (2014) and Dehliz et Guenaoui (2015).

Results and discussion

Studies showed the importance of sex pheromones in managing *T.absoluta* because we can detect the first flights of moths. Using trapping by sexual confusion was very useful in choice of type of control according to the system cropping. New bio pesticides were recommended to growers receiving an efficient training (Gasmi et Guenaoui, 2012). Recruitment of natural enemies by *T.absoluta* was widely reported in Guenaoui et al., (2013) and Dehliz et Guenaoui, (2015) but misidentification of native species (Gebiola et al., 2015) introduced confusion in some results. Conservative biological control (Guenaoui et al., 2014) and more biodiversity with use of intercropping as seen in the Oued Righ valley (Dehliz et Guenaoui

2015), could contribute to a better sustainability (fig. 2). In Algeria growers are facing several problems because greenhouses are not isolated; using insect-proof nets and trapping by sex pheromones could reduce damages until 50% (Guenaoui et al., 2011a). Good control can be obtained if the treatments are carried out in greenhouses with good isolation which prevent moth from entering. More difficulties can appear when the number of males caught increase or is not adequate with the rate of larval populations. This situation leads to use more pesticides and induces growers to have a false opinion in mind because they believe use of trapping could increase damages. Conservative biological control with native natural enemies such as predatory mirids well adapted to the climatic variation (Guenaoui et al., 2011b) development of intercropping or presence of weeds around tomato greenhouses or in open field will be preferred to increase biodiversity (Guenaoui et al., 2014) (Fig.1).

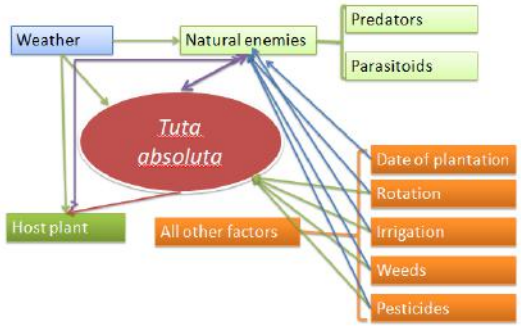

Fig.1: Interrelationships between the host plant/ *T.absoluta* and all other factors (biotic or abiotic)

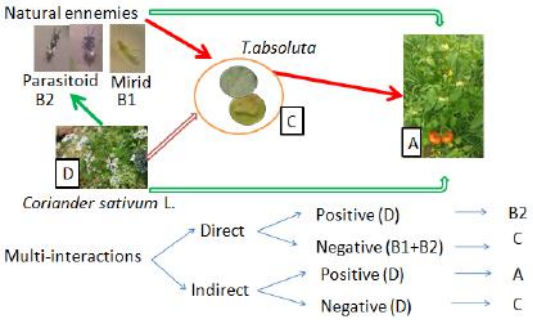

Fig.2: Interactions between *T. absoluta*, biocontrol plant and beneficials

General conclusion

In Algeria, since the occurrence of *T.absoluta* in 2008 biological and ecological studies have increased in number and sophistication over the types and severity of its impact on tomato production, economical and ecological aspects during the last seven years. The number of papers on the problematic *T.absoluta* is increasing but data on the effectiveness of different methods of control are diversely appreciated. In despite considerable support to tomato growers, many of them still face unacceptable losses. Adoption of Integrated Pest Management is slow. Studies have shown that several species of natural enemies associated with *T.absoluta* exist, showing that most parasitoid species are not efficient and may give useful control of this pest only in specific conditions.

It is so difficult to explain why and how to manage the pest when growers have not the adequate knowledge for understanding how to prevent attacks in order to reduce pesticides spays and favor natural enemies. If in developed countries (Europe) this period has created a much clearer picture of the biology and ecology with a increasing number of natural enemies species of *T. absoluta* that has led in the same time to increase studies for management studies, we believe without a clear understanding of the economic activities, it is impossible to explain and understand biology in a context where there is a lack of coordination between growers, managers, scientists, teachers and consumers. The insecticidal sprays are applied using high volumes that lead to more residues on marketable tomato fruits and less efficacy with promoting resistant populations strains as in Mediterranean countries. Integration of augmentative biological control with adequate releases of predatory mirids with other control methods could be complex but feasible however in Algeria this method has not been sufficiently explored to improve performance. Innovations are now costly; we really need a public understanding of the environmental consequences of insecticide alternatives for use of

biological control. We should increase efforts keeping in mind that the success of control of a pest depends also on the individual competence of farmer. A better understanding the interactions between human activities and natural environment integration is possible only when growers are able to take decisions towards more efficient and sustainable agricultural practices.

Abstract

Date fruits of date palm (*Phoenix dactylifera* L.), are among the most important agricultural products of Algeria. The biochemical composition of the two varieties of dates: Deglet-Nour and Mech-Degla, is marked by the high sugar content 70.92-74.07% fresh weight (fw). Due to its high level of sugar, the dates are suitable for production of syrup. The physicochemical characterization of dates syrups has revealed that this product has a Brix of 70.46-70.56%, total sugars (60.28-61.41% fw), sucrose (35.97-36.25% fw), reducing sugars (24.31-25.16% fw), pectin (0.74-1.43% fw) and ash (1.24-1.35% dry matter). Determination of minerals indicated that syrup is good source of many important elements such as potassium and magnesium. In addition, dates syrups are a good source of polyphenols, with a limit of 57.95-72.50 mg gallic acid equivalent (GAE) per 100g of fresh weight. Their antioxidant capacity ranged between 48.34-90.43% on DPPH assay, which leads to consider dates syrups as a functional food. Significant differences ($p<0.05$) were observed on pH, sugars, ash, potassium, calcium, copper, pectin, phenolics and antioxidant activity between the two dates syrups studied. Date fruits are products which could be processed into syrup with good nutritional values and broad prospects in food and pharmaceutical industries.

Keywords: date fruits, syrups, physicochemical composition, antioxidant activity, functional food.

Introduction

The date palm has been an important cultivar in arid and semi-arid regions of the world. It is principally cultivated in North of Africa and Middle East. Dates, the fruit of the date palm, is constituted the main food for the people of desert and its world production is estimated 7 127 952 in 2010 (FAO, 2012), more than 80% of this production comes from the Arab World (Al-Mamary et al., 2011). Algeria is the 4th largest producer of dates with a rich genetic heritage reaching 940 cultivars (Hannachi et al., 1998) and an annual production of about 789357 tons (FAO, 2012). Approximately, 48.21% of the annual production is made up of good varieties: Deglet-Nour (MADRA, 2010). The remaining production includes common dates, which are less appreciated by consumers and not valued especially dried varieties. Nancib et al. (1997), reported that 60000 tons of dates are lost every year in Algeria. The rejection of these dates is a real economical loss, because they are rich in noble components especially sugars, and as they may be transformed into products of high added value such as: jams, dates flour, syrup, vinegar, juices (Al-Farsi et al., 2007; Benamara et al., 2008; Al-Mamary et al., 2011). Date syrup is one of the products issued from dates processing, the well known, is prepared by a traditional process: concentration of an extract of dates by boiling, at atmospheric pressure. The date syrup is consumed either directly or can be used as an ingredient in the formulation of many foods, such as cakes, juices, confectionery, ice cream, yogurt and bread (Khalil et al.,

2002; Sidhu et al., 2003) and pharmaceuticals products like tablet binder (Alanazi et al., 2010).

The objective of this work is to investigate the possibility of the transformation of local dates varieties like Mech-Degla and Deglet-Nour to syrup in order to improve the traditional process using vacuum concentration and to preserve the nutritional and organoleptic syrup quality (color). In addition, this study evaluates the nutritional quality and antioxidant capacity of the elaborated dates syrups.

Material and methods

Raw materials

Two dried dates are selected for this study, namely Mech-Degla and Deglet-Nour. They come from the palm groves of the South-East of Algeria. They are harvested at full maturity and stored at 4 °C.

Syrups production

In the laboratory, dates are first cleaned and sorted out to remove soiled and molded fruits. Sorted dates are pitted and crushed, then mixed with distilled water at a ratio flesh/water: 1/3. The mixture is heated at 72°C for 30min with periodic stirring, then filtered through a sieve of 50 microns; the obtain extract dates is concentrated at 70 °C and under vacuum (410-430 mmHg).

Analysis Method

Fresh dates and syrups

The moisture content is determined by drying the sample of flesh dates in a vacuum oven at 70 ± 2°C. The pH was measured by a pH meter ADWA type, AD1030, at 20 °C (AFNOR, 1970). The soluble solids content is determined by measuring the Brix at 20 °C by using a Digital refractometer, Reichert type, AR 200. After clarification of aqueous extract of date, total sugars were determined by the method of Dubois et al. (1956). Reducing sugars were determined by the method dinitrosalycilic acid (DNS) (Miller, 1956). The sucrose content is deduced by the difference between the rate of total sugars and reducing sugars.

The percentage of purity is determined as follows (Mathlouthi and Reizer, 1995):

Purity = (Total sugars /TSS ratio) x100.

The ash is determined by official method of the AOAC (1995, No. 940.26). Minerals (K, Ca, Mg and Cu) were determined by atomic absorption spectrometry according to the AOAC standards (1995), using an atomic absorption spectrophotometer (Perkin-Elmer AAnalyst 100).

Pectin was dosed in the form of aluminium pectate according of method described by De Luca and Joslyn (1957).

Polyphenols extraction

The extraction of phenolics from dates is made as follows: 1g of crushed dates was macerated in 40ml of methanol with continuous agitation for 24 hours. The mixture was filtered, and then the filtrate was evaporated using rotary evaporator (Heidolph type).

Total polyphenols determination

The total polyphenols were determined colorimetrically using Folin Ciocalteu reagent as described by Meda et al. (2006). The date's extract (500µl) was mixed with 2.5ml of Folin Ciocalteu reagent (0.2N). A 2 ml of Na_2CO_3 (7.5%) was added to the mixture, and then the mixture is incubated for two hours in the darkness. Read the absorbance at 760 nm. The total polyphenol content is expressed as gallic acid equivalents (GAE).

Determination of antioxidant activity by DPPH radical

To 250 µL of methanol extract, was successively added 01.75 ml of methanol and 0.5 ml of the solution of DPPH (0.2 mmol). The mixture was placed in darkness at room temperature for 15 min, then its absorbance was measured at 515 nm. A control sample, free from dates

extract was prepared under the same conditions. The inhibition of the oxidation of DPPH was calculated using the following equation:

Inhibition (%) = $[(A_0 – A_1)/A_0]$ x100

Where A_0 is the absorbance of the control and A_1 is the absorbance of the sample.

Statistical Analysis

Results were expressed as mean ± standard deviation and analyzed by SPSS (version 20). Duncan's test ($p< 0.05$) was used to determine the significant differences between mean values. All analyses were conducted in triplicate.

Results and discussion

Physicochemical characterization of flesh dates

The results of the physicochemical date's composition are shown in table 1.

Table 1. Physicochemical characterization of dates varieties

Parameters	Mech-Degla	Deglet-Nour
Moisture (%) [1]	11.80 ± 0.24a	09.94 ± 0.55b
Total sugars (%)[1]	70.92 ± 1.55a	74.07 ± 01.47a
Reducing sugars (%) [1]	10.89 ± 0.33a	13.26 ± 0.01b
Sucrose[1]	60.03 ± 1.41a	60.80 ± 1.48a
Ash [2]	02.05 ± 0.11a	02.42 ± 0.12b

[1]: fresh weight.

[2]: dry weight.

Means in line with different letters are significantly different ($p< 0.05$).

The moisture content of dates varieties: Mech-Degla and Deglet-Nour are respectively 11.80 and 09.94 %, with a significant difference ($p< 0.05$). These values are similar to those cited by Al-Hooti et al. (2002), with contents of 11.53 and 11.55% respectively for the two Saudi varieties: Birhi and Safri. These dates could be classified as dry dates where the moisture content is less than 20% (Booij et al., 1992).

The studied dates were characterized by the predominance of sugars. The rate of total sugars is respectively 70.92 and 74.07% for Mech-Degla and Deglet-Nour dates of fresh weight (no significant difference).

It is well to note that the difference in the biochemical composition recorded between varieties of dates depends on several factors such as: variety, soil type, fertilization, irrigation conditions and climatic conditions (Booij et al., 1992, Al-Farsi et al., 2007).

Physicochemical characteristics of dates syrups

Table 2, shows the results of the physicochemical composition of dates syrups.

The moisture content of dates syrups Mech-Degla and Deglet-Nour, is respectively 24.64 and 25.49 %, with no significant difference ($p<0.05$). These values are relatively low and guarantee syrups conservation. From table 2, sugars are the major components of syrups, they contain a rate between 60.28 and 61.41% of fresh weight, representing 79.98 and 82.41% of the total dry matter respectively of Mech-Degla and Deglet-Nour syrups.

The reducing sugar content was recorded as 24.31 and 25.16 % for the date syrups of Mech-Degla and Deglet-Nour respectively, with a no significant difference. Whoever, acidity and thermal treatment applied during the concentration accelerated the conversion of sucrose into reducing sugar (Ben Thabet et al., 2009).

The date syrup is a good source of energy; it is rich in sugars, easily assimilated by the human body. In addition, the syrup could be used as a liquid sugar in many food products.

The purity of syrups is respectively 85.42 and 87.14% for the syrup of Mech-Degla and Deglet-Nour, with no significant difference ($p<0.05$). This purity is lower to that found by Mohamed and Ahmed (1981), which is 93.42% for the date syrup of Libya. The pH of

Deglet-Nour syrup (4.88) is more acidic than Mech-Degla (5.31), with a significant difference. The acidity of Deglet- Nour syrup is much higher than that of Mech-Degla. This is related to the acidity of the date used for the production of syrups (table 2).

Table 2. Biochemical characterization of dates syrups

Parameters	Mech-Degla syrup	Degle Deglet-Nour
Dry matter (%) [1]	75.36 ± 0.24a	74.51 ± 1.74a
pH	05.31 ± 0.01a	04.88 ± 0.01b
Brix (%)	70.56 ± 0.11a	70.46 ± 0.05a
Total sugars (%)[1]	60.28 ± 2.54a	61.41 ± 1.45b
Reducing sugars (%)[1]	24.31 ± 3.37a	25.16 ± 3.74a
Sucrose (%)[1]	35.97 ± 02.43a	36.25 ± 03.74a
Purity (%)	85.42 ± 3.73a	87.14 ± 1.99a
Ash (%)[2]	01.24 ± 0.03a	01.35 ± 0.05b
K[2]	512.63 ± 01.06a	634.27 ± 44.64b
Ca[2]	20.94 ± 0.26a	27.97 ± 0.02b
Cu[2]	0.84 ± 0.01a	01.53 ± 0.01b
Mg[2]	43.60 ± 2.15a	39.44 ± 0.07a
Pectin (%)[1]	01.43 ± 0.19a	0.74 ± 0.03b

[1]: Fresh weight.
[2]: Dry weight (mg per 100g).
Means in line with different letters are significantly different ($p < 0.05$).

Ash content of Mech-Degla syrup is 1.24%. This value is less than that of Deglet-Nour, which is 1.35% of dry weight, with a significant difference. These levels are comparable to those quoted by Al-Farsi et al. (2007), giving a percentage of 1.23 and 1.76% dry weight for the two dates syrups obtained from the Omani varieties: Shahal and Um-Sellah respectively. The ash content in the produced syrups dates is much higher (1.24-1.35% dry weight) compared to honey content, with an average value of 0.169% (Suarez et al., 2010). Indeed, sucrose contains minerals traces of potassium, calcium and magnesium with the following values 2.2, 0.6 and 0.2 mg per 100 g, respectively (Vierling, 2003).

The date syrup is a good source of minerals (table 2). Potassium is the dominant element of the mineral profile dates syrups. This has been reported by several studies (Khalil et al., 2002; Abbes et al., 2011). They contain 512.63-634.27 mg/100g of dry matter. Significant differences were also observed between levels of potassium, copper and calcium. The highest level of calcium and copper, are noted for Deglet-Nour syrup, on the other hand Mech-Degla syrup is higher in magnesium content (table 2).

The content of pectin found in date syrups is 1.43 and 0.74% respectively for the syrup of Mech-Degla and Deglet-Nour, with a significant difference. These values are comparable to those found by Alanazi et al. (2010), which is 1.46% for the date syrup Khalas (Saudi Arabia), but much higher than those reported by Abbes et al. (2011), which are 0.43 and 0.449% of fresh weight, respectively for dates syrups obtained from Tunisian varieties: Deglet-Nour and Kentichi. These differences appear to be due to varieties of dates. Pectin is soluble fiber. They have a beneficial effect on health, it improves intestinal transit and prevents against cancer. In the food industry, they are used as additives for gelling and stabilizing role in the production of jams, fruit juices, jellies and milk drinks.

Total phenolics and antioxidant activity

Results of the polyphenols content and antioxidant potential of dates syrups are presented in table 3.

Table 3. Polyphenols content and the reducing power of dates syrups

Parameters	Mech-Degla	Deglet-Nour syrup
Polyphenols [1]	57.95 ± 0.40a	72.50 ± 4.21b
Antioxydant activity [2]	48.34 ± 3.11a	90.43 ± 6.87b

[1]: mg of gallic acid equivalents (GAE) /100g.
[2]: on %.
Means in line with different letters are significantly different ($p < 0.05$).

The date syrup is a good source of natural antioxidants (polyphenols) and could be considered as a functional food (Abbes et al., 2011). A significant difference was observed between the rates of polyphenols dates syrups. They contain a 57.95 and 72.50mg of GAE/100g, respectively for Mech-Degla and Deglet-Nour syrup. In comparison, these levels are lower than those quoted by Al-Farsi et al. (2007), which gave values of 96, 141 and 162 mg of GAE/100g of fresh weight for syrups obtained respectively from varieties of Omani dates following: Shahal, Um Sellah and Mabseeli. This difference amounts recorded at polyphenols contents is due to the variety of dates used for the production of syrups.

The date syrup has significant antioxidant potential, which has been noted by several studies (Al-Farsi et al., 2007; Al-Mamary et al., 2011). The antioxidant activity was 48.34 and 90.43 % of DPPH scavenging activity, respectively for the syrups of Mech-Degla and Deglet-Nour, with a significant difference. A significant correlation was observed between the rate of total polyphenols and antioxidant activity ($r = 0.91$, $p < 0.05$).

Conclusion

According to this work, it is possible to develop this type of dates, in order to produce syrup from the perspective of date processing in the form of marketable products and high added value. The date syrup is a promising product that offers many advantages over sucrose syrup (refined white sugar): rich in certain nutrients such as minerals and other phytochemicals with health benefits such as pectin and polyphenols. The latter wich displays an interesting antioxidant activity. The date syrup provides unique functional and nutritional properties. It could be used in many foods preparations and therefore improves their nutritional quality and allows consumers to return to natural products. In the future, it will be interesting to determine the flavoring and rheological characteristics of syrups.

Abstract

Chickpea *Cicer arietnum* is an important legume cultivated worldwide owing to its nutritional value, agronomic, ecological and economic importance. Its culture is exposed to various abiotic and biotic constraints, mainly ascochyta blight caused by fungus *Ascochyta rabiei*. When interacting with this parasite, the plant displays a cascade of defense mechanisms and undergoes changes in its metabolism. The purpose of this work is to follow some biochemical compounds evolution in different chickpea genotypes, ICC3996 C, INRA 199, ILC 200 and ILC483 inoculated with *Ascochyta rabiei*. A pathosystem including callus (host) and spores (pathogen) is used as a simple way to study this interaction *in vitro.* To obtain calluses, stems cut are cultivated on Murashige and Skoog (1962) medium added with ANA/ BAP plant growth regulators. They are then inoculated, harvested after 0, 5, 10, 15 and 20 days then analyzed. Soluble sugars total, proteins, polyphenols and flavonoids are extracted and quantified.

These markers can possibly serve as indicators in the selection of resistant genotypes.

Key words *Cicer arietinum*, callus, *Ascochyta rabiei , polyphenols, flavonoids*.

Introduction

Chickpea (*Cicerarietinum* L.) is an important grain legume cultivated on about 12 million ha worldwide with a yield of 8.28 million tons annually (Akidobe and Maredia, 2011). It offered high quality proteins, vitamins and minerals for human consumption especially in developing countries where the nutritional intake from animal sources is limited. It’s also a hopeful crop for alternative agriculture in industrialized countries due to its capacity to fix near 70% of atmospheric nitrogen mainly by its symbiotic relationship with *Rhizobiumciceri* (Zaman et *al*., 2010). Unfortunately and in spite of the large important needs, yield of chickpea has not significantly increased these last decades mostly in Mediterranean basin countries (Benzohra et *al*., 2010), due to several biotic and abiotic factors. This culture is mainly influenced by Ascochyta blight as a biotic stress. This interaction causesbiochemical metabolisms changes.

Biotechnology tools especially callogenesis provide a simple system to quantify some compounds, aim of this research. Calluses derived from chickpea host plant are interacted with pathogenic agent spore suspension. Thereafter, their biochemical profile is studied. This can provide explanation about chickpea resistance or susceptibility and promote this plant Ascochyta blight resistance screening.

Material and methods

Chickpea genotypes namely, ILC 200 and INRA 199, ICC 3996 C and ILC 483 were as calluses source, used as host (Fig 1).

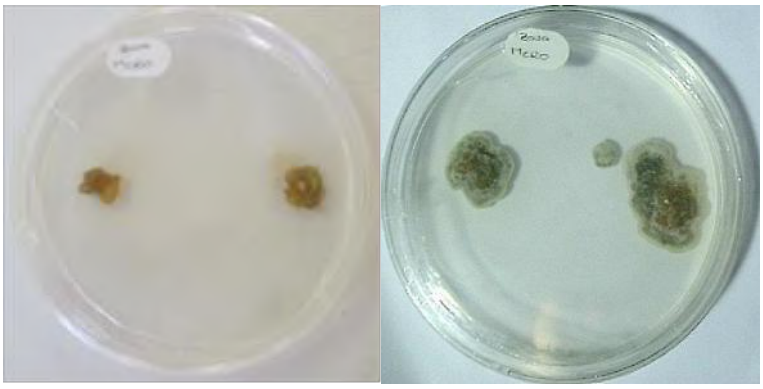

Figure 1 Pathosystem using Callus and spores suspension in early stage of interaction (a) and after one week (b)

Stem cuts were cultivated *in vitro* on Murashige and Skoog (1962) supplemented with 0.5mg/l NAA (1-Naphtyl acetic acid) and 1mg/l 6-benzylaminopurine (BAP). They were incubated under 22° ± 2C and 16h light/ 8h darkness photoperiod regime. Obtained calli were inoculated with a 10^6 *Ascochyta rabiei* spore suspension. Samples were harvested after 0, 5, 10, 15 and 20 days after inoculation to estimate biochemical compounds related to host and parasite interaction in chickpea Ascochyta blight. A methanolic extract is prepared for each genotype.

Soluble sugars were quantified following Dubois *et al*. (1956) method, total polyphenols with the Folin-Ciocalteu reagent method (Marigo, 1973), total proteins rate using Lowry et *al*. (1951) techniqueand flavonoids $AlCl_3$ essay(Quettier *et al*., 2000). A Completely Randomized experimental Design (CRD), with 3 replications was used. A multivariate analysis of variance (MANOVA) was used to study genotype, inoculation and interaction time effect on metabolites rates. The means comparison was done via Duncan's Multiple Range Test at 5% level.

Results and discussion

Generally, the results of MANOVA showed that genotype, inoculation and interaction time effects and their interaction were highly significant (P ≤0.001; Table 1).

Table1 Multivariate tests (MANOVA) results on biochemical compounds *Cicer arietinum*L. callus inoculated with *Ascochyta rabiei*

Effect		Value	F	ddl	Sig.

Total Proteins

Proteins produced by host plant cells are determining to plant tissue defense against pathogen (Nawrot- Chorabik, 2013). Some of them may be enzymes involved in phytoalexin biosynthesis, or are related to plant defensins, while others are proteinase inhibitors that disrupt pathogen (Guest and Brown, 1997). For INRA 199 (Fig.2 c), inoculated showed a 23% increase in total proteins rate in the initial stage of infection and then decreased to 0.0273mg/ g fresh weight callus ± 0.0039. ILC 483 proteins levels were generally lower in inoculated calli compared to control. During the 5 first days, in both inoculated and control was relatively constant and no significative difference was observed. Five days post inoculation, proteins rates remained constant in inoculated calli, however, it showed a 50% increase for control and was significantly ($p<.0.05$) twice higher than inoculated one (Fig.2 d). For ICC3996 C no significant difference in proteins rates was observed during this experiment between control and inoculated calli (Fig. 2 a). In ILC 200 (fig. 2 b) case, generally proteins rates were significantly lower in inoculated callus compared to control especially in the 10^{th} day where were registered 0.056 mg/ g fresh weight callus ± 0.0009 and 0.0387mg/ g fresh weight callus ± .0056 for inoculated and control respectively. Same results were reported by Hamid et *al*. (2014), and in control proteins amount was generally higher compared to inoculated calli. Lower proteins levels could be correlated to a decline in callus growth.

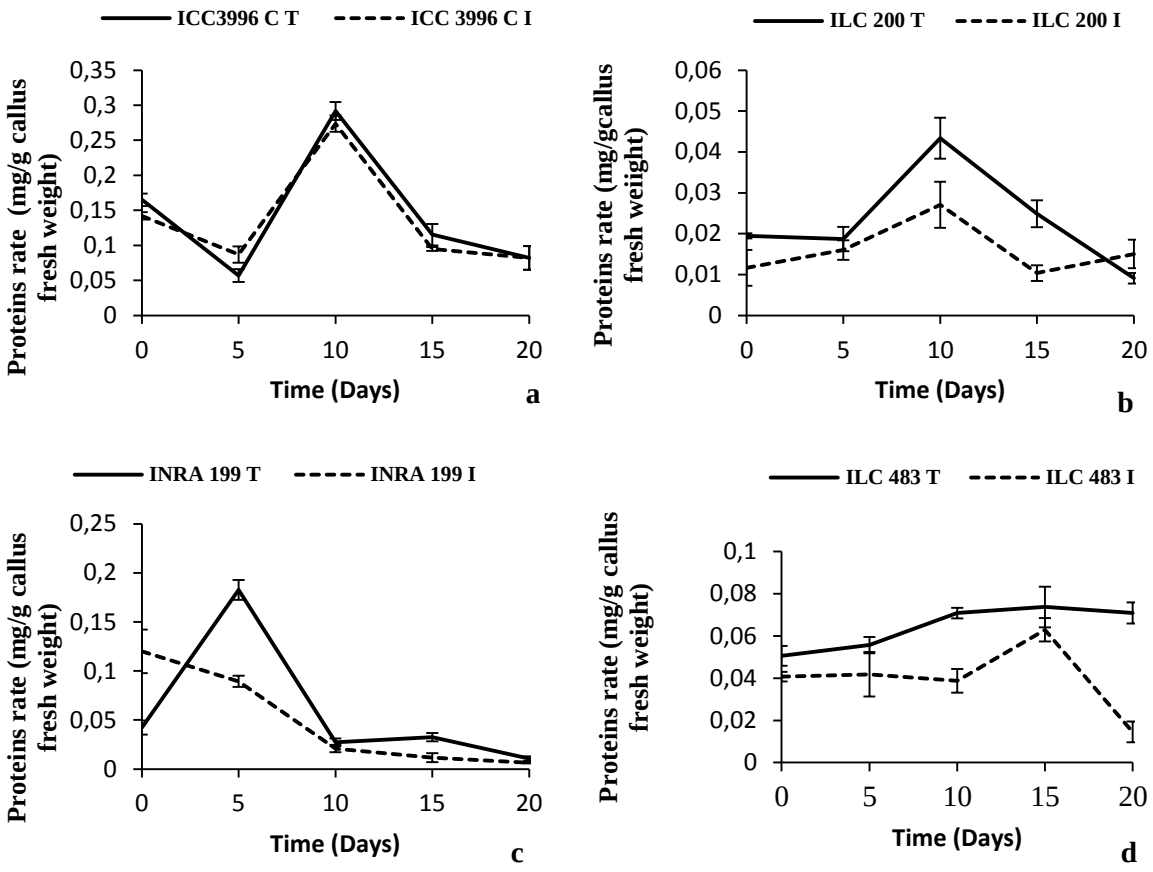

Figure 2 Total proteins rates in control (T) and inoculated (I) chickpea genotypes with *Ascochytarabiei* spores; ICC 3996C (a), ILC 200 (b), INRA 199 (c), ILC 483 (d)

Sugars are not only the main energy source and structural components, but also may control expression of many plant genes and metabolic processes pathogen defense (Platek and Niemczyk, 2000). Sugars may act as priming agents may also be useful in programs to generate stress-resistant cultivars (Morkunasand Ratajczak, 2014). This suggests that increasedsoluble sugar content may be pivotal in the ability ofelicitors to stimulate secondary metabolite biosynthesis Fan *et al.*(2011).

In this experiment, in soluble sugars accumulation as defense response, generally two phases was observed for ILC 483 (Fig.3 b). In the initial days control calli showed generally a decrease in soluble sugars rates.Sugars are probably used intensive respiratory process or for compound connected with interaction response. This biphasic response was reported in many stress reaction (Platek and Niemczyk, 2000). In INRA 199 (Fig. 3 d) characterized as often resistant to *Asochytarabiei*, an increase in soluble sugar amount was observed with significant difference after 10 days in inoculated callus (1.3260.5144 mg/ g fresh weight callus ± 0.0109 ±0.143) with compared to control (0.5144 mg/ g fresh weight callus ± 0.0109)it is generally assumed that these compounds levels are in resistant varieties Surrendranatha Reddy *etal*., 2011).

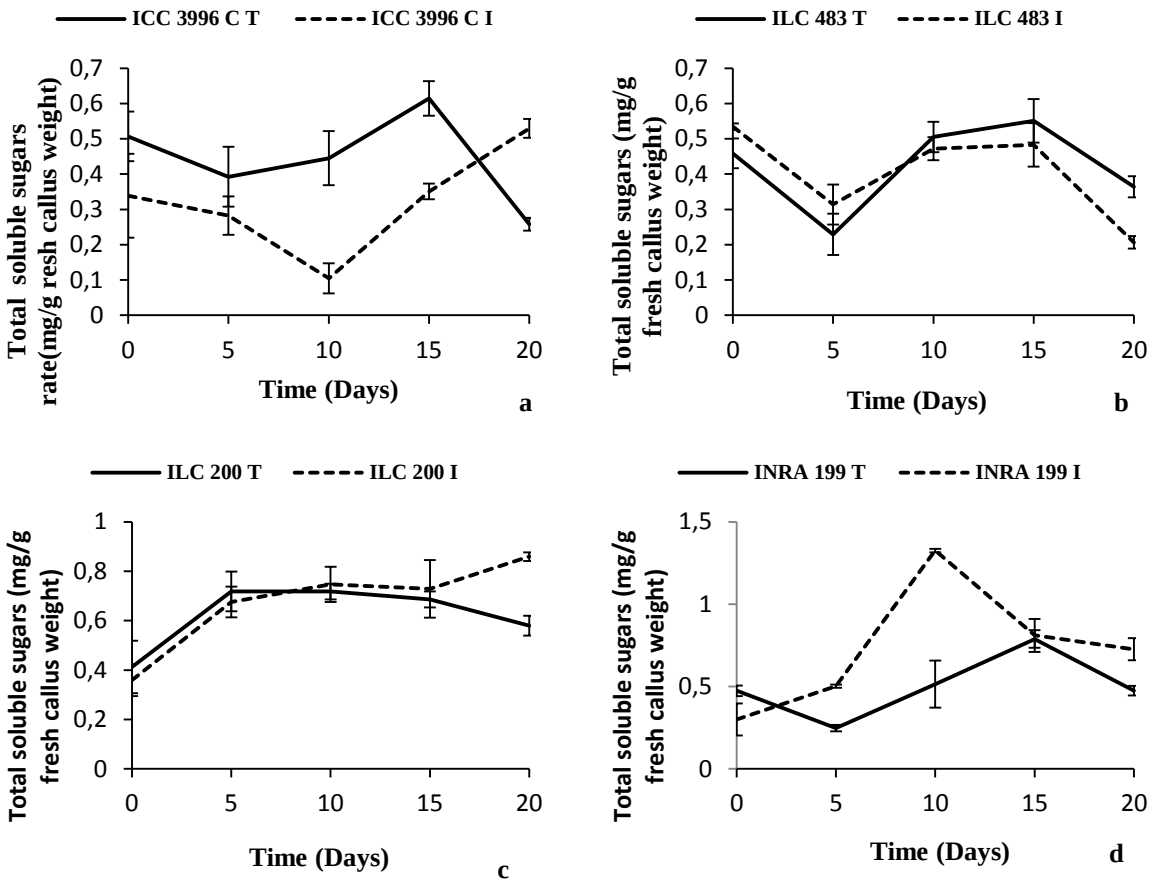

Figure 3 Soluble sugars rates in control (T) and inoculated (I) chickpea genotypes with *Ascochytarabei* spores; ICC 3996C (a), ILC 483 (b), ILC 200 (c), INRA 199 (d).

Phenolic compounds are secondary metabolites related with plant defense (Lattenzio et *al.*, 2006). Their levels are higher in resistant genotypes compared to tolerant and susceptible ones Surrendranatha Reddy et al., 2011).

INRA 199 (Fig.4 a) genotype polyphenols rates decreases gradually with time while for ILC 200 (Fig.4 c), a visible increase in inoculated callus, and for ILC 483 (Fig.5 d) it remained stable until 20th day and then decreased and reached 0.0156 mg/ g fresh weight callus ± 0.0024.The post inflectional increase in phenolic content could be due to their release by pathogen.

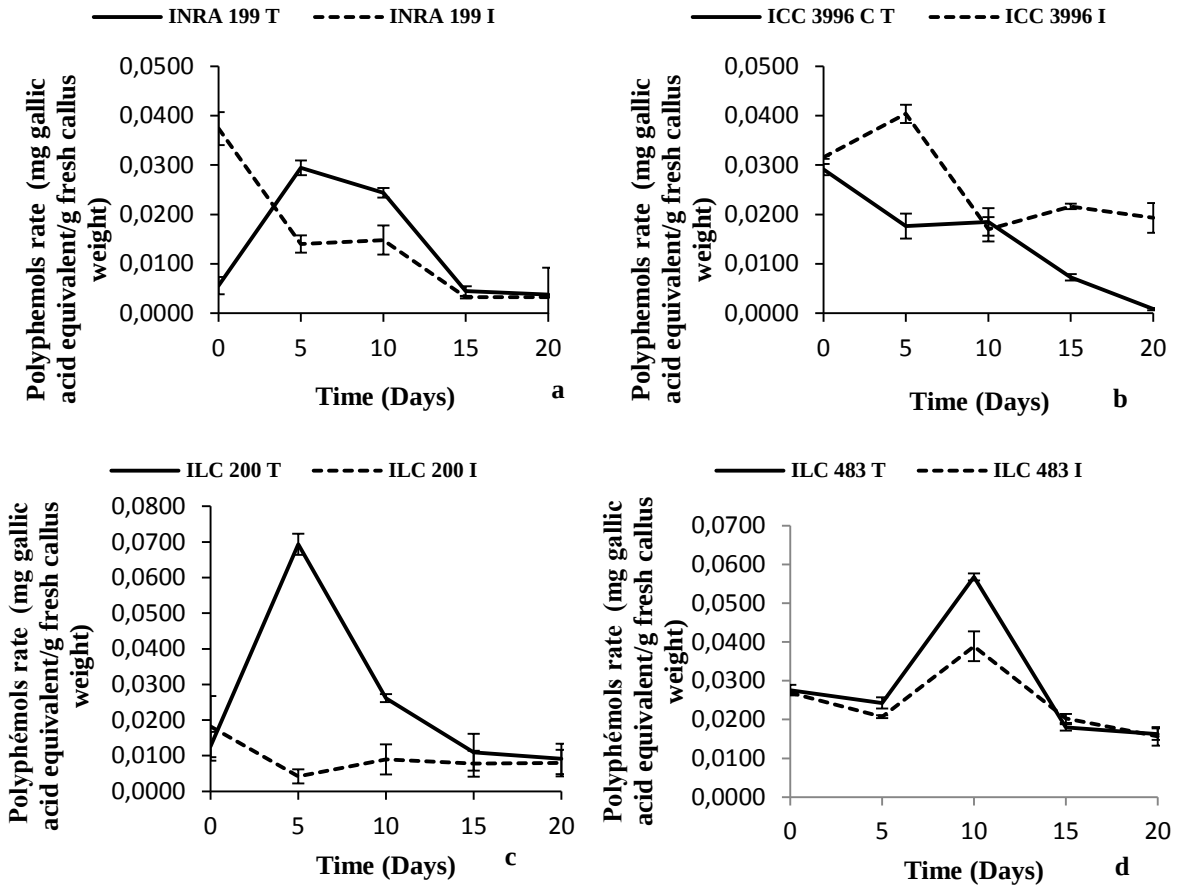

Figure 4 Polyphenols rates in control (T) and inoculated (I) chickpea genotypes with *Ascochytarabei* spores INRA 199 (a), ICC 3996C(b), ILC 200 (c), ILC 483 (d).

Flavonoids

Flavonoidshave recently been implicated as a secondary metabolites involved in plant resistance. (Duressa *et al.*, 2010). In this experiment, INRA 199 (Fig.5 a) showed a distinct significative difference in inoculated calluses then a decrease with interaction time .Same profile was observed with ILC 483 (Fig.5 c). This finding is confirmatory with Mathpal *et al*., (2011) who reported that flavonoids content decreases with age advancement of age in infected plants. For ICC 3996 C (Fig. 5 b), flavonoids rate was different after 10 days of inoculation, then a noticeable decrease was observed even in control (0.022 mg/ g fresh weight callus ± 0.0009) and inoculated callus (0.0189 mg/ g fresh weight callus ± 0.0025).

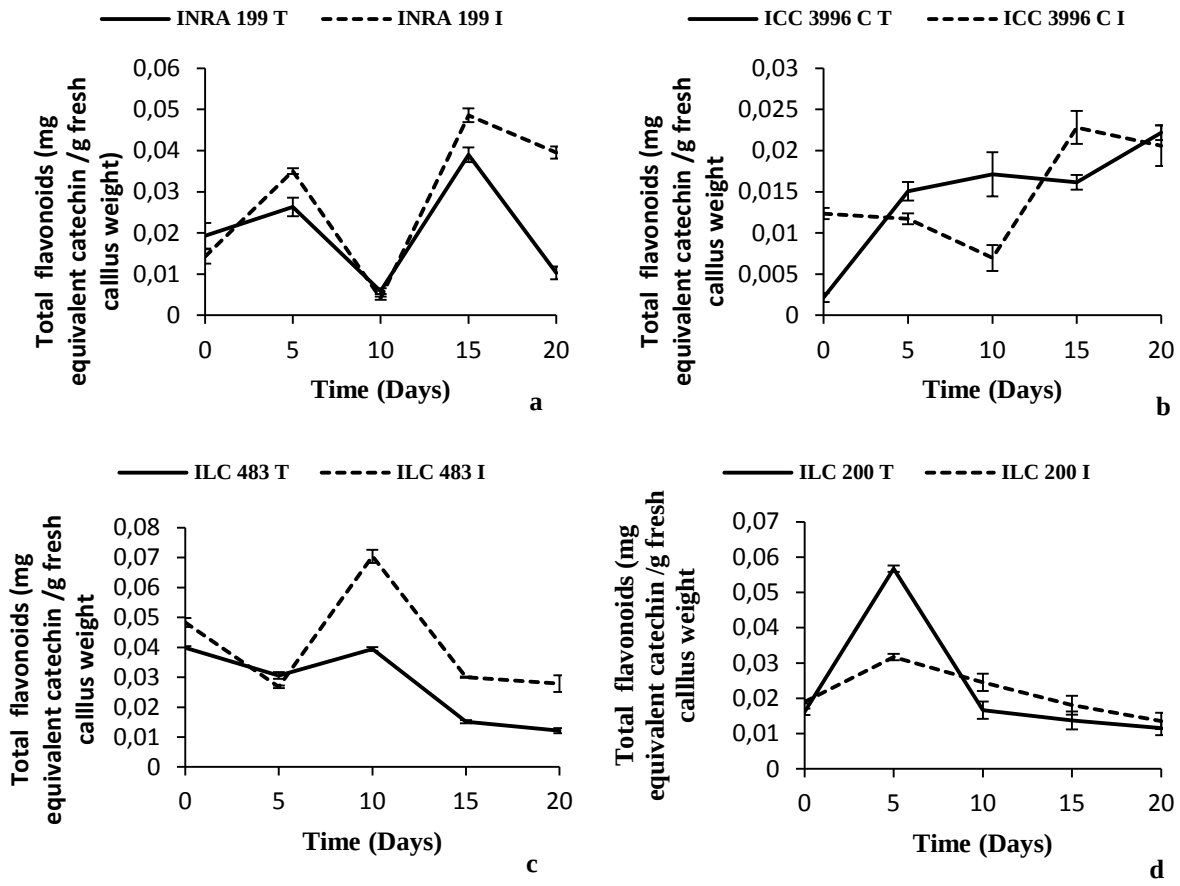

Figure 5 Total flavonoids rates in control (T) and inoculated (I) chickpea genotypes with *Ascochytarabei* spores; INRA 199 (a), ICC 3996C (b), ILC 483 (c), ILC 200 (d).

Using a pathosystem including calli and fungi spore suspension provide a simple method to study host and parasite interaction biochemical profile.

Based on present finding, it may be concluded that the interaction between Chickpea calluses and spores of *Ascochyta rabiei* triggers processes such as proteins, carbohydrates, polyphenols and flavonoids synthesis. These important biochemical compounds are related with host and its parasite relationship.

Their accumulation level seems depending on genotypes used as source of calluses, time of inoculation and parasite nature.

Further investigations especially qualitative analyses may provide more information which can lead to resistant plant selection.

ORGANOLEPTIC ASSESSMENT OF FIG STRUDEL WHERE SUCROSE WAS SUBSTITUTED WITH HIGH FRUCTOSE SYRUP

Hanadija OMANOVIC*, Alma MICIJEVIC, Dzenan VUKOTIC, Maja VRLJIC, Amna BIJEDIC

Agro Mediterranean Faculty, Dzemal Bijedic University of Mostar, Bosnia and Herzegovina
*Correesponding author: hanadija.omanovic@unmo.ba

Abstract

The goal of this paper is to perform an organoleptic analysis with fig strudel, which had, during a technological process, substituted sucrose with high fructose syrup in ratio of 20%, 25% and 30% and to carry out the organoleptic analysis of the very product as well as its quality after one and two months long storage. The organoleptic analysis of the samples was carried out by reviewers from Agro Mediterranean faculty by establishing a commission and evaluation sheet with following characteristic listed: colour, taste, smell, structure and the shape, which were then put into table and statistically analysed. The obtained results show that the product with the partial level of sucrose with high fructose syrup of 25% has 88 points and it has an excellent score. However, other products also, both experimental and standard have obtained excellent score. Authors of this paper have carried out organoleptic assessment of products that were storage for more than 30 days, where all the products had scores with minimal variance as with the first analysis. After 60 days of storage, the product with 25% of substituted sucrose had score of 81 points what still have the product excellent quality score, while in other products we noticed the decrease in points what gave them score of very good. Statistical data analysis was carried out by using analysis of variance and based on the obtained results we can conclude that analysed samples are different and that they are products with different characteristics what improves the understanding of the difference in descriptive method of organoleptic assessment of analysed samples.

Key words: *organoleptic analysis, strudel, assessment*

Introduction

This science and research paper is based on an attempt to decrease energetic value of waffle products by substituting sucrose with high fructose syrup that is contained in a very product in a significant percentage. People’s everyday habits are based on consumption on sweet industrial products. Due to the lack of physical activities as well as large number of diabetics, the sweets are being left out from our nutrition, what makes certain categories of population inferior. There is an apparent wish to eat sweets, while our health rules this wish out.

In order to decrease the energetic value of the final product during the process, authors have used sucrose substitute with high fructose syrup in ratio of 20%, 25% and 30% in the strudel filled with fig marmalade (Omanović, 2008). High fructose syrup, in theory, is equivalent to sucrose in terms of sweetness, because it contains glucose and fructose in proportion similar to sucrose with 52% and 42%. The texture of the sweet waffle is more or less strong, more or less sweet and les fragile. It has aromatic and neutral aroma and sweet flavour, (Gavrilovic, 2003). In order to control minimal conditions of the quality standards stipulated by relevant Rulebooks, that stipulates standards for cookies and products similar to cookies. The usage of high fructose syrup in production of cakes has an effect on the flavour, volumes, texture and the colour of the very product. Organoleptic analysis of the tested products will determine the level of acceptability of the product on the market because it represents the decision of the very consumers in terms of the quality of the given product.

Material and methods

Organoleptic assessment of final fig strudel products where we substituted sucrose with high fructose syrup as in the standard product was carried out in 2008 at Agro Mediterranean Faculty of Dzemal Bijedic University of Mostar, City of Mostar, Bosnia and Herzegovina. Organoleptic assessment includes the reaction of human senses to smell, taste, shape and structure what is a result of sending of impulses to central nerve and from it to the very brain where we form and define our impression about the product. Organoleptic analysis was carried out in conditions of controlled moisture, at room temperature with daylight and in serenity. The samples were selected in a separate rove m and then prepared for assessment. In order to carry out an organoleptic assessment, we have formed a commission of (judges) whose senses of smell and taste are normally developed, who are in good health and psychologically stable. The judges had a prior knowledge in regard to assessment material as well as the form of production, different faults and defects as well as the causes of these phenomena. There were in total five judges of different age. In order to neutralise the previous flavours, the judges used clear water. Before the very assessment, the commission adopted the assessment system i.e. the system of grading. The assessment of grading quality was applied for the entire organoleptic assessment by testing and examining of the product. The grade for each characteristic was given in number from one to five. The quality of the product was determined based on the sum of the grades. We measured the organoleptic durability also after 30 and 60 days.

Image 1: products for sensor analysis

Authors used organoleptic analysis to assess the following characteristics of the product:
The shape,
Structure,
Colour,
Smell,
flavour,

Cumulative evaluation sheet was used to enter the results from the evaluation sheets. The judges entered their data into the cumulative evaluation sheet for each sample separately. The quality of the product was determined based on the results that were obtained based on the following grading system:
from 81 to 100 points – excellent
from 61 to 80 points – very good
from 41 to 60 points – good
from 21 to 40 points – satisfactory
from 0,0 to 20 points – dissatisfactory

The data obtained through organoleptic assessment were statistically processed. Authors used the ANOVA analysis (analysis of variance) to test the population of the products, i.e. whether they belong to the same population or not.

Results and discussion

After the sensory analysis of all treated products, the obtained results are shown in the following table:

Table 1 results of the organoleptic assessment of the fig strudel

PRODUCT	***CODE***	***NUMBER OF JUDGES***					***TOTAL SCORE***
		1	***2***	***3***	***4***	***5***	
FIG STRUDEL	***PR-1 25%***	***20***	***16***	***19***	***16***	***17***	***88***
FIG STRUDEL	***PR-230%***	***18***	***17***	***16***	***16***	***18***	***85***
FIG STRUDEL	***PR-320%***	***18***	***18***	***17***	***15***	***18***	***86***
FIG STRUDEL	***PR-4 standard***	***19***	***18***	***17***	***13***	***20***	***87***

Table 2 summary assessment of the product per characteristic

Product	**Shape**	**Structure**	**Smell**	**Flavour**	**In total**
P1	21,00	22,00	23,00	22,00	**88,00**
P2	18,00	21,00	25,00	21,00	**85,00**
P3	20,00	23,00	20,00	23,00	**86,00**
P4	22,00	23,00	21,00	21,00	**87,00**

After summation, product with code PR-1 had 88 points, this implies that product with 25% of sucrose substituted with high fructose syrup received an excellent quality grade. However, other products as well both experimental and standard received excellent quality grade.

Authors have also carried out the organoleptic assessment of the product after 30 days where all products received identical grades as after the first summation. Analogously, the product with code PR 1 had the highest score again and was assessed as a product of excellent quality. Therefore, we can conclude that during the 30 days period there were no significant changes in terms of product quality.

The grading after 60 days gave the following results:

PR-1 total score of 81

PR-2 total score of 78

PR-3 total score of 79

PR-4 total score of 80

After 60 days of conserving the product with 25% sucrose substituted with high fructose syrup PR1 received a score of 81 what gave it a grade of excellent quality, while other products suffered a decrease in the summation and received a very good quality grade. .

The data obtained through organoleptic assessment were statistically processed. Authors used the ANOVA analysis (analysis of variance) to test the population of the products, i.e. whether they belong to the same population or not.

Authors have tested hypothesis H0 (that all products belong to the same population) as opposed to the hypothesis H1 (that products do not belong to the same population).

Table 3: Results of the statistical data processing

ANOVA: Single Factor

SUMMARY				
Groups	*Count*	*Sum*	*Average*	*Variance*
Row 1	4	17,6	4,4	0,026667
Row 2	4	17	4,25	0,33
Row 3	4	17,2	4,3	0,12
Row 4	4	17,4	4,35	0,036667

ANOVA						
Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*F crit*
Between Groups	0,05	3	0,016667	0,12987	0,940486	3,490295
Within Groups	1,54	12	0,128333			
Total	1,59	15				

Result implies to reject the H0, therefore we can conclude that we are dealing with product of different characteristics.

Conclusion

Strudel filled in with fig marmalade where we substituted sucrose with high fructose syrup were assessed in three different series according to the given variables, shape, structure, smell and flavour. Organoleptic assessment of the product was carried out immediately after the production, but also after thirty, that is sixty days.

The results have shown that the product with partial substitution of 25% sucrose with high fructose syrup had the biggest number of points – 88, what means that it was graded as the product of excellent quality, while other products both experimental and standard had somewhat less scores.

Authors carried out an organoleptic analysis of experimental and standard products after thirty days in conditions of set storage. The analysis showed that all products kept their excellent quality. Therefore, we can conclude that there were no changes in terms of product quality.

Organoleptic analysis after sixty days have shown that product with 25% of high fructose syrup has maintained its excellent quality while other products were graded as very good. We can conclude that they suffered a change and decrease in quality.

The data obtained through organoleptic assessment were statistically processed and the results of ANOVA analysis show that the products have different characteristics.

The judges decided that the tested products have a good quality and recommend them for the market placement.

Even though, sensory analysis is somewhat subjective, this method is important because it represents a consumers' judgement regarding the quality of certain product.

Abstract

This paper presents a structure and floristic composition, biological spectrum, gradient analysis, areal range, numerical classification and ordination of widespread association *Cynodono-Sorghetum halepensae* (Laban 1974) Kojić 1979 in wine-growing regions of Bosnia and Herzegovina. It was taken a 32 relevés, and characteristics of the investigated sites date are presented. The total number of 79 plant species make floristic structure of the association. Typical types of associations are: *Cynodon dactylon* (L.) Pers. and *Sorghum halepense* (L.) Pers. In composition of the association apart of characteristic species, *Convolvulus arvensis* L. was present. Biological association spectrum shows domination of terophytes and hemicryptophytes. Gradient analysis shows the greatest dependence on floristic composition of the association in related with soil moisture. Areal spectrum of association are characterized by the dominance of species of wide distribution. Numerical classification of analyzed association can clearly distinguish three groups of sites, which is confirmed by the results of ordination that was performed correspondent analysis.

Key words: *correspondent analysis, vineyards, weed associations.*

Introduction

The study of weed flora and vegetation of the vineyard were less studied in comparison to other agrophytocenoses. However, a number of authors has made a significant contribution to understanding the characteristics of the weed of vineyards. Those research papers in one way was related to the state and prospects of viticulture and general questions about the characteristics of weed in vineyards (Tarailo, 2001), while in the other way they performed floristic and phytocoenological research (Jovanović, 1999; Dujmović-Purgar and Hulina, 2004; Pál, 2004; Lososová et al., 2004; Kovačević, 2008), often related to the monitoring of seasonal dynamics (Crnčević et al., 1992; Lososová et al., 2003) and indicative role between microhabitats (Ubavić et al., 2004). A large number of research were related to the effects of herbicides use, economic aspects and tillage methods (Poldini et al., 1998; Leeson et al.,1999; Baumgartner et al., 2007; Baumgartner et al., 2008; Vrbničanin et al., 2009). A numrous papers were related to synmorphologycal changes in weed communities, as well as changes of taxonomic position, as result of applying of herbicides for many years (Ajder 1992). Our research covers the area of the two wine regions: the northern region of Bosnia and region of Herzegovina, splited due to morphostructural properties clearly differ in terms of climate and soil characteristics. The aim of the present study is the floristic-phytocoenological research of weed flora and vegetation of vineyards, which should provide current status of weeds amount, floristic composition and structure of weed communities, in this completely unexplored area of Bosnia and Herzegovina.

Materials and methods

Floristic-phytocoenological research was carried out according to the principles and methods of the French-Swiss phytosociological school of Braun Blanquet (1965). Determination of plant species is done on the basis of publications: Flora Europaea I-V (Tutin ed., 1964-1980), Flora SR Srbije I-IX (Josifović ed., 1970-1977), Flora Hrvatske (Domac 1994), Ikonographie

der Flora des Südöstlichen Mitteleuropa (Javorka and Csapody, 1979) and Flora Italiana (Fiori and Paoletti, 1921). Taxonomy and nomenclature follows Flora Europaea I-V (Tutin ed., 1964-1980). Sintaxonomic review of vegetation is shown acording to publication Sintaksonomski pregled vegetacije Srbije (Kojić et al., 1998). Life forms of plants were determined according to the publication Flora Srbije (Sarić ed. 1992). Floral elements identified species is represented by Oberdorfer (2001). Multivariate statistics was performed by using a computer package program Biodiversity Pro (McAleece, 1998). Numerical classification of the analyzed sites was performed by method of correspondent analysis (Hill 1974) and UPGMA methods (Sneath and Sokal, 1973).

Results and discussion

Floristic structure of the association are shown in table 1. The floristic composition of the association are presented with 79 species. The sites of the association are developed on flat terrain at an altitude of 53 to 281 meters above the sea level. Characteristic species of the association are *Cynodon dactylon* (L.) Pers. and *Sorghum halepense* (L.) Pers. Species *Cynodon dactylon* (L.) Pers., is not typical only for this association, because it has high abudance in other weed associations (Crnčević, 1988). However, in this association it is present in all sites and with very large number and cover value (Cover 4671,54), so its role in the structure of this association is extremely important. Due its biological and morphological properties *Sorghum halepense* (L.) Pers. have considerable influence on the genesis and structure of the association, but much smaller number than *Cynodon dactylon* (L.) Pers. This leads to the fact that mentioned species has a smaller role in structure of this association. A special feature sites of this association is that all three species of characteristic association set are geophytes. Their spreading is probably conected to low level of agricultural practices and their morphological characteristics (Baumgartner et al. 2007).The composition of the characteristic set, besides typical species, also makes the species *Convolvulus arvensis* L.

The biological spectrum of association shows domination of therophytes and hemicryptophytes, that consitute almost 90% of all species (Table 2). Of the total number of therophytes (45), the highest cover values have following species: *Amaranthus retroflexus* L., *Chenopodium album* L., *Euphorbia helioscopia* L., *Lamium purpureum* L. and *Hibiscus trionum* L.

Table 2. Biological spectrum of association

Life forms	The number of species	%
Therophyte	45	56,96
Hemicryptophyte	24	30,38
Geophyte	7	8,86
Scandenophyte	2	2,53
Phanaerophyte	1	1,27

The living area spectrum of association are characterized by the presence of nine groups of floral elements (Table 3) with the dominance of species of wide distribution. Most of the weeds in both studied areas belogs to the cosmopolitan element, followed by euro-asian, mediterranean and adventive.

Table 3. Floristic elements of association

Floristic elements	The number of species	%
Cosmopolitan	27	34,18
Euro-Asian	12	15,19
Mediterranean	12	15,19
Adventive	11	13,92
Boreal	6	7,59
Sub-Mediterranean	6	7,59
Sub-Atlantic	3	3,80
Continental	1	1,27
Moderate Continental	1	1,27

Correspondence analyses (Figure 1) performed on the basis of weed species of the higest abundance and coverage has showed the floristic diferences in vegetation of the studied areas. As floristically similar sites it is possible to separate the first group of sites (marked by numbers from 1 to 17), the second group of sites (marked by numbers from 18 to 27) and the third group sites (marked by numbers from 28 to 32), as it is presented in the dendrogram (Figure 2).

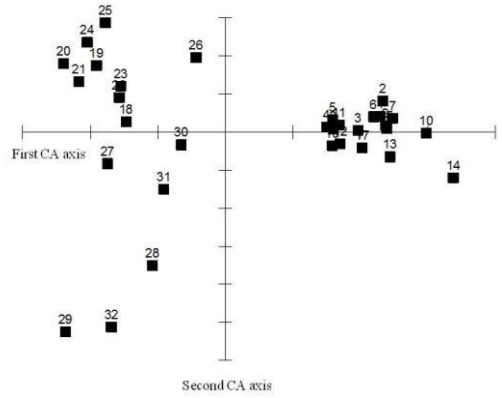

Figure 1. Ordination of sites association

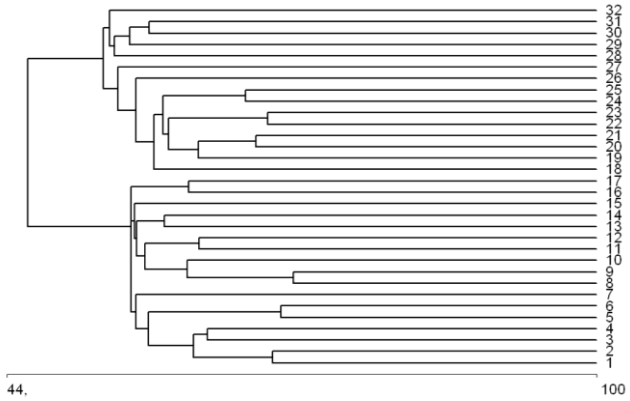

Figure 2. UPGMA classification sites of association

Sites in the 2 areas were grouped together with distinctive feature of the 3 areas. The first group of sites is typical for the summer and autumn aspect of the vineyards of Herzegovina, and it is reflected by the presence of a large number of species characteristic for higher syntaxonomical unit. Second group of sites is characteristic for the spring aspect in the vineyards of Herzegovina. The third group of sites is typical for the summer and autumn aspect of the vineyard of northern Bosnia.

Conclusion

In Bosnia and Herzegovina the association *Cynodono-Sorghetum halepensae* (Laban 1974) Kojic 1979 is typically developed in the vineyards of Herzegovina, primarily among the microhabitats of row in which chemical weed control dominante. In the vineyards of northern Bosnia sites this associations are developed over the entire surface. They partly have the character of meadow type, caused by low-intensity of agricultural practices.

The sites of the association in the vineyards region of Herzegovina are usually developed in the microhabitats of row, because the intet-row is intensively farmed. The analysis range of the spectrum has showen importance of cosmopolitan and Eurasian species in this association. In floristic composition of association influence of mediterranean area is obviosly.

From a cosmopolitan group of floral elements the greatest cover value have: *Cynodon dactylon* (L.) Pers., *Stellaria media* (L.) Vill. and *Convolvulus arvensis* L.

Numerical classification of the analyzed sites of association *Cynodono-Sorghetum halepensae* (Laban 1974) Kojić 1979 clearly distinguish three groups of sites, which is confirmed by the Correspondence analysis.

Great importance of the association *Cynodono-Sorghetum halepensae* (Laban 1974) Kojić 1979 is related to the great number of geophyte species (*Cynodon dactylon* (L.) Pers, *Sorghum halepense* (L.) Pers. and *Convolvulus arvensis* L.), their biological characteristics as they presence in the whole growing seasons, which is a major problem in taking measures to weed control especially among microhabitats.

Abstract

The crop damage caused by cereal leaf beetles of the genus *Oulema* Gozis 1886 (Coleoptera: Chrysomelidae) has been increased in recent decades in different regions of Europe and North America. The purpose of these studies was to evaluate the antixenosis resistance to cereal leaf beetles in modern and old cultivars, local forms and breeding lines of winter wheat (*Triticum aestivum* L.) created in Bulgaria. The investigations were conducted under field conditions by monitoring and reporting on natural infestation of existing local populations of cereal leaf beetles on wheat plants. The extent of differences between 54 genotypes was established to the infestation of cereal leaf beetles and their host suitability. The lowest density of cereal leaf beetles was observed in cultivar Enola (1.2 ind./m^2), breeding lines №301 (1.3 ind./m^2) and Sofia № 312 (2.8 ind./m^2), while the highest was found in cultivar Nedan (22 ind./m^2).
Results of our investigations can contribute to the identification of genotypes as host plants of the cereal leaf beetles and their usage in the bridging process.

Keywords: antixenosis, winter wheat, *Triticum aestivum* L., *Oulema* spp.

Introduction

Common winter wheat *(Triticum aestivum* L.*)* is the staple cereal crop in many countries of the world including all European countries. The wheat production is accompanied by a number of abiotic and biotic stress factors. The technologies of ecological and organic farming and the plant resistance to biotic stress factors are becoming more current and important.

In recent decades in several European and North American regions, the crop and economic damage caused by cereal leaf beetle is increasing. The cereal leaf beetles *Oulema melanopus* (Linnaeus 1758) and *Oulema gallaeciana* (Heyden 1879) (Coleoptera: Chrysomelidae) are oligophagous insects, whose host plants belong to the family Gramineae, but preferring wheat, barley and oats. In these agroecosystems, they are pests with economic importance. The phase of population gradation of *O. melanopus* and important economic damage were reported in North America (Olfert et al. 2004, 2006, Philips et al. 2011, Onychko 2012). The crop damage from cereal leaf beetles in certain areas of Europe could also lead to yield losses (Huusela-Veistola 2010, Tanasković et al. 2012, Onychko 2012). In a mass attack caused by *Oulema* spp., the assimilation processes of infested plant can be reduced up to 80% (Campbell et al. 1989) and yield losses reach 1t/ha, or 0.5-4% in winter wheat and 3-8% in barley (Ulrich et al. 2004).The current control methods of this pests are mainly chemicals. The natural enemies (predators and parasitoids) have not a determining role in lowering the density or maintain them below the economic threshold (Laznik 2010).

The modern tendency in the wheat breeding is not only aiming to increase the productivity of cultivars and to improve grain quality, but also to create plant cultivars, which are resistant to pests.

As the result, the effectiveness of plant breeding increases significantly, because the additional costs for the application of chemicals (insecticides) are not required and thus

reduces the danger of environmental contamination. In this aspect, the growing of resistant varieties is a desirable non-chemical control method.
The purpose of these study was to evaluate the antixenosis resistance to cereal leaf beetles in modern and old cultivars, local forms and breeding lines of winter wheat (*T. aestivum*) created in Bulgaria. The establishment of the resistance of wheat varieties and lines to biotic stress factors and the causes of specific reaction of genotypes, suggest studies on the suitability of various wheat genotypes as host plants of the cereal leaf beetles.

Materials and methods

Field trials and experimental genotypes

Studies were conducted under field conditions in the experimental field in Lozen, Sofia ($42^{o}60`16``$ N, $23^{o}48`27``$ E). The field observations were carried out in period 2010-2013 by assessment of the natural infestation by existing local populations of cereal leaf beetles on various wheat varieties and breeding lines.
As experimental materials 54 genotypes of *T. aestivum* were used, including 31 old cultivars and 8 local forms of wheat, selected and grown in the first half of the 20^{th} century and 15 modern cultivars created since 1960 in the main breeding centres of Bulgaria. Each genotype was sown in triplicate plots. The plots were consisted of two rows spaced 20 cm apart with 25 seeds/row spaced 20 cm within rows. Genotypes were randomized within three repetitions.

Estimation methods

After the overwintering period of adults, the monitoring and assessment were carried out every 5 days. The species *Oulema melanopus* (Linnaeus 1758) and *Oulema gallaeciana* (Heyden 1879) (Coleoptera: Chrysomelidae) were established in a mixed population. The dynamics of number of settled individuals (different development stages of cereal leaf beetles: larvae, pupae and adult) was followed by visual observation of the tested cultivars and lines. The degree of attack (infestation) was estimated by visual counting of the number of each development stages and presented as total average number of individuals per m^2.
The degree of damage was determined during the phase of flowering (BBCH 61-69) after the development of the larvae and was defined as a percentage of leaf area damaged by cereal leaf beetles over the entire surface of the leaf flag. The percentage of infested plants was evaluated on a scale ranging from 1 to 5 (Rouag et al. 2012).

Statistical analysis

The results were analysed using the software package “Statistica 7” (StatSoft 2005). A one-way analysis of variance and Tukey's Test were used to determine the influence of various factors on the investigated characteristic.

Results and discussion

The results of the number of development stages of cereal leaf beetles in the tested genotypes (cultivars, lines and local forms) are presented in Fig. 1 as the total average number of individuals/m^2 for the period 2010-2013. All plants in entire plots were sampled during the BBCH growth stages 31÷89 on assessment date. It should be noted that the species of larvae could not be visually identified. Furthermore, the pupae of *O. melanopus* were not reported, because this species pupate in the soil. The first adults of both species were reported in early May in cultivars Pobeda, Maritsa and Knezha. Adults were observed after the second half of May, in Enola and Rusalka cultivars. The tested genotypes during this period were in growth stage BBCH 47÷59. Their colonizing ability on the plants was so that the highest number was observed in BBCH 69÷71 at 80% of genotypes. The lowest number of individuals was counted in Enola (1.2 ind./m^2), №301 (1.3 ind./m^2), Sofia № 312 (2.8 ind./m^2), and the

highest in Nedan (22 ind./m^2). The adults of the new generation were found to BBCH 89 (fully ripe).

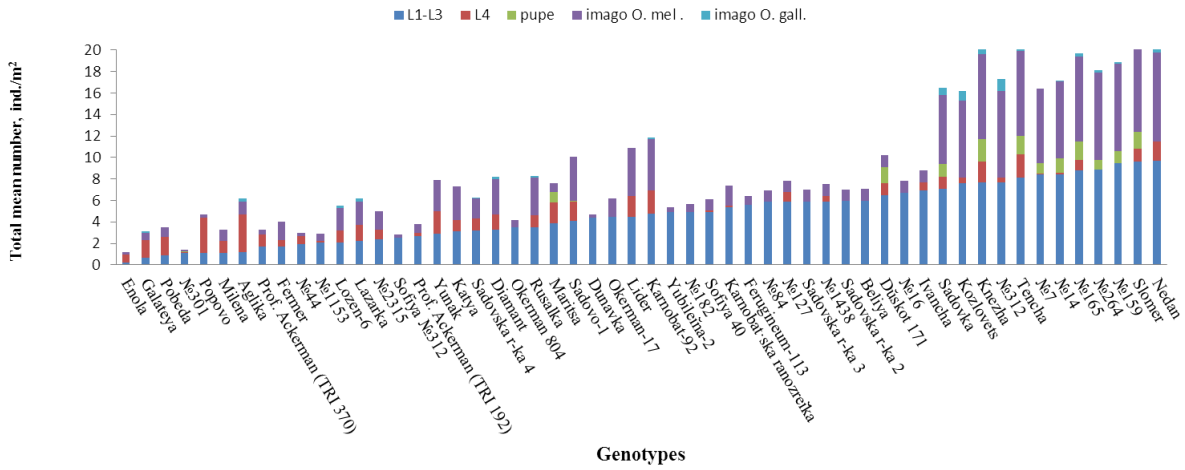

Figure 1. Degree of attack by cereal leaf beetles (*Oulema* spp.) in growth stage BBCH 31÷89 in 54 genotypes *T. aestivum*

The highest infestation level was recorded also in Sadovka №14, №312, №264, №159, №165, Knezha, Slomer, Tencha. Sortovete Diamant, Rusalka, Ivancha, Sadovo-1, Dŭskot 11, Lider, Karnobat-92, Kozlovets at which were reported by 8.2 ind./m^2 to 16.2 ind./m^2 and they occupy an intermediate position as suitable hosts.

The Analysis of variance of the data showed that the effect of genotypes on degree of attack is not statistically significant (Tab. 1). The absence of a significant difference allows us to conclude that the studied genotypes do not differ in their suitability as host plants for the cereal leaf beetles.

Total	33838.3	161			

Unlike plant pathogenic microorganisms, the insect pests can move actively and choose purposefully their host plants. The mechanisms of resistance to cereal leaf beetles in wheat have been extensively studied (Papp et al. 1992, Delaney et al. 2013, Kher et al. 2014). A lot of investigations found that the resistance to the cereal leaf beetles is conditioned by the presence of trichomes with a specified length and density on the epidermis of the leaves (Wellso 1973, Hoxie et al. 1975, Webster et al. 1972, Haynes and Gage 1981). Wheat varieties with shorter and fewer trichomes are more preferred as oviposition hosts for *O. melanopus* (Hoxie et al. 1975), and these with high tricome densities reduced egg laying rate by 90% or more (Gallun et al. 1973). Those plants make the insect difficult to achieve in the leaf epidermis; the time required for feeding and development of larvae increases; the presence of trichomes limited the movement of larvae on plant surfaces and they can fall from the plants. Because of the presence of leaf pubescence, the wheat can be classified as a cereal

plant with a higher degree of resistance to *Oulema* spp. compared to oats and barley (Konyspaevna 2012).
Production of volatile compounds by some host plant species can have antixenosis effect on pest insects. In most cereals, a secondary volatile substance is DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one) (Jonczyk et al. 2008, Meihls et al. 2012). Additionally, in a form of antixenosis, the larvae migrate away from high-DIMBOA maize varieties toward those with low DIMBOA content (Robinson et al. 1978). In corn, DIMBOA also has an antibiotic effect and negatively affects longevity of overwintered *O. melanopus* adults (Wellso 1978).

The degree of damage on the leaves of 54 genotypes showed variation in average values in wheat genotypes from 3 to 43% and the total average for all genotypes was 21.1% (Fig. 2).

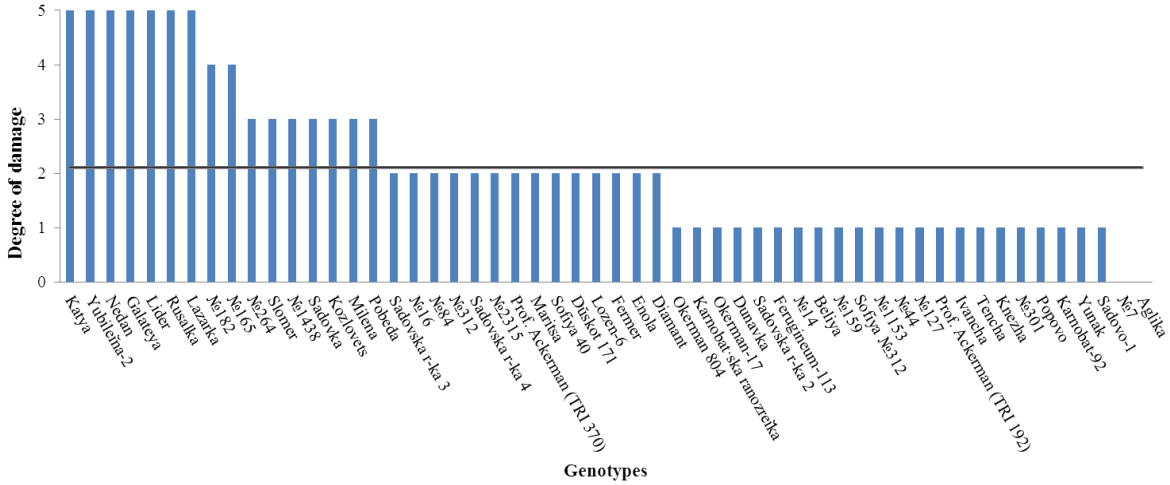

Figure 2. Degree of damage by *Oulema* spp. in 54 genotypes *T. aestivum* ; the line marks the average value

Very low damages were reported on one of the oldest Bulgarian cultivar №7, which was established in 1911. The old cultivars Okerman (Prof. Ackerman TRI 192) and Aglika (Breeding centre Dobrudzha Agricultural Institute, General Toshevo) were with a low degree of damage (9 % resp.0.2 %). The highest damage (43 %) was found on the old cultivar №301, and also on the modern cultivars Katya and Rusalka (37%).
In our studies, the observed differences between the genotypes could be explained by a non-preference reaction (antixenosis) of cereal leaf beetles to resistant plants. In this aspect, further is research needed to done in term to identify which are the factors determining the different degrees of attack and damage in inspected genotypes.
The breeding and cultivation of wheat varieties with genetically determined resistance is an alternative approach to control the insect pests and is particularly important for organic wheat production (Serpolay et al. 2011). Local forms and old varieties of wheat have developed adaptation mechanisms to specific environmental conditions of the area and resistance to plant pests. It is considered that they are a source of genes for improvement of modern varieties as regards resistance to biotic and abiotic stresses (Newton et al. 2010).
Results of our research showed that after comparing the group local forms and old cultivars with the group of modern cultivars no significant differences in the degree of damage by cereal leaf beetles was found (Fig. 3). This shows that modern selection of wheat has not created prerequisites for increasing of the attack and damage on the new cultivars compared with the local forms and old cultivars.

The ecological approach to control of insect pests required the conclusion that the genotypes with moderate resistance, coupled with good wheat properties and quality, are more promising and suitable for application implementation in practice.

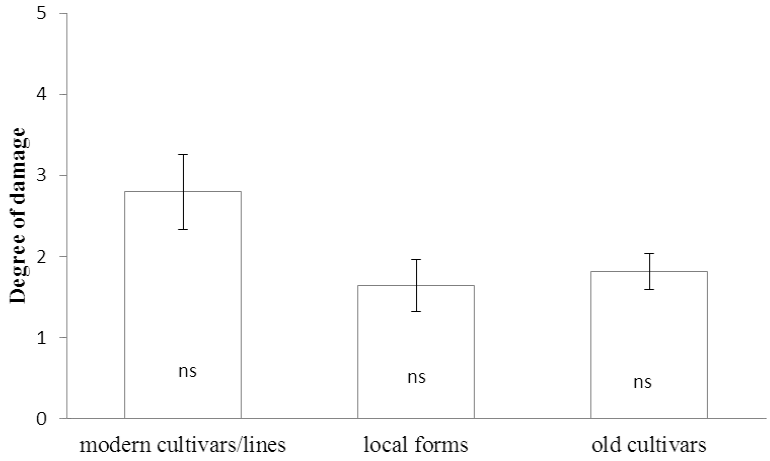

Figure 3. Comparing the genotypes of wheat to degree of damage caused by cereal leaf beetles (*Oulema* spp.); Mean-±SE, Tukey test, $P < 0.05$

Conclusions

The genotypic characteristics of the 54 cultivars, breeding lines and local forms of winter wheat have not shown statistically significant antixenosis effect on settlement preference.

The examined plants were analyzed for assessing the degree of attack and of damage caused by cereal leaf beetles. The lowest number of individuals was observed in cultivar Enola (1.2 ind./m^2), breeding lines №301 (1.3 ind./m^2) and Sofia № 312 (2.8 ind./m^2), and the highest wad found in cultivar Nedan 22 ind./m^2. The smallest damage was reported in Aglika and №7, and the largest in Katya and Yubileĭna-2.

The local forms and old cultivars of wheat do not differ significantly from modern cultivars about the degree of damage caused by cereal leaf beetles.

Results of this examination can contribute to the identification of genotypes as suitable hosts of cereal leaf beetles and their usage in the bridging programs.

INFLUENCE OF DIFFERENT HERBICIDES ON THE GROWTH AND YIELD OF WHEAT

Maya DIMITROVA, Ivan ZHALNOV, Dochka DIMOVA, Ilian ZHELYAZKOV, Plamen ZOROVSKI

Agricultural University, Plovdiv 4000, Bulgaria
*Corresponding author: mayadimitrova30@yahoo.com

Abstract

Within the period 2011-2014, field experiments were conducted at the experimental base of the Agricultural University, Plovdiv. We studied the effectiveness and selectivity of 9 different herbicides applied to the leaves in order to control the weeds and their influence on the growth and yield of wheat of the Diamant variety.

It was established that during the period of the experiment, the height of the wheat plants varied from 75,1 to 79,9 cm as the highest values were those of the herbicides Pasifica BG and Axial 1 plus EK and the lowest values were registered after applying Laren 20 SL.

The most efficient herbicides in the fight against the weeds in the winter wheat are Pacifica WG in a dose of 350 g/ha (79,2%), Pallas 75 WG in a dose of 200 g/ha (76,2%) and Axial 1 plus 050 EK (73,8%). They control 100% of the weeds Avena fatua L. and Alopecurus myosuroides Huds. The weakest is the effect of the herbicide Axial 050 EK in a dose of 600 cm^3/ha (16,7%), because it controls only the monocotyledonous weeds and their density among the crops is low.

The best results regarding the yield were obtained after applying the herbicides Pasifica BG (5214 kg/ha), Sekator OD - 5200 kg/ha and Axial 1 plus 50 EK - 5186 kg/ha. The lowest yield was obtained from the variants treated with Axial 050 EK - 4067 kg/ha and Laren 20 SL - 4665 kg/ha. The results correspond to the data about the effectiveness of the tested herbicidal preparations.

Key words: *wheat, herbicides, growth, yield*

Introduction

Weeds are the main competitors of the winter wheat regarding the nutrients, the water and the light. Their negative influence increases when applying inefficient methods to fight them, which include mainly the use of selective herbicidal preparations (Tonev T. et all, 2007; Qazi, M. et all, 2002; Cheema, M.S. and M. Akhtar, 2005).

The weeds species are changed under the influence of the ecological conditions, agricultural activities and crop rotations (Mitkov A., Tonev T., Tityanov M., 2010). Application of the leaf herbicides in winter wheat is important factor for the weed control (Besolds B., 2002; Dimitrova M. and T. Georgieva, 2005; Haker E.,1999; Khormann P.,2002; Mitkov A.,2012; Weber R., Kieloch R., 2013).

The high level of weed presence directly affects the growth, the development and the yield obtained from grain crops (Dimitrova M. and T. Georgieva, 2005; Haker E.,1999; Khormann P.,2002; Mitkov A.,2012; Weber R., Kieloch R., 2013). This necessitates exercising control over weeds by using various selective herbicides for the purpose of restricting their negative influence on the production results.

For this reason it is necessary to study new possibilities for chemical weed control and to establish the influence of different herbicides on the growth and yield of wheat.

Materials and methods

Conducting the experiment

Within the period 2011-2014 in the experimental field of the Agricultural University, Plovdiv, we made field experiments using new herbicides applied to the leaves during the vegetation period of the wheat, variety *Diamand*. The sowing during the three years of the experiment was performed on October 20-30. The experiments were made using the block method over an area of 21 m^2 in four repetitions (table 1).

Table 1. Herbicide treatments

9	Pacifica WG	*	*mezosulfuron*	30	*iodosulfuron*	10	350	
10	Control		untreated				0	0

The agrotechnical activities were conducted in accordance with the commonly used technology for wheat (processing of the soil, fertilization, sowing, rolling). The herbicides were applied using a knapsack sprayer and a solution of 300-400 l/ha. The efficiency of the herbicides was registered in sample areas (2 for each repetition), i.e. 8 per variants on the 30-th days after spraying.

Method ANOVA was used to determine the significance of the differences between the tested variants (Fowler, Jand L. Cohen, 1992).

Results and discussion

During the period of the experiment, a total number of 16 types of weeds were established in the experimental fields sown with wheat, as the following annual deciduous weeds were predominant: *Veronica hederifolia L., Stellaria media L, Capsella bursa pastoris L., Chamomilla recutita l, Galium aparine l, Agrostemma githago l, Fumaria officinalis l, Papaver rhoeas L., Lamium amplexicaule L.*, and the density of the following annual cereal plants was lower – *Avena fatua L., Lolium temulentum L.* and *Alopecurus myosuroides Huds.* The highest was the density of *Veronica hederifolia L., Stellaria media L, Chamomilla recutita L. and Lamium amplexicaule L.* The variety of the perennial plants was smaller. The following wheat weeds were found: *Johnson grass - Sorghum halepense L.* and the deciduous weeds *Cardaria draba L., Convolvulus arvensis L.* and *Cirsium arvense L.* (table 2).

The applied herbicides control the weeds to a different extent depending on the scope of their activity. The preparations Pacifica WG, Pallas 75 WG and Axial 1 plus 050 EK, which fight not only deciduous but also wheat weeds, control 100% of *Avena fatua L.* and *Alopecurus myosuroides Huds.*. The herbicides used to fight deciduous weeds such as Derbi super, Lintur

70 WG, Arat, Laren 20 CG and Sekator OD, have a good control over the annual deciduous weeds as their density is 2-3 times lower compared with the density of the control sample. Regarding the herbicide Axial 050 EK, which is used to fight only wheat weeds, the density of the deciduous weeds is high and close to the density of the control sample. The density of the weeds in the zero control sample reaches 43.2 plants/m^2.

The growth of perennial weeds is very uneven, which is typical of these types. The perennial wheat weeds are represented by the *Sorghum halepense L.* only. This weed is not affected by the used herbicides and its density ranges from 4.0 to 11.7 plants/m^2.

The used herbicides have a good effect on perennial deciduous weeds, reducing their density to 0.3 – 1.0 plants/m^2 compared with the density of 6.0 plants/m^2 of the zero control sample. The only exception is variant 7, where the applied herbicide is used to fight wheat weeds. The heavy rainfall during the period following the application of herbicides (84.6 l/m^2 in April 2013 and 123.0 l//m^2 in 2014) provided favourable conditions for the repeated growth of weeds.

During the three years of the experiment, the herbicides that proved to be the most efficient in the fight against weeds, compared with the control sample, are Pacifica WG in a dose of 350 g/ha (79.2%), and Pallas 75 WG in a dose of 200 g/ha (76.2%), followed by Axial 1 plus 050 EK (73.8%). The weakest was the effect of the herbicide Axial 050 EK in a dose of 600 cm^3/ha (16.7%). This is due to the fact that this herbicide controls only annual wheat weeds and their density within the experimental field is relatively low.

In table 3 below, we have presented the results showing the effect of the tested herbicides on the formation and the manifestation of the main features determining the productivity of wheat. In the scheme illustrating the experiment, we have compared the variants with the zero control sample – variant 10. We have conducted a biometric analysis in order to study the effect of the herbicides on the features: height of the plant, number of grains and weight of the grains on the class.

The provedness of the differences in the features has been assessed using the method of Student (Shanin, 1977).

We can see that the lowest values of the studied features were obtained in the untreated variant (№ 10) and the highest values were registered in variant № 9 (Pacifica WG in a dose of 350 g/ha).

The common characteristic in the growth of the crops, which also affects the formation of the studied features, is that the best values were those obtained from the variants treated with Arat - 100 g/ha, Derbi super - 33 g/ha, Sekator OD in a dose of 100 cm^3/ha and Pallas 75- 200 g/ha (variants 2,1,4,8). The other variants showed lower values in a descending order. For most of the features, the values registered in variant № 7 (Axial 050 EK - 600 cm^3/ha) are the same as those of the control sample.

The provedness of the differences between the studied variants regarding the registered yield (kg/ha) in table 3 has been assessed by means of a dispersion analysis (ANOVA method). As with the analyzed features, the lowest values of the yield were registered in the variants treated with Axial 050 EK – 600 cm^3/ha and Laren 20 SG – 30 g/ha, and the highest yield was obtained after applying the herbicide Pacifica WG – 350 g/ha. The data correlates with the specified effectiveness of the herbicidal preparations (table 2).

Conclusions

During the period of the experiment, it was established that the most efficient herbicides in the fight against the weeds in the winter wheat are Pacifica WG in a dose of 350 g/ha (79.2%), Pallas 75 WG in a dose of 200 g/ha (76.2%) and Axial 1 plus 050 EK - 1000 cm3/ha (73.8%). They control 100% of the weeds *Avena fatua L.* and *Alopecurus myosuroides Huds.* The weakest is the effect of the herbicide Axial 050 EK in a dose of 600 cm^3/ha (16.7%), because it controls only the monocotyledonous weeds and their density among the crops is low.

The highest values regarding the number of grains per ear, the weight of the grains on the ear and the yield were registered in variant № 9 (Pacifica WG in a dose of 350 g/ha) followed by Sekator OD in a dose of 100 cm^3/ha, Arat - 100 g/ha, Pallas 75 WG in a dose of 200 g/ha and Axial 1 plus 050 EK - 1000 cm3/ha as the differences with the untreated control sample (№ 10) have been statistically proven.

No differences have been proven between the separate herbicides regarding the yield, with the exception of variant 7 (Axial 050 EK in a dose of 600 cm^3/ha).

By eliminating the competition of the weeds, the herbicides have a favourable effect on the height of the wheat plants.

Abstract

Within the period 2006-2009 in the experimental field of the Department for Plant Production at the Agricultural University – Plovdiv, Bulgaria, we conducted a field experiment for the purpose of following and comparing the duration of the inter-phase periods for three winter genotypes of oats (cv. Dunav 1, cv. Resor 1 and line M-K) and also to establish the correlative dependence on the quantity of the rainfall during the respective periods. The sowing was conducted in mid-October based on the split plot design method in four repetitions over an area of 10,5 m^2 and a sowing rate of 500 k.s./m^2 (kernel seeds) after previously grown sunflower. The statistical processing of the experimental data has been made using SPSS V.9.0 for Microsoft Windows.

It has been established that the line M-K develops faster by the third-leaf stage and earlier enters the stage of panicle emergence but its period from panicle emergence to full maturity is longer. The vegetation period is 3-6 days longer compared with Dunav 1 and Resor 1 which develop in parallel. For the tested cultivars, the duration of the periods till germination and the third-leaf stage is in significant positive dependence on the registered rainfall. The larger quantity of the rainfall shortens the period from stem elongation to the panicle emergence for line M-K and Dunav 1 but this dependence was not registered for cv. Resor 1. For all tested genotypes, the quantity of the rainfall within the period from panicle emergence to the full maturity stage and the duration of the period are in a state of significant positive dependence (R=0,874 to 0,962).

Keywords: *winter oat, phenological stages, rainfall, correlative coefficients*

Introduction

The production potential of the crops is to a large extent a function of the combination of agro-meteorological factors in each year. The changes in the climate over the last few years are mostly related to the increase of the temperatures and the reduction of the water resources. In their in-depth survey Porter and Semenov (2005) analyzed the reaction of the main crops towards the climatic changes. They emphasized that temperature rise and significant rainfall variation decreased the chance of obtaining high yield.

A number of surveys have been aimed at establishing the influence and mechanisms by which climate change might affect crop and food quality, for either human or animal nutrition. Crop quality is a multi-faceted and complex subject involving growth, storage and processing pre- and post-harvest, and including nutritional, technological and environmental aspects (Kettlewell *et al.*, 1999; Gooding *et al.*, 2003; Martre *et al.* 2003). There are Bulgarian authors who are also looking for dependence and are trying to explain the influence of the main agro-meteorological factors on the yield and the quality of the field crops (Georgieva, 1996; Georgieva & Kostov, 1996)

The oats are a crop which is very sensitive to high temperatures during the summer and low temperatures during the winter. In addition, it is very demanding with reference to the rainfall during the vegetation period. In relation to this, it is crucial to be familiar with the reaction of each cultivar to these factors, which can be of use when deciding on their agrotechnology

(Georgieva,1996). The purpose of the conducted observations and analyses was to establish some basic dependence between the duration of the interphase periods and the quantity of the registered rainfall under the conditions of Central Southern Bulgaria.

Materials and Methods

Within the period 2006-2009 in the experimental field of the Department of Plant Production at the Agricultural University – Plovdiv a field experiment has been conducted on soil of the type Mollic Fluvisols based on FAO (Popova end Sevov, 2012). The development was followed by comparing the duration of the inter-phase periods (sowing – emergence (SE); emergence-3rd leaf (E3); 3rd leaf -tillering (3T); tillering -stem elongation (TS); stem elongation -panicle emergence (SP); panicle emergence – full maturity (PF) and growing season (GS) of three winter oat cultivars – Dunav 1, Resor 1 and line M-K. The correlative dependence between the periods was established, as well as the dependence of each period on the amount of rainfall.

The sowing was conducted in mid-October based on the split plot design method in four repetitions over an area of 10,5 m^2 and sowing rate of 500 kernel seeds/m^2 after previously grown sunflower. The fertilization rate used was N- 60 kg/ha, P – 80 kg/ha and K – 80 kg/ha. The statistical processing of the experimental data has been made using SPSS V.9.0 for Microsoft Windows (SAS Institute Inc.1999).

The combination of the meteorological factors within the survey period varied which determined the years of the yield as specific with reference to the agro-meteorological conditions for growing the crop. The first year of the experiment 2006/2007 started with favorable temperatures. The average temperatures from October 2006 to March 2007 were 2 to 12º C higher than those in the long term. At the same time, we registered extremely low values of the rainfall in that period, which compromises the germination and the optimal development of the plants. The limited quantities of the rainfall in combination with the high temperatures in March and April shorten the phenological stages which determine the number and the size of the reproductive organs of the panicle of the tested genotypes. Although the better conditions for the oats occurred later, they could not influence significantly the formation of the yield. This made the vegetation year 2006/2007 unfavourable for the optimal development of the winter oats.

The vegetation period 2007-2008 was the most favorable for the development of the oats. The temperatures in October and November 2007 were close to normal, but the heavy precipitations (115 mm/m^2 higher the norm) impeded the sowing within optimal terms. However, the favorable temperatures during the following period allowed the germination of 97% of the sown seeds and their survival in winter. The favorable temperatures and the high values of the rainfall evenly distributed in May and June from the panicle- emergence to the full-maturity stage resulted in the optimal formation of grains on the panicle.

During the vegetation year 2008-2009, the winter was mild, with temperatures close to the norm in spring and there were frequent heavy precipitations. This allowed the normal development of the plants. However, later in April, May and June, the rainfall was insufficient (81,2 mm/m^2) and significantly below norm (107 mm/m^2), which substantially impeded the formation and the optimal development of the components of the panicle.

Results and Discussion

Cultivar Dunav 1. Cultivar Dunav 1 is characterized by its flexibility and adaptability to the various agro-climatic conditions. Table 1 shows that even when sowing 2-3 weeks later than the optimal term in 2007, the vegetation period for the year 2007/2008 was only 4 days longer than the vegetation period in 2006/2007. The sowing in 2008 was conducted during the most favorable period but despite this, the vegetation period in 2008/2009 was the longest. There is

no proven relation between the optimal period of sowing and the duration of the vegetation period.

We discovered (Table 2) strong positive dependence between the duration of the emergence and the period from the emergence to the formation of the third leaf and also between both periods and the period extending from the formation of the third leaf to the tillering stage. The duration of these periods is in strong positive dependence on the precipitations during that period. Between the duration of the inter-phase period from tillering to the stem elongation stage and the duration of the previous stages there is strong negative dependence (R= -0,866 до R= -0,965). The registered precipitations had a positive influence on the duration of the periods of sowing till germination, from the tillering stage to the stem elongation stage and from the period of panicle emergence to full maturity but the influence on the duration of the period from tillering to stem elongation is negative. The duration of the period from panicle formation to full maturity manifests strong positive correlative dependence on the quantity of the registered rainfall within this interval since the vegetation period (R= 0,890). The running of this inter-phase period does not depend on the total quantity of the rainfall during the vegetation period.

Cultivar Resor 1. This cultivar is of interest to us because it has been determined as a reference for quality in Bulgaria. The duration of the inter-phase periods and the conditions under which they develop affect the quality and the determination of the dependence explains to a large extent the obtained results. The stages of tillering and in particular stem elongation

are crucial for the formation of the future reproductive organs of the panicles. For that reason, the good knowledge of this dependence would help to plan the optimal period for sowing and the cares for the plants. The duration of the periods from tillering to stem elongation and from stem elongation to panicle emergence (Table 3) are in reverse dependence on the period from panicle emergence to full maturity but also in strong positive dependence on the duration of the vegetation period.

For example, very strong positive relations were established between the duration of the period from sowing to germination, from germination to the third-leaf formation and from the third-leaf formation to tillering. They all are in negative dependence on thefollowing two periods – from tillering to stem elongation and from stem elongation to panicle emergence.
The periods from sowing to the third-leaf formation largely depend on the registered precipitations. The established dependence once again confirms the restrictive influence of the rainfall on the determination of the sowing time and the initial development of the oats plants. The larger quantity of the rainfall extends the periods from the third-leaf formation to tillering. They have even stronger negative influence on the period from tillering to stem elongation. Between the duration of the entire vegetation period and the quantity of the registered rainfall there is strong negative dependence (R=-0,884). The longest vegetation period was registered in 2009 – 240 days during which the quantity of the rainfall was the smallest (370 ml/da). All of this once again proves that the total quantity of the rainfall, its distribution over the vegetation period is crucial for the duration of the separate inter-phase periods and the latter affect the duration of the vegetation. The total quantity of the registered

rainfall extended the period from tillering to stem-elongation in 2009 (Table 4) but significantly shortened the period from panicle emergence to full maturity.

Line M-K. The line has been selected at the Department for Plant-growing at the Agricultural University and is considered to be promising in terms of yield and quality indices. In its development there are some differences in the running of certain stages. For example, the line germinates in a shorter period of time (two to three days) but it takes longer for the line to reach the third-leaf formation and tillering stages. In spring the development is again faster as it enters the stem elongation and the panicle emergence stages earlier than the other two tested cultivars (Table 5).

Table 5. Duration of inter-phase periods (number of days) and amount of rainfall (mm /m^2), in the respective period, Line M-K

Inter-phase period	SE	E3	3T	TS	SP	PF	GS
2006/ 2007							
Duration	10	21	9	88	33	54	205
Rainfall	59,5	15,7	0,0	122,7	15,3	272,7	485,9
2007/ 2008							
Duration	31	75	14	38	30	51	208
Rainfall	146,9	93,1	2,5	41,2	29,5	98,8	412,0
2008/ 2009							
Duration	10	8	5	159	29	41	243
Rainfall	0,0	0,0	4,2	280,4	28,0	17,5	330,1

The results from the conducted correlative analysis (Table 6) give us additional information on the dependence between the duration of the interphase periods and the registered rainfall. The data shows that between the periods from sowing to germination, from germination to the third-leaf formation and from the third-leaf formation to tillering there is strong positive dependence. The duration of the same interphase periods is in negative dependence on the duration of the period from tillering to stem elongation. The extension of the period from tillering to stem elongation affects the duration of the entire vegetation period.
The period from panicle emergence to full maturity, in which the grains are formed and their quality is determined, is in negative dependence on the duration of the period from tillering to stem elongation.
The precipitations extend the period of germination and the third-leaf formation as well as the duration of the period from tillering to stem elongation and from panicle elongation to full maturity. The registered larger quantity of the rainfall during the stem elongation period accelerates the entering of the plants into the panicle emergence stage (R=-0,943). The duration of the vegetation period is in negative dependence on the registered rainfall.

Conclusions

The tested cultivars show certain specific features in their phonological development and the duration of the interphase periods. Line M-K develops faster by the third-leaf formation and earlier enters the panicle emergence stage but the period from panicle emergence to full maturity is longer. The vegetation period is 3-6 days longer compared with Dunav 1 and Resor 1, which develop in parallel.

Between the periods from sowing to germination, from germination to the third-leaf formation and from the third-leaf formation to tillering there is strong positive correlative dependence. However, their duration is in negative dependence on the duration of the stage of tillering and stem elomgation. We have established strong positive correlative dependence between the duration of the period from stem elongation to panicle emergence and the period from panicle emergence to full maturity for cultivar Dunav 1 and line M-K and negative dependence for cultivar Resor 1.

The correlative dependence between the quantity of the registered rainfall and the duration of the inter-phase periods shows that for the tested cultivars the duration of the periods from germination to third-leaf formation has strong positive dependence on the registered rainfall. The larger quantity of the rainfall shortens the period from stem elongation to panicle emergence for line M-K and Dunav 1 but this dependence has not been registered for cultivar Resor 1. For all tested genotypes the quantity of the registered rainfall within the period from panicle emergence to full maturity and the duration of the period are in strong positive dependence (R=0,874 to 0,962).

FIRST RECORD OF PHOMOPSIS SP. ON CHICK PEA (Cicer arietinum) IN BULGARIA

Yordanka STANOEVA*, Magdalena BELEVA

Dobroudja Agriculture Institute, General Toshevo, Bulgaria
*Corresponding author: y_zdravkova@abv.bg

Abstract

Genus *Phomopsis* includes saprophytes and pathogens on a large number of plants and can cause several diseases, some of them economically important. This paper presents the results of investigation on the occurrence of *Phomopsis/Diaporthe* sp. on *C. arietinum* in Bulgaria. It describes the symptoms of infection on chickpea, the morphological and cultural characteristics of the pathogen on acid PDA (APDA), the biometrical values and reproductive structures on naturally infected plants as wel on artificial nutrition medium. The isolates produced white to light grayish colonies which grew fast and filled the petri dishes for 6-7 days. The mycelium later turned dark, gray-greenish and finally brownish-black. The stroma was black, with irregular shape and size, and pycnidia was rarely observed in it. The pathogen formed two types of conidia - α и β. The α-conidia were unicellular, elliptical, hyaline, containing 2 – 4 fatty cells, although most often two. The β-conidia were observed more rarely. They were unicellular, filamentous, hyaline, straight or slightly curved. Pycnidia with α- and β- conidia were later formed in the infected tissues. Our results showed that the cultural and morphological characteristics of the isolated pathogen coincided with the description of *Phomopsis / Diaporthe* sp. This investigation is the first record of the *C. arietinum* as a host of *Phomopsis / Diaporthe* sp. in Bulgaria.

Key words: *Phomopsis/Diaporthe* sp., chickpea ,*Cicer arietinum*, first record

Introduction

Genus *Phomopsis* includes saprophytes and pathogens on a large number of plants and can several diseases, some of them economically important. The species from this genus are mainly described on the basis of their hosts, and to a lesser degree on the basis of the morphological and cultural characteristics, as well as the biometrics, the anamorph and teleomorph structures. The investigations, however, have revealed that the relation with the host has little taxonomic significance due to the wide range of hosts for some species (Santos and Phillips, 2009). Such species are *Phomopsis longicola* and *Diaporthe phaseolorum* var. *sojae*, which were isolated from *Glycine max* (Gomes et al. 2013: Zhang et al. 1997; Santos et al. 2011), *Abutilon theophrasti* (Li et al. 2001; Vrandecic et al. 2007), *Arachys hypogaea* (Sanogo & Etarock, 2009), *Capsicum annum* (Pennycock, 1989), *Cucumis* melo (Zhang et al. 1997), *Lycopersicum esculentum, Phaseolus acutifolius, Ph. lunatus, Ph. vulgaris, Pisum sativum, Trifolium pratense, Vigna unguiculata* (Aćimović M., 1988; Malvick, 1997; http://cropgenebank.sgrp.cgiar.org). Additionally, several phomopsis species can attack a single plant species. On the other hand, the morphological characteristics are not always suitable for specific identification due to their plasticity and concurrence with the other species.

In this paper we presented the results regarding investigation on the occurrence and first record of *Phomopsis/Diaporthe* sp. on *C. arietinum* in Bulgaria.

Material and method

In July 2011 and 2012 a field survey was done on the experimental *C. arietinum* crops in Dobrudzha Agricultural Institute – General Toshevo. Presence of symptomatis plants were observed and samples taken for further analyzis. The chickpea stems were washed with running water and 5 mm pieces of it were cut and disinfected in 1 % solution of NaOCl for 3 min. After they were triple washed with distilled water, left to dry on filter paper and placed in petri dishes (ø 90 mm) with acid PDA (APDA). The petri dishes were incubated in thermostat, in dark, at 25°C. Pathogen was isolated by direct transfer of pycnidia and exsudate of conidia on APDA. The pure cultures were kept in thermostat for 45 days and continuously observed for growth and spore formation. The diameter of pycnidia and perithecia was measured, as well as the length and width of pycnidiospores, asci and ascospores by light microscopy. The ascospores were spread on water agar and subsequently transferred one by one on APDA to confirm their anamorph form.

To check the pathogenicity of the fungus species, two-week chickpea plants (cultivar Balkan) were used. Tips of plants were cut off above the second internode. Mycelium discs were excised from the ends of the 5-day cultures using plastic straws about 3 cm long and directly transfered on the cut plants. The inoculated plants were kept in a greenhouse at 25^{o} C and RH 90-95 %. After three weeks, the size of lesion on inoculated plants was measured. Plants, on which PDA disks without the pathogen were placed, were used for control.

Results and discussion

Our observations showed that the typical symptoms of infected plants were dry rot, with lighter areas around the stem nodes and the petioles, which caused wilting or death of the plants. Usually these lesions were not surrounded with stripes. Small black pycnidia dipped in the epidermis were found on the main stem and the branches (Fig. 1). The pycnidia were most numerous at the base of the main stem, around the nodes, and less on edges of lesions. Also, V-shaped necrotic spots were found on the leaves, beginning from the tip downwards along the main nerve.

The isolates produced white to light grey colonies which grew up quickly and filled the petri dishes for 6-7 days. The mycelium later turned dark, grey-greenish and finally brownish-black. The mycelium was branched and septate. The stroma was black, of irregular shape and size and pycnidia were rarely observed in it. The pathogen formed two types of conidia – α and β (Fig. 2, 3). After placing infected plant parts on moist filter paper, in a next few days white drops of α-conidia were detected to emerge from the pycnidia ostiole (Fig. 4). The size of the pycnidia was 120 – 298 x 95 - 202 μm. The α-conidia were unicellular, elliptical, hyaline and containing from 2 to 4 fatty cells, althoug most often two.. The size of the α-conidia was 4.5 – 10.0 μm x 2.0 – 3.5 μm. The β-conidia were observed less frequently. They were unicellular, filamentous, hyaline, straight or slightly curved.

The symptoms which cause on infected plants, cultural and morphological characteristics of the isolated pathogen allowed referring it to genus *Phomopsis* (Aćimović, 1988; Costamilan et al. 2008).

Both, pycnidia and perithecia were observed on over wintering infected plant parts (Fig. 5). The perithecia had protruded elongated tips and size 185 – 350 μm x 150 – 310 μm. The size of asci was 27 – 58 μm x 5.0 – 10.3 μm (Fig. 6). The ascospores were two-cellular, hyaline, elongated to elliptical, clamped at the septum, with size 8.5 – 13.5 μm x 3.0 – 4.5 μm.

The morphological characteristics and biometrical values of the reproductive structures of isolated fungus corresponded to the description of *Diaporthe* sp. (Aćimović, 1988; Vrandecic et al. 2005; Grijalba and Guillin, 2007).

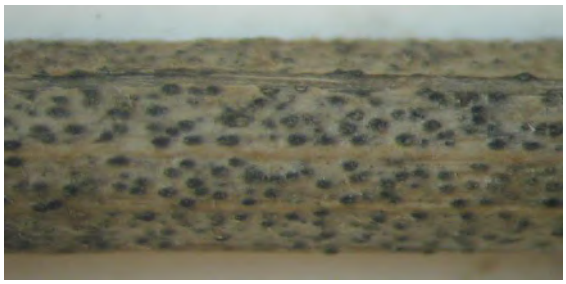

Figure 1. Chickpea stems: symptoms of *Phomopsis*

Figure 2. Phomopsis sp.: α- conidia

Figure 3. Phomopsis sp : β- conidia

Figure 4. Pycnidia and leaking of spore mass

Figure 5. Perithecia on a stem of a naturally infected chickpea plant

Figure 6. Asci with ascospores of *Phomopsis*

After three weeks of inoculation passed, the infected plants showed brownish coloration of stems, and the length of the lesions varied from 5 to 30 mm. The symptoms on the artificially

infected plants were the same as those naturally infected. The necrotic tissue grew upwards and downwards from the place of infection. Pycnidia with α- and β- conidia were later formed in the infected tissues. On the control plants lesions were not observed. To confirm the pathogen identification, re-isolation from lesions on artificially infected plants was done.

Conclusion

Based on the results from this investigation, symptoms, cultural and morphological characteristics of the isolates from chickpea, it can be concluded that isolated fungus belongs to *Phomopsis / Diaporthe* sp.

Our results aslo present the first record of chickpea as a host of *Phomopsis / Diaporthe* in Bulgaria.

MODELING THE PRODUCTION AND THE PROTECTION OF THE TOMATO CROP IN MIDDLE EGYPT

Ahmed Abdu Hamed AMIN

Plant Protection Res. Institute, ARC, MOA- 7, Nady El-Sayied Street, Dokki, Giza 12311, Egypt
*Corresponding author:aahakaa@yahoo.com

Abstract

In order to create successful program for the integrated management of pests in tomato, the simulation's software was used in this study as tools for the pest management. The used program begins with series of screens that enables the user to modify any of the default data at the beginning of the simulation. The key data that required for starting simulation are: tomatoes varieties, dates of cultivations, the geographical location, and the climatic data. Essential data for insects that required for starting the simulation are: insects' life tables, numbers of individuals in the examined samples and climatic data. Actual growth curve for tomatoes, and the predicted by the forecast model as expressed it through average deviations from averages of vegetative growth phenomena such as dates of agriculture, vegetation growth, blooming, formation of fruits, and the fruits ripening were compared. Results showed the average of deviation as follows: 0.00,-2.33-2.44,-4.00 and 13, 44 days respectively for the planting dates, vegetative growth, blooming, formation of fruits, and the fruits ripening. The Differences between expected and actual numbers in the numerical density of insects on tomato were tested also. The model explained the level of accuracy in predicting the density of pests in three seasons (2011-2013): 66.35% of aphid, 68.62% for red spider mite, 82.78% of white fly, 64, 11% cotton leaf worm. 73.96% for potatoes tuber moth, 56.43%, for tomato fruit worm, 50, 83% tobacco bud worm. Results indicated that the actual growth's curves not much different from those obtained by the laboratory model and can be implemented as a tool of integrated production and the protection for protection for tomato.

Key words: *Tomatoes, modeling, protection, prediction, middle Egypt.*

Introduction

Prediction is the expectation of a particular act in the future and prediction of plant pests is the expectation of the occurrence of such lesions early, before it takes place with the appropriate period of time. This critical period can be taken where necessary to resist the disease, and thus avoid the heavy loss caused by pests. In other words, the prediction of plant pests explain to farmers in a particular area that the conditions are right enough for the disease and that the use of effective means to resist the disease would lead to the survival of crop injury and consequently a large profit to the farmer.

Despite many Integrated Pest Management (IPM) successes using technologies such as host plant resistance and biological control, synthetic pesticides have remained the predominant component of IPM programs through the last three decades (Allen and Rajotte, 1990). Wearing (1988) has pointed out that the delay in the adoption of IPM has to do with the complexity of the programs and the considerable time and resources that must be devoted to implementation.

Despite the complexity, looking at pest management from the whole-farm level opens new avenues for pesticide and pest management (Stone and Warren, 1993). By anticipating how the overall farm plan contributes to pest outbreaks, one can avoid cropping systems and practices that lead to pest management problems. To help manage the complexity of this process, a multi-objective computer decision aid was designed to help farmers generate

alternative whole-farm plans that are profitable and environmentally sound (Buick *et al.*, 1992: Stone 1995).

A decision support system (DSS) is a computerized system for accessing and processing data and providing recommended courses of action as developed through the use of analytical methods (Ignizio 1991). In agriculture, a DSS may help farmers make tactical and strategic management decisions in areas such as cultivar selection, timing of planting and harvesting, and pest management (Plant and Stone, 1991).

The crops system is a whole-farm planning and scheduling system that considers soil conservation, nutrient management, pest management, and economic constraints to generate farm plans (Buick *et al.*, 1992). Each of the areas of consideration requires an automated evaluator to provide input for the process of assessing potential farm plans. This research deals specifically with the pest management aspect of this system.

In Egypt Tomatoes are subject to attack by a large number of insect pests from the time plants first emerge in the seed bed until harvest, however, severe damage may result either from their feeding on the fruit or by spreading certain diseases .i.e. Cutworm *Agrotis ipsilon* (BCW), tomatoes' whitefly *Bemisia tabaci* (CWF), tomatoes' aphid *Aphis gossypii* (CA), green peach aphid *Myzuz persicae* (GPA) , Potato tuber moth *Phthorimaea operculella* (PTM), tomatoes' leaf worm *Spodoptera Littoralis* (CLW) , Faba bean leaf miner *Liriomyza trifolii* (FBLM) , two spotted spider mite *Tetranychus urticae* (TSSM), tomatoes fruit worms *Helicoverpa zea*,(TFW), and tobacco budworm, *Heliothis virescens* (TBW).

Climate has a profound effect on the distribution and abundance of invertebrates such as insects, and the mathematical description of the climatic influence on insect development has been of considerable interest among entomologists. Additionally, as temperature exerts great influence among the climate variables, by directly affecting insect phenology and distribution, most of the models that describe insect development are temperature driven.

The rates of development in insects under natural conditions are largely determined by temperature. In most microenvironments, temperature is characterized by daily and seasonal cyclic variations with superimposed irregular fluctuations. However, studies of insect development rate most often involve experiments performed under constant temperatures (Howe 1967). In the development and application of development-rate models, it is always assumed that development rate at a given temperature is independent of thermal regime, whether the model is linear or nonlinear in relation to temperature. This assumption is also inherent in efforts to derive development-rate models from data obtained under varying temperatures, such as the work by Dallwitz & Higgins (1978). According to this assumption, development rate follows a definite function with respect to temperature, when other factors are equal and the amount of development can be calculated by ac-cumulating the fraction of development per unit time; i.e., rate summation (Kaufmann 1932). The procedure may be expressed as:

$$D = f\, r\,[T\,(t)]\,DT$$

Where development D: is a function of temperature. T: which in turn is a function of time, t, and the development rate, r; adjusts instantaneously to temperature.

The above assumption is fundamental to the formulation of development-rate functions for phonological models. Life table studies are fundamental to not only demography but also too general biology. In such studies, development tunes and survival rates of each stage, longevity of adults, and the daily fecundity of females are recorded for every individual. Using elementary statistics, means and standard deviations can be calculated. In traditional life-table analysis, these means are used to calculate age-specific survival rates and age-specific fecundity using either the Leslie matrix (Leslie 1945) or Birch's method (Birch 1948). These procedures have been widely used by researchers in many different fields (Laing 1969, Shib *et al.* 1976, Cave & Gutierrez 1983, Vargas *et al.* 1984, Carey & Vargas 1985). The number

of days between observable events, such as tomatoes' seedling emergence and first squares of the duration of insect generations can characterize the growth and development of plants and insects. The number of days between events, however, may be misleading because growth rates vary with temperatures. The measurement of events can be improved by expressing development units in terms of the temperature and time. The deviation between events is then based on accumulated degrees per unit time above a lower temperature re-presenting a threshold of growth.

The goal of this study is to test the accuracy of the "Model Cottamin” (under publication) in measuring the interaction of pest-plant-weather components on two tomatoes' varieties in forecasting the occurrence timing of plant phenomena's and pests infestation’s peak as well as the density of its populations.

Materials and methods

COTTAMIN **(under publication)** is method derived from temperature for measuring the organisms' growth based on cumulative heat above the lower growth threshold**.** (Wilson and Barnett 1983).

It is consisting of two modules: one for plant phenomena's and the second for the pest's populations. The crop module predicts the four main plant organs; seedlings, leaves, flowers, and bolls. Each component has its own life table measurements such as birth rates, death rates, and growth rates. Pest's module also has the same features for the five tested pests

COTTAMIN validation data were collected from Fayum Governorate tomatoes' fields (90 Km south Cairo) in Middle Egypt.

Data were collected throughout three successive Tomatoes-growing seasons (2011-2013). Hybrid 737 and Kassel Rock varieties cultivated. Data was collected on: 1-pests numbers 2-injured plant numbers, 3-tometoes fruits numbers, 4- predator numbers, and 5-current weather's data.

Protocol was as follows: 1- pheromone traps: Seven BCW, TBW, TFW, PTM and CLW pheromone delta traps were placed from January 1st to the end of December.

The lure baits were replaced with new one every 2 weeks or less depending on the weather. Adult males from each pheromone trap were checked twice per week.

Yellow sticky traps were used for aphids and white fly. Visual examination for red mite was made on all plants found in 25 m quadrate randomly selected.

2- Tomatoes' plants: Twenty-five meters of canopy were examined weekly for:

a) Plant height/m b) Crop injury (serpentine mines in leaves, and holes are chewed in fruits and buds and the infestation percentages were estimated in the lab

Results and discussion

Knowledge acquisition is the process of collecting the knowledge necessary for solving a problem and encoding it into a form that allows for efficient computer manipulation. Knowledge acquisition is comprised of two tasks: knowledge elicitation and knowledge representation. These two tasks do not necessarily occur in sequence and both usually take place throughout the development life cycle as deficiencies in the knowledge base are realized and modifications are made. In knowledge elicitation, domain knowledge is obtained through various means including interviews with experts and book and journal references. In knowledge representation, the elicited knowledge is converted to a form for efficient computer manipulation (Nikolopoulos 1997).

I - Prediction of Tomatoes phenomena's

In 2011 tomatoes' growing season data were collected from three different planting dates in Fayum Governorate cultivated with tomatoes Hybird 737. The three planting dates were: 20/07/2011, 12/08/2011, and 27/08/2011. In 2012 tomatoes' growing season the cultivated

tomatoes' variety was Kassel Rock and the Planting dates were: 15/07/2012, 01/08/2012, and 24/08/2012. The Cultivation Dates for 2013 tomatoes' growing season for Hybrid 737variety were: 28/05/2013, 03/07/2013, and 26/08/2013.

Table (1) illustrated the plant phenomena's; seedling date, 5th vegetative node to 18th node, flowering, fruit formation and fruit ripening. The table shows deviation between the observed data that collected from the fields and the predicted that obtained after applying the Cottamin model by days.

As it could be seen the average of deviation ranged from 0.00, -2.33, -2.44, -4.11, and 13.44 days for; seedling date, 5th vegetative node to 18th node, flowering, fruit formation and fruit ripening respectively.

As it could be concluded from the obtained results, the growth development curves observed actually did not differ significantly than those obtained by COTTAMIN model **(under publication)** as all observed curves demonstrated a similar growth rate curve prior to the COTTAMIN model.

Data in Table (2) demonstrate the deviation of means between observed and predicted tomatoes' phenology by means of heat units.

The careful examination of date in the table reveal that the general average of devotion of DD’s for the nine cultivation dates for the five plant stages tested ranged from 14.40, -2.00, 4.04, -8.22, -5.88 seedling date, 5th vegetative node to 18th node, flowering, fruit formation and fruit ripening respectively.

II – Prediction of Tomatoes' key pests

The proposed model (COTTAMIN) predicate the occurrence of insect pests, consequently the goals of this work is to make the validation of that model.

Simulated and observed tomatoes tested insect pests densities are depicted in Table (3). COTTAMIN Model explained only 66.15 % of the variability in the field for all the tested insects, 66.35% for aphid as an average for the three seasons, 68.62% for red mite, 82.78 % for the white fly, 64.11 % for the cotton Leafworm and 73.96 % for the potato tuber moth, 56.43% for tomatoes fruit worms and 50.83% for tobacco budworm. The predicted trend of population peaks is closed to the actual population peaks, the general average for pest component as whole reached to 66.15 %.

However, the COTTAMIN model **(under publication)** could be successfully used for tomatoes' insect pests' predictions in Fayum, Middle Egypt.

The first effort for a formal description of the relation between temperature and developmental rate was taken by botanists, to model the effect of temperature on plant growth and development. However, similar modeling procedures extended to most of the poikilothermic organisms, including insects as well. To date, the earliest experiment that related the velocity of insect development and heat, was made by Bonnet (1779) on the study of the reproduction rate of *Aphis evonymi*, F. , while the major assumption and principles that have been brought out by these earlier works, constituted the basis for all future research. Nevertheless, since then, several theoretical and experimental works have been carried out and current progress in entomology, mathematics and computation offers new means in describing the relation of temperature to insect development. Based on such linear relationships, between thermal constants and lower temperature thresholds, for several cold-blooded species, it is suggested that there is an inverse relationship between lower temperature thresholds and the thermal constant associated with latitude and/or habitat that adapts each species also based on the particular morphology and size of the species. For example, size at maturity is a function of the rate and duration of growth, and large size at maturity implies a long generation time and a correspondingly large requirement.

Thus, although simple predictive models have been developed during the last century, the development and broader availability of personal computers in the 70s and 80s resulted in the

rapid development of computer-based models to predict responses of insects in relation to climate.

Conclusion

The results show it is possible to simulate the expertise of integrated pest management with a reasonable degree of accuracy.

It is only with this gathering of disciplines that it will be possible to make holistic choices about pest management in our diverse ecosystems.

This expert system, as a standalone decision support tool, needs more testing before it can be used in the field. While the insect component has reached an acceptable level of performance and is ready for further implementation. In this research all weather events were given equal

chances of occurring throughout the state. By incorporating historical weather patterns in to the knowledge base there may be a way to weight weather events by region or by county.
In conclusion, it has been shown that preventive IPM can be implemented through whole-farm planning. More specifically, crop-specific decision supports systems help facilitate preventive IPM.

RECOGNITION OF TWO BIOCONTROL AGENTS AND THEIR LABORATORY EVALUATION FOR CONTROLLING WOOD BORERS

Ahmed MERGHEM

*Department of Wood borers and Termites, Plant Protection Research Institute, Agricultural Research Center, Dokki, Giza, Egypt
*Corresponding author: ahmedmerghem@yahoo.com

Abstract

Recording of the natural enemies of wood-boring pests which attack date palm trees and apple fruit trees in Ismailia and Qalubeia governorates was explored. This aim was further supplied with the laboratory evaluation experiments of the gained biocontrol agents against their natural target borers. The present study revealed that two different types of natural enemies had been detected. These two natural enemies were the aphid lion, *Chrysoperla carnea* (Neuroptera: Chrysopidae) which was recorded attacking the leopard moth, *Zeuzera pyrina* (Lepidoptera: Cossidae) while the other one was the green muscardine fungus, *Metarrhizium anisopliae* (Hypocereales: Clavicipitaceae) which was recorded infecting the stages of red palm weevil (RPW), *Rhynchophorus ferrugineus* (Coleoptera: Curculionidae). Laboratory screening tests with 10^{11} spores/ml of *M. anisopliae* and the three larval instars of *C. carnea* were undertaken against RPW stages and *Z. pyrina* stages, respectively. Laboratory experiments confirmed the susceptibility of RPW stages to the infection with *M. anisopliae* spores resulting in an average mortality reached 63.4 and 45.9% for larval and adult stages, respectively. On the other hand the three larval instars of *C. carnea* showed considerable predation rates against *Z. pyrina* eggs resulting in 81.3, 87.4 and 47.3% mortality, respectively while this figure was 41.6, 47.8 and 38.9 % for the larval mortality, respectively. Obtained laboratory results showed the possibility for the usage of these two natural enemies to control the tested wood borers.

Keywords: *Records, Biocontrol agents, wood borers, Metarrhizium anisopliae, Chrysoperla carnea.*

Introduction

Leopard moth, *Zeuzera pyrina* (Lepidoptera: Cossidae) is an injurious wood borer attacking apple trees *Malus sp.* (Rosales: Rosaceae) causing severe economic damage. Also, Red palm weevil (RPW), *Rhynchophorus ferrugineus* (Olivier) (Coleoptera: Curculionidae) is the most serious one which extensively attacks date palm trees, *Phoenix dactylifera* L. (Palmea: Palmaceae). Both apple and date palm trees are important economic crops worldwide. *Z. pyrina* and RPW are widely distributed boring pests infesting apple and palm orchards in many regions all over the world; in southern Asia, India, United Arab Emirates (UAE), Saudi Arabia, Iran, Egypt, Palestine and Jordan (Cox, 1993; Murphy and Briscoe, 1999 and Mani *et al.*, 2014).

In Egypt, both *Z. pyrina* and RPW stages are considered as major destructive and devastating pests causing a great significant damage as their stages existed around the year seasons and all over almost Egyptian governorates (El-Sebaey, 2004 and Merghem and Bibars, 2014). No method for their control is used except chemical control. Attempts to control these pests with chemical insecticides got limited success associated with development of insecticide resistance and pesticide residuals in nature. Extensive use of chemical insecticides resulted in environmental and economic problems such as hazard effects against human, beneficial animals and insects, and environmental pollution (Abo El-Saad *et al.*, 2001). Thus, alternative tools for effective, safe, and cheap control were encouraged to solve these problems. Among these tools was the use of the biological control measures either by their application

individually or by their use in integrated pest management (IPM) programs (Denny, 2005 and Roy *et al.*, 2006). Entomopathogenic fungi and natural predators are considered potential and environmentally safe biocontrol agents which are widely used to control many insect pests (Zimmermann, 1993). The green muscardine fungus, *Metarhizium anisopliae* (Hypocreales: Clavicipitaceae) and the aphid lion, *Chrysoperla carnea* (Neuroptera: Chrysopidae) are effective biocontrol agents against many insect pests (Driver *et al.*, 2000).
The present study aimed to explore and recognize the presence of the natural enemies of wood-boring pests attacking date palm trees and apple trees in Ismailia and Qalubeia governorates. This aim was further supplied with the laboratory evaluation experiments of the gained biocontrol agents against their natural target borers.

Materials and Methods

1. Survey, sampling and identification of the biocontrol agents of target wood borers:
Diseased RPW stages were examined and collected from infested date palm orchards in Ismailia governorate till spring of 2015. The stages were collected from trees with no previous insecticidal treatments. On the other hand, different developmental stages of the existed neuropteran species were also sampled from apple trees orchards in Qalubeia governorate to the laboratory for identification. The fungal culture was prepared using the naturally infected stages of RPW in Ismailia governorate and was identified on the base of the morphological characteristics of fungi as described by Barnett and Hunter (1999). Fungal isolate was confirmed by verification with postulates of Goettel and Inglis (1997). On the other hand, collected samples of the predator stages were examined for identification at Aphid-lion Rearing Laboratory in Plant Protection Research Institute, Dokki, Giza.

2. Collection of the target boring pests:
Healthy RPW and leopard moth stages were collected from infested date palm and apple orchards at the surveyed governorates. These collected stages were used for further experimental laboratory tests.

3. Laboratory screening tests:
Identified fungal isolate, *M. anisopliae* was tested against RPW stages collected from infested date palm trees orchards in Ismailia governorate. *C. carnea* larval instars were also released against the cossid borer stages sampled from Qalubeia governorate.

4. Propagation and screening of *Metarhizium anisopliae*:
The fungal isolate, *M. anisopliae* was used as a concentrated stock suspension to prepare 10^{11} spores/ml. concentration for preliminary screening and bioassay studies as described by (Yeo *et al.*, 2003).

5. Laboratory screening tests of the two biocontrol agents:
To test the efficacy of *M. anisopliae* isolate against RPW stages, five individuals of full grown larva or adult were used and exposed to 10^{11} spores/ml through topical application. In a second series of experiments, a check treatment of five individuals of each developmental stage was inoculated with distilled water as control. The glass jars were incubated for 15 days after treatment then mortality readings were recorded. Laboratory tests were also extended to test the predation of *C. carnea* instars upon *Z. pyrina* immature stages; eggs and larvae. Ten individuals of each larval instar of *C. carnea* were separately released to each borer stage. Five replicates for each treatment were made and mortality readings were recorded and corrected. The mortality percentages were recorded then corrected with Abbott's formula according to Abbott (1925).

Results and Discussion

1. Identification of the gained biocontrol agents:

Identification tests for the diseased RPW stages indicated the presence of the fungal disease namely *Metarhizium anisopliae* (Hypocereales: Clavicipitaceae). Plates for this fungus are presented in Fig. (1). Meanwhile, sampled stages of the neuropteran predator were mainly identified as *Chrysoperla carnea* (Neuroptera: Chrysopidae). Developmental stages of this chrysopid predator are shown in Fig. (2).

A.  B. 
Fig. (1): Plates (A&B) show the green muscardine fungus, *Metarhizium anisopliae*

A.  B. 

Fig. (2): Developmental stages of the aphid-lion, *Chrysoperla carnea*. (A. adult & B. immature larva)

Tables (1-2) showed the taxonomic positions of the two recorded natural enemies that infesting the host wood borers additionally to their target stages in relation to the existed locations and orchards either of apple and date palm trees in Ismailia and Qalubeia.

Table (1): Natural enemies attacking wood borers at apple and date palm orchards in Ismailia and Qalubeia governorates.

Scientific name	Common name	Systematic position	
		Order	Family
1- *Chrysoperla carnea*	Aphid-Lion Predator	Neuroptera	Chrysopidae
2- *Metarrhizium anisopliae*	Green Muscardine Fungus	Hypocereales	Clavicipitaceae

Table (2): Natural enemies and their host borers' stages in relation to their host plant trees in Ismailia and Qalubeia governorates.

Biocontrol agent	Borer species	Target stage	Host plant	Locality
C. carnea	*Z. pyrina*	Larval	Apple	Qalubeia
		Egg		
M. anisopliae	*R. ferrugineus*	Adult	Date Palm	Ismailia
		Larval		

Results obtained in Tables 1&2 elucidate *C. carnea* larval instars are natural enemies of the leopard moth as they were found to be predators for both eggs and larvae of *Z. pyrina* on apple trees at Qalubeia governorate. This finding is matching with Öztürk *et al.* (2005) in Turkey as they stated that the predator *C. carnea* was used on a narrow scale for the control of the cossid borer, *Z. pyrina*. Similarly, the gained results revealed that *M. anisopliae* fungus was noticed to be a natural enemy infecting the larval and adult stages of RPW that attack date palm trees at Ismailia governorate. This observation agrees with the results of Gindin *et al.* (2006) which confirms the infection of RPW with the fungus *M. anisopliae*.

2. Laboratory screening tests:

Results of the screening experiments with suspension of *M. anisopliae* at 10^{11} spores/ml concentration on stages of *R. ferrugineus* and those with the release of *C. carnea* larval instars against *Z. pyrina* stages are shown in Figs. 3&4. Obtained data revealed that these two biocontrol agents induced considerable mortalities for both those borers' stages.

The screening tests revealed that larval and adult stages of RPW are both susceptible to the infection with *M. anisopliae* fungus as shown in Fig. (3). The larvae showed a higher susceptibility to the fungal infection than adults as 63.4 and 45.9% mortalities were recorded for RPW larvae and adults, respectively. These obtained results were in accordance with Gindin *et al.* (2006) as they found that *M. anisopliae* were virulent against RPW under laboratory testing.

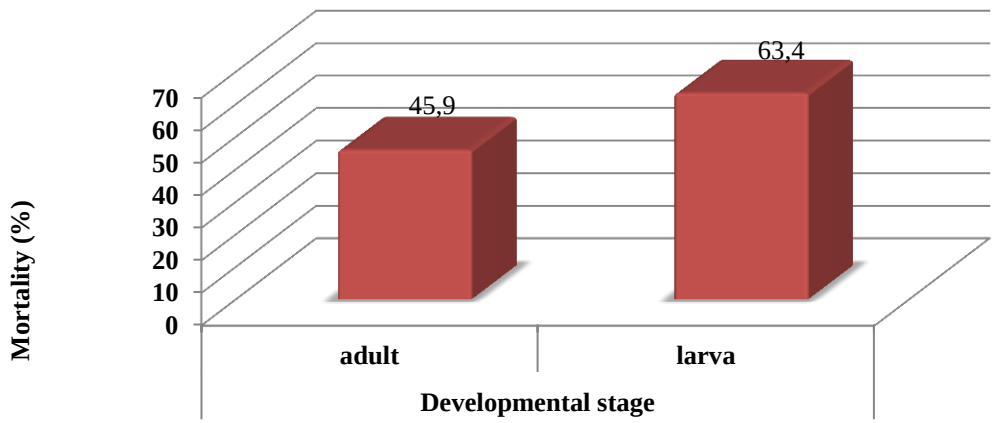

Fig. (3): Average mortality rate of *R. ferrugineus* stages caused by treatment with 10^{11} spores/ml *M. anisopliae* in the laboratory

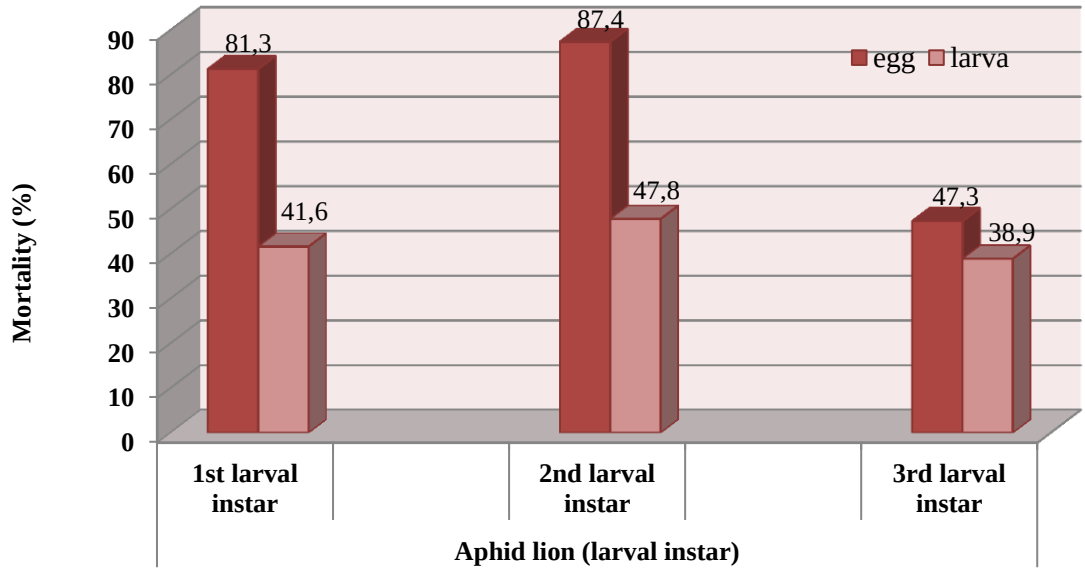

Fig. (4): Predation percentages of *c. carnea* larval instars against *Z. pyrina* stages

On the other hand, releases of aphid-lion larvae against immature stages of leopard moth resulted in high mortality levels for *Z. pyrina* stages. The 2nd larval instar of *C. carnea* revealed the highest predation rates against this borer stages recording 87.4 and 47.8% mortalities for its eggs and larvae, respectively.

Conclusion

Obtained results confirmed the presence of the two biocontrol agents*; C. carnea and M. anisopliae* naturally attacking *Z. pyrina* and *R. ferrugineus*, respectively. Furthermore, laboratory screening tests showed the possibility to use these biocontrol agents to reduce the infestation levels with those borers encouraging further field trials to assess the ability of these bio-agents to control both *Z. pyrina* and *R. ferrugineus* as host target borers.

SURVEY ON DISEASES AND PESTS ATTACK QUINOA IN EGYPT

Tawfik H. ABD EL MOITY[1]*, Haitham B.M. BADRAWY[2], Ayat M. ALI[1]

[1]Central lab. Of organic Agriculture, Agricultural Research Center, Giza, Egypt
[2]Entomology Department, Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt
*Corresponding author: tawfikabdelmoity@yahoo.com

Abstract

Quinoa, was introduced to Egypt through the few past years. According to available-data, no complete survey on pests and diseases attack quinoa in Egypt is available. The present work was designed to detect and identify diseases, and insects attack quinoa in five different Egyptian governorates (Giza, Fayium, Ismailia, Beheira and Monufia). Detection was carried out by examine different location, every 15 day and determine occurrence of diseases or pests. Data obtained showed that in all previously mentioned governorates, *Rhizoctonia solani* and *Macrophomena phaseolina* appeared as aggressive causal organism for root rot and damping off disease for young quinoa seedling. *Fusarium solani* was isolated only from samples were collected from Giza location. *Peronospora farinosa* f.sp. *chenopodii* was detected in all locations. This disease appeared during vegetative growth stage and before flowering or just after flowering. Insects survey was also carried out. Attacked plants were collected and transferred in ice box to laboratory for further identification. Data obtained showed that two aphid species (*Myzus persicae* and *Aphis gossypii*, Hemiptera) were detected in all location. Two pests belong also to order Hemiptera were detected in Ismailia governorate during vegetative growth and flowering stages. These two pests were identified as (*Nysius cymoids*) whereas the other was (*Creontiades pallidus*). Another Hemiptera pest, Cotton mealy bug (*Phenacoccus solenopsis*) was detected only in Giza on individual plants at seed formation stage. Only, in Faiyum governorate, a weevil belongs to Coleoptera (*Sitophilus granaries*) was detected during late flowering and grain formation stages (April- May), on few individual plants. A shoots feeder belongs to Diptera, *Atherigona theodori* was found in Ismailia and Faiyum. This pest penetrate plant stem and feed on inner stem content eventually causing wilt and collapse for infected plants. This pest was recorded on few individual plants. *Tuta absoluta* (Lepidoptera) was also detected in Giza, Faiyum and Ismailia. It attacks fresh green leaves. Cotton leaf worm (*Spodoptera exigua*) was detected in Faiyum on very few plants during early stages of growth (October).

Keywords: *Quinoa – Egypt – pest – disease*

Introduction

Quinoa (*Chenopodium quinoa* Willd., Caryophyllales, Amaranthaceae) is considered as a very important grain crop for the Andean region of Latin America. It was domesticated 3000 – 4000 years ago for human consumption (Shukla and Ohri, 2006). Quinoa has a high nutritive value because its grains contain high protein quality and quantity as well, all essential amino acids and trace elements and vitamins. Quinoa has the ability to adapt to different ecological environments and climates (Rasmussen *et al*., 2003 ; El- Assiuty *et al*., 2014). Plants can be grown under poor, saline soils conditions. For all these advantages quinoa can be considered as the most promising crop especially in poor new reclaimed rural area. According to (Danielsen *et al*., 2003) quinoa is more susceptible to soil borne pathogens in comparison with other species belong to the same family. Quinoa is attacked by several pests and diseases in many south American countries (from Colombia in the north through Ecuador, Peru and Bolivia to Chile in the south). These pests and diseases attack all plant parts during all stages of growth (Drimalkova and Veverka, 2004).

The aim of the present study is to survey pest and disease that may attack quinoa in different Egyptian governorates. These studies will offer a map and data regarding distribution of disease and pest attack quinoa. High authority and decision maker can use these data to build up their decision or plans on scientific base and also prepare the suitable mean to control each pest and disease.

Materials and Methods

Commercial Quinoa seeds were used in this study. Quinoa seeds were planted in five different governorates, to study disease and pest that can attack this crop at different climatic conditions, different type of soil, and at different degrees of salinity (280 – 1800 ppm) in irrigation water. These five governorates were (Giza, Fayium, Ismailia, Beheira and Monufia).

Quinoa seeds were sowed during last week of September in rows 70 cm apart. Five to ten seeds were planted in holes distanced at 25 cm. All plants received fertilizers at the rate of 90: 40: 100 N: P: K in addition to two sprays with calcium chloride and two sprays with trace elements (Fe – Zn –Mn and Mo). Different locations were examined every 15 day to detect diseases and pests presence. Suspicious samples that showed presence of disease symptoms or insects attack were collected and transferred to laboratory for further analysis. All pathogenic fungi were identified at the central laboratory of organic agriculture. Isolated, purified fungi or fresh plant materials with symptoms of downy mildew were used to identify different pathogens according to their morphological characteristics .*Rhizoctonia solani* was identified according to key developed by **Sneh *et al*. (1992);** *Fusarium* spp. according to **Booth (1971)**; *Macrophomina phaseolina* according to **Ellis (1976)**; *Peronospora farinosa* was identified according to **Choi *et al*. (2010)**. Samples of quinoa attacked by insects were transferred in ice boxes to laboratory. All plants attacked with registered larval presence were kept in separate jars with pieces of quinoa plants under room temperature to allow larvae to complete life cycle in laboratory conditions. Larvae, pupae and adults were sent to the museum of Entomology Department, Faculty of Science, Ain Shams University for identification.

Results and Discussion

The selected five governorates were chosen to represent different type of soils, water salinity and weather conditions. In Giza, soil belongs to clay type with high water holding capacity, flood irrigation system with Nile water (280 – 350 ppm), while the weather is almost dry warm. Faiyum is located about 100 km to south west from Giza with light clay soil and moderate water holding capacity. Salinity of irrigation water is (about 350 ppm). Beheira governorate about 230 km northern from Giza. The selected farm in this governorate has sandy soil with low degree of water holding capacity. Drip irrigation system with slight saline water (700-1000 ppm), wet cold weather. The governorate Monufia is located in the delta of Nile river about 120 km north of Giza. The soil is clay with high water holding capacity the weather is wet and cold, flood irrigation using Nile water (280-350 ppm).The governorate Ismailia is located about 130 km eastern from Giza with sandy soil, low water holding capacity, drip irrigation system, saline water (1200–1800ppm) and warm wet weather. Samples were collected periodically every 15 days. Quinoa plants were examined visually using binocular or light microscope to identify the causal organism. Pure samples from isolated pathogens or fresh leaves show identical symptoms (for obligate pathogen) were examined and systematically identified according to approved identification keys. Data obtained in this survey are illustrated in Table (1), Table (2) and Fig1.

Data in Table (1) show that *R. solani* and *M. phaseolina* appeared as a very aggressive pathogens and cause damping off on new sprout. To avoid these diseases quinoa seeds must

be treated with seed disinfectant prior sawing in soil. This disinfectant may be biocide (**Abd El-Moity, 1985**) or chemical preparation (**Anonymous, 2011**). Downey mildew also appeared as a sever disease for quinoa. Copper preparation can be used before flowering stage to protect quinoa against this disease (**Chaudhry *et al.*, 2009**).

Data in Table (2) indicate that Aphids, *Tuta absoluta* and cotton leaf worm can attack quinoa causing considerable loses. These pests can be monitoring by adhesive yellow sheets or pheromone traps and controlled with suitable means either chemical or biological means according to (Approved recommendation for agriculture pest control, **Anonymous, 2011**).

Some pests appeared only on very few individual plants. Such as, shoots feeder and cotton mealy bug. These insects must be monitoring using suitable traps , avoid repeating quinoa or wheat cultivation in the same field for two successive years to reduce pest problem and to prevent spread of these pests.

Table 1: Pathogens detected on quinoa in Egypt.

pathogens	**Location / period of occurrence**	**Host range**	**Infected parts of the host plant and type of damage**
Soil borne pathogens			
Ceratobasidiales Ceratobasidiaceae) *Thanatephorus cucumeris* (teleomorph) *Rhizoctonia solani* (anamorph)	Giza, Fayium, Beheira, Ismailia Monufia/ Seedling stage Wide spread with serious damage	*R. solani* causes root rot and damping –off for quinoa and many commercially cultivated crops and causes significant damage for seeds and yield.	Young sprout are attacked followed by pre-emergence damping off or mature seedling are attacked with post-emergence damping off. In old plant, brown lesion on the main root and discoloration in hair roots are detected leading to reduction in yield (Manici *et al*., 2005).
pathogens	**Location / period of occurrence**	**Host range**	**Infected parts of the host plant and type of damage**

Botryosphaeriales Botryosphaeriaceae *Macrophomena phaseolina*	Giza, Fayium, Beheira, Ismailia Monufia/ Seedling stage Wide spread with serious damage	*M. phaseolina* attacks many hosts include: peanut, Cabbage, pepper, chick pea, strawberry, soybean, sunflower, sesame, potato, sorghum, corn. and quinoa as detected	Attacks roots and causes charcoal rot. Reducing root system capacity consequently reduce yield. (Zveibil and Freeman, 2005)
Hypocreales **nectriaceae** *Fusarium solani*	Giza Seedling stage In few plants	*F. solani* cause root rot for many hosts include potato, bean, cucurbits and quinoa as detected.	Attacks all plant parts in the soil. At early stage causes damping off, while in older plants discoloration and root rot. This attack reduces yield quality and quantity. (Booth,1971)
Downy mildew			
Peronosporales Peronosporaceae *Peronospora farinosa*	Giza, Fayium, Ismailia, Beheira, Monufia/ before flowering Wide spread with serious damage	Obligate parasite, on many Chenopodiaceous family host plants, (ex: sugar beet, quinoa and spinach).	Attack plants through stomata, mainly lower surfaces, it can severely reduce the growth of plants and yield under favorable conditions. (Choi *et al*., 2010)

Table 2: Insects detected on quinoa in Egypt.

No	Insects	Location / period of occurrence	Host range	Infested part of the host plant and type of damage
1-	Hemiptera Miridae *Creontiades pallidus* (green mired)	Ismailia Blooming stage	Cotton, Clover, Alfalfa, Corn, Grasses and sorghum. (Buyckx 1962)	It damages many types of field crops. Nymphs and adults both feed on young bolls or head of sorghum or on quinoa as detected in this work. (Wheeler 2001)
No	**Insects**	**Location / period of**	**Host range**	**Infested part of the host plant and type of damage**

		occurrence		
2-	Hemiptera Lygaeidae *Nysius cymoides*	Ismailia / Blooming stage	Cruciferous crops, Jojoba, Canola, Tobacco, Grape. (Gentry 1965)	It causes damaging to seed pods of crucifers or head of quinoa as detected. (Beardsley 1971, Parenzan 1985)
3-	Hemiptera Sternorrhyncha *Pseudococcidae –Phenacoccus solenopsis* (cotton mealy bug)	Giza/ Harvest time	This bug attacks numerous crops, weeds, ornamentals and medicinal plants. Cotton is one of its most favored hosts, (Ibrahim *et al.* 2015)	Larvae leaves of the plant turns yellow and becoming crinkled or malformed. It infests the leaves, fruit, branches, main stems, feeding on phloem sap and egesting copious, sugary honeydew. (Dutt 2007, Hodgson *et al.* 2008)
4-	Hemiptera Aphididae *Aphis gossypii* *Myzus persicae-*	Giza, Fayium, Beheira, Ismailia Monufia/ All growth stage	polyphagous (Abou-Elhagag 1998, Capinera 2001) -highly polyphagous (Blackman and Eastop 1984).	Aphids suck nutrients from the plant. Their feeding causes a great deal of distortion and leaf curling, hindering photosynthetic capacity of the plant. (Abou- Elhagag 1998, Margaritopoulos *et al*. 2006) It can attain very high densities on young plant tissue, causing water stress, and reduced growth rate of the plant. It can cause appreciable reduction in yield of root crops and foliage crop. (van Emden *et al*., 1969)
5- **No**	Coleoptera Curculionidae Dryophthorinae *Sitophilus granaries* (wheat weevil or grain weevil) **Insects**	Fayium/ Seed formation **Location / period of occurrence**	Wheat, Barley, Maize, Sorghum, Oats, Rice(Alfieri 1976, Trematerra *et al.* 1999), and quinoa as detected. **Host range**	Weevils (Larva as well as the adult) causing destruction of grains and reduce yield quality and quantity. The developmental stages of *S. granarius* are not normally seen as they occur inside intact grains. Adult emergence holes with irregular edges are apparent some weeks after initial **Infested part of the host plant and type of damage**

.				
				attack. Adults can be found wandering over the surface of grain especially if the grain has been disturbed. (Longstaff 1981)
6-	Diptera Muscidae *Atherigona theodori*	Ismailia, Fayium/ Harvest time	Sorghum, Maize, Wheat, Rice, Sugarcane, Alfalfa. (Deeming 1971, Reddy e*t al.* 1981, Pont and Deeming 2001), and quinoa as detected	The larvae cut the growing point, resulting in wilting and drying of the infected plants and produce a bad smell. (Pont and Magpayo, 1995)
7-	Lepidoptera Gelechiidae *Tuta absoluta*	Giza, Fayium, Ismailia/ All growth stage	Tomato, Potato, Eggplant, Tobacco. (El-Arnaouty and Kortam, 2012), and quinoa as detected	The larva feeds voraciously upon tomato plants, producing large galleries in leaves, burrowing in stalks, and consuming apical buds and green and ripe fruits. It is capable of causing a yield loss of 100%. (Desneux 2010)
8-	Lepidoptera Noctuidae *Spodoptera exigua*	Fayium / seedling stage	The wide host range of beans, corn, peas, sugar beets, celery, lettuce, potato, tomato, cotton, cereals, oilseeds and many flowers. (Wilkerson *et al.* 2005, Robinson *et al.* 2010), quinoa also consider as a host as detected.	The larvae feed on the foliage of plants, and can completely defoliate small ones. Smaller larvae devour the parenchyma of leaves, so that all that remains is the thin epidermis and veins. Larger larvae tend to burrow holes through thick areas of plants. (Tingle and Mitchell 1977)

Conclusion

According to results obtained from this study it can be concluded that quinoa plants can be successfully cultivated with considerable yield at different degrees of water salinity till 1800 ppm. It can also be grown under wet or dry weather and in sandy or clay soil. Variation in yield due to these factors needs another study to exactly determine variation in yield. Our results also showed that quinoa is attacked by numerous pests and diseases. The most destructive disease is root rot and damping off caused by *R. solani* and *M. phaseolina.* Data also show that quinoa plants are susceptible to downy mildew. Aphids, *Tuta absoluta* and cotton leaf worm can attack quinoa plants and cause considerable damage for yield. Some

other pests were appeared only on few individuals plants such as shoots feeder and Cotton mealy bug. Special studies will carry out to exactly determine losses can be occurred due to these diseases and pests.

Abstract

Bacterial canker caused by *Pseudomonas syringae* pv. *actinidiae* (PSA) is affecting kiwifruit cultivation worldwide. In infected orchards the removal of diseased vegetation is essential for control. The bacterium can survive on woody residues becoming a source of inoculum for subsequent infections. Open burning of prunings is a common orchard management practice, shredding of residues is a feasible alternative but disease issues in kiwifruit would require actions to disinfect them first. In this context an innovative flame treatment prototype was recently developed for processing the prunings directly in the aisle. The tractor drawn prototype has two main parts: a shredding unit and a heating unit. The horizontal flail blade rotor shreds the prunings, the thin layer of wood chips flow into the heating unit, where LPG burners produce a turbulent flux of hot gasses increasing the temperature of residues for sterilization. Preliminary field tests were conducted to assess treatment effectiveness in relation to thermal dose, treatment speed and mass of residues per unit area. Forward speeds compared were 700 and 1400 m/h, resulting in an exposure time to the flame of 4 and 2 seconds, respectively. Treatment effectiveness was assessed through biological assays on treated and untreated samples taken from infected vines. Flame treatment disinfected the treated samples, but the bacterium was isolated from the untreated samples and PSA identity was verified via PCR analysis. Hourly working capacity and fuel consumption were estimated for both forward speeds. The machine is especially intended for organic farming systems.

Keywords: *flame, LPG, disinfection, prunings, PSA bacterial canker*

Introduction

Bacterial canker caused by *Pseudomonas syringae* pv. *actinidiae* (PSA) has spread to all major kiwifruit growing regions and is endangering kiwifruit crops worldwide (Vanneste et al., 2011). Since 2008, the emergence of a severe epidemic in Italy was caused by a highly virulent strain. (Ferrante et al., 2010). The outbreak has caused important economic loss in Italy and a decline in cultivated surfaces, after the removal of devastated orchards and a stop in new plantings.

Control of bacterial canker has required the adoption of extraordinary protection measures, causing an increase in production costs. All cultivated varieties (*Actinidia deliciosa* and *A. chinensis*) are affected by PSA and curative treatments for bacterial canker do not exist (EPPO, 2012). Conventional control strategies, based on use of existing chemicals, are successful to some extent against PSA. Phytotoxicity, resistance development and regulatory measures restrict the use of copper compounds and antibiotics, which are the key chemicals used to fight bacterial plant diseases. (Cameron et al., 2014).

Synergy between different crop protection strategies is necessary. Additional phytosanitary measures for prevention and containment are essential to fight the spread of PSA. Prevention requires continuous inspection of the fields for early detection of symptoms and early diagnosis of diseased plants. Containment is achieved by eliminating infected plants or plant

parts to reduce field inoculum. The timely removal of prunings from the field can also be effective for sanitization purposes, since it has been proven that PSA can survive on residues for some time (up to 45 days), and therefore those left lying on the orchard floor represent a further source of inoculum for subsequent infections in the orchard (Scortichini, 2012). Kiwifruit plants have a very exuberant vegetative growth, therefore winter vine pruning drops a great amount of wood residues, up to 10 t ha^{-1} (fresh weight) on the orchard floor (Nati et al., 2011). Infected fields benefit from more intensive pruning to remove older vines (2 to 4 years of age), in these plant structures the bacterium lives endophitically. Reducing the amount of permanent wood improves disease containment (Mazzaglia et al., 2011). Summer pruning is carried out on a monthly basis to shorten new shoots and replacement canes, starting a couple of weeks before blossom time. Herbaceous residues from infected plants may also be a source of inoculum. The open burning of prunings is a common practice in orchard management for disposing of residues and burning is nowadays the main destination of kiwifruit prunings. The application of fire, also referred to as 'thermal sanitation', is helpful in reducing the incidence of plant pathogens (Desilets, 1997). Burning of overwintering inoculum on fallen leaves reduces apple scab (*Venturia inaequalis*). Control of dieback (*Diaporthe vaccinii*) and canker (*Godronia cassandrae*) in blueberries was tested through burning of crop residues (Hardison, 1976). Open burning at the orchard site doesn't require a specific mechanization, for this reason it is often preferred as an effective solution, although handling of residues requires high working time and high costs. Furthermore some twigs escape collection and remain on the orchard floor, carrying inoculum. There are additional options for handling prunings that are intended for biomass valorization. For example kiwifruit prunings are often shredded directly in the field, leaving the residues in place to return organic matter to soil. The recovery of biomass for use in energy generation or for composting is another alternative, adding value to residues. Although shredding is technologically feasible, when cleaning up the orchard floor in infected kiwifruit orchards disease issues are a concern and the phytosanitary legislation in force prohibits mulching and transportation of infected material to other sites. Farmers must therefore consider the adoption of additional measures to disinfect the residues before shredding, in order to avoid the spread of inoculum in the field. In this context, 'OFFICINE MINGOZZI', a company specialized in the construction of flame weeding equipment and machines for horticulture, has developed an innovative technology to process kiwifruit prunings directly in the aisle. (Tomasone et al., 2014). The heat treatment is intended to reduce field inoculum, so that the shredded material can be safely released on the ground. The same technique is also proposed for removing the inoculum carried on fallen leaves and residues produced after summer pruning operations.

The aim of the present paper has been to determine the effectiveness of the flame technique in achieving a reduction of the inoculum, performing the treatment on naturally infected vines, pruned from diseased plants and treated by shredding and heating in a field trial. The experiments also were intended to establish the choice of operating parameters in field treatments, in relation to the amount of residue to treat, to the speed of the tractor assembly and to the arrangement of materials on the ground, determining the dose of gas per surface unit in the orchard.

Materials and methods

The machine was designed to perform two operations in a single-step, i.e. to shred all the residues and simultaneously to heat them via LPG flaming. By design, the tractor-mounted prototype was limited in size and weight, and made suitable for use with compact power class tractors, the most common in orchards. The two main components in the assembly are the shredding unit and the heating unit (Figure 1). The tractor, moving along the row, picks up the pruning residues, which are immediately shredded by the front flail rotor, producing a thin

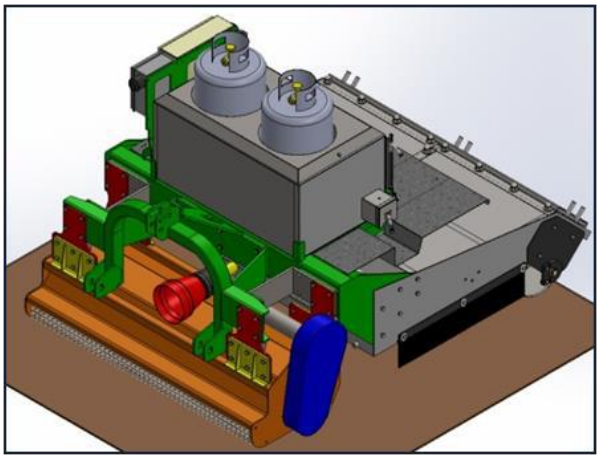

Figure 1: CAD images of the combined assembly

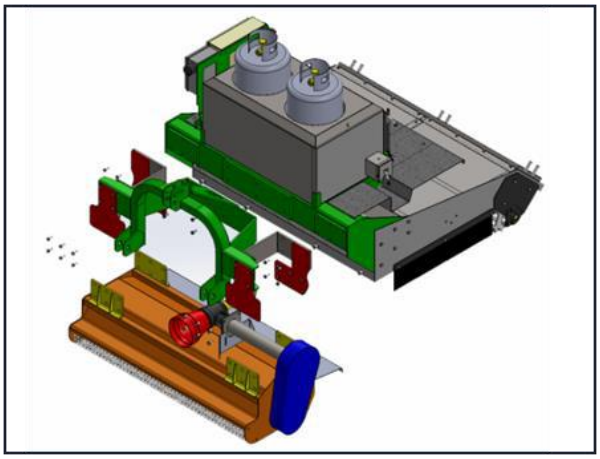

Figure 2: CAD schematic of the bolted linkage

layer of wood cuttings delivered rearward into the heating unit, amongst the open flames. The horizontal flail rotor, perpendicular to the row, carries a series of standard "Y" shaped flail knives, attached to the rotating shaft by means of brackets. In total 56 flail blades are arranged on 8 staggered rows, providing an effective cut. The PTO drive is set at standard 540 rpm speed. Front and rear rollers are included to maintain the correct work height as the machine moves over the ground. The unit is provided with a structural frame for attachment to the tractor's three-point hitch and for the connection with the heating unit placed behind. Dimensions of the shredding apparatus are 1500 x 960 x 855 mm (Length x Width x Height) weighing 260 kg, cutting width is 1400 mm and range of power requirement is 26-30 kW.

The heating unit is connected to the flail shredder by means of bolted metal plates. The two units are easily disconnected for separate use, either mowing and shredding or broadcast surface flaming, respectively (Figure 2). Two LPG steel cylinders (25 kg capacity each) are carried in a tank filled with warm water: the water bath supplies the thermal energy required as latent heat for the vaporization of LPG from liquid to gas, when gaseous LPG is drawn at high flow rates, maintaining constant pressure and constant flow rate to the burner's nozzle.

The heart of the unit is the hot chamber: it is closed above by an insulated stainless steel hood, it is connected in the front to the flail shredder, on each side metal chain curtains close the gap between frame and soil, in the rear a cage roller acts as the chimney to extract the hot exhaust fumes. The flames are fired by an array of 8 burners, aligned across in a single row, evenly spaced from side to side (Figure 3).

Figure 3: intensive flames under the heat chamber

Figure 4: field treatment of prunings along the row

The gaseous fuel burner used on the machine is of the premixed type, in which the gas and air are mixed before passing through the nozzle. The stability of fuel combustion was checked, reducing the negative effect of the air turbulence produced by the rotating flails and by the mass of cuttings flowing into the combustion chamber. The burners were studied to give a stable flame, burning gas efficiently and producing a powerful turbulent flux of hot gasses, maintaining a high temperature inside the chamber, constantly above 650 °C.

The operative parameters used for the field trials were as indicated: gas flow rate was set at 3.0 kg h^{-1} per torch at an average gas pressure of 0.14 MPa, for a nominal thermal power of about 38 kW per burner; the resulting total hourly gas consumption is about 24.0 kg h^{-1}, for an overall power of about 304 kW. The flaming unit is operated by the driver directly from the tractor's cabin by means of an electronic connection box having a magnetic base, placed in the cabin for remote operation.

Field trials

Field tests were conducted with the innovative prototype in order to assess bactericidal effectiveness of the treatments carried out on naturally infected pruning material, in relation to the thermal dose and to flame exposure time. The prunings were collected in an infected kiwifruit orchard and were arranged in windrows at the centre of the aisle (4.5 m row spacing) in order to complete the treatment through a single pass along the row (Figure 4). The symptoms of the disease were assessed visually on some vines taken from infected trees. Symptoms were identified on the vines as red spots beneath the lenticels, also brown streaks in the subcortical tissues when the bark is peeled from the infected vine (Figure 5). These infected vines were marked with spray-paint and placed in the windrows along with the other prunings. Following the heat treatment the vines are shredded and samples of these coloured cuttings were collected to be used for the microbiological analysis in the laboratory. Prior to the treatment, control samples were also taken from these coloured vines to be used as the untreated control, for the comparison of the bacterial load carried by the residues before and after the heat treatment.

The prunings were treated with the innovative machine making a single pass over each row, simultaneously shredding and heating the prunings for disinfection. The thermal power employed in field operations was fixed by setting the gas pressure gauge at a constant 0.14 MPa. The thermal dose is thus derived as a function of both treatment speed and mass of residues per unit area. Two forward speeds were compared in the tests: a slow 750 m/h forward speed and a fast 1500 m/h, the latter being a drive speed that is common for ordinary vine shredding operations. The amount of pruning residues present on the orchard floor was measured by sampling segments of known length along the windrow and weighing the mass of the sample. The time required by the heat chamber to move over the material deposited on the ground is easily calculated for each of the two speeds. The heat chamber is 1.25 m in length and so the material on the ground is under the effect of the flames for a time of exposure corresponding to 6 and 3 seconds, for the slow and fast work speed, respectively (Figure 6).

These two plots have been referred to as the long and the short treatment time. Microbial assays were carried out to verify the effectiveness of the disinfection of the treated samples, compared to the control samples (not treated) taken ahead of treatment from the same infected vines. In the laboratory, using aseptic technique, portions of tissue were taken from the samples and put into a sterile saline solution, held in oscillation for 45 min so that all the microorganisms could move to the liquid medium. Next, aliquots (100 uL) of the solution were taken to be transferred into test tubes containing nutrient broth for liquid culture.

The tubes were incubated at 25 °C for 24 h and subsequently bacterial growth was assessed by analyzing the turbidity of the broth. Isolation of bacteria was later done in Petri dishes with solid substrate NSA, streaking tenfold dilutions for the isolation of colonies. The following

step for the identification of PSA was performed by molecular analysis, via duplex-PCR according to the diagnostic protocol described by Gallelli et al. (2011).

Figure 5: symptoms on vines, spots and streaks

Figure 6: heat chamber seen from underneath

Results and discussion

The microbial culture in liquid broth established the absence of microbial growth for all the samples collected from the flame treated residues, for both the 750 and the 1500 m/h treatment speeds. Instead the assays with the untreated control samples have seen the liquid broth turn opaque after 24h of incubation, meaning that PSA was indeed present on the symptomatic vines taken from the infected plants. The bacteria isolated from the control samples was identified as PSA bacterium by molecular analysis.

For the given amount of residues in the row, a good efficacy of disinfection was reached already with the slow 3 seconds treatment time. In the specific situation of the field trials conducted, the total mass of pruning residues present on the ground weighed on average 5.5 t ha^{-1} in fresh weight. This quantity is about half the amount of total residues that can be produced annually by pruning in winter a kiwifruit orchard in full production, having a ordinary tree density of about 550-620 plants per hectare. In the case of more intensive winter pruning and thus more residues on the ground, the same ratio of thermal dose per unit mass of residue can be achieved by reducing the speed of the treatment appropriately.

Table 1: Operative parameters in field trials

Plot	measure unit	slow speed plot	fast speed plot
treatment speed	(m h^{-1})	750	1500
heat exposure time	(s)	6	3
hourly work capacity	(ha h^{-1})	0.3375	0.6750
work time	(h^{-1} ha)	2.96	1.48
LPG consumption	(kg ha^{-1})	71	35
cost for LPG (current prices)	(€ ha^{-1})	124	62

The operative results achieved by the machinery in the tests conducted are shown in Table 1. The hourly working capacity and the consumption of LPG fuel are acceptable when treating at 1500 m/h. The slow speed tested might be necessary for greater quantities of residues to be reclaimed in the orchard, but in that case the feasibility of the treatment from an economic point of view needs to be further considered.

Conclusions

The field tests have shown so far very good results, but further tests are needed to define the parameters when treating different quantities of residues, for establishing the consumption of

LPG fuel and all the costs associated with the treatment. This machine may be used both in conventional and organic farming because the LPG is allowed by relative crop regulations. The heat treatment could give a hand towards reducing the chemical sprayings in the orchard. Following disinfection, the organic material provided by prunings could be safely shredded in place in the orchard, accumulating organic material on the orchard floor that will definitely contribute to the content of soil organic matter and to soil fertility, otherwise all the residues should be removed and burned outside of the orchard. The treatment could be proposed for a more general application regarding other fruit species, intended furthermore to achieve the remediation of the orchard site after winter pruning, disinfecting the residues.

Abstract

Currently, many pathogens are at the origin of disease and considerable economic losses. By secretion of highly toxic substances, the toxigenic fungi are a real danger to human and animal health.

The *Penicillium genus* is considered as especially useful fungi in the food and pharmaceutical industry. However, some studies have shown that they secrete certain mycotoxins. This toxicity may appear even for useful species, in cases when some physicochemical or trophic factors are changed. *Penicillium aurantiogriseum* (known by its lipase activity) is a species that frequently contaminates olives and other foodstuffs namely the cereals and derivatives. Because its mycotoxins that produces, *Penicillium aurantiogriseum* is used in food and pharmaceutical industry.

The strain used in this study was identified as *P. aurantiogriseum* based on morphological basis according to Pitt's key of determination. Also, its toxic profile was determined by thin layer chromatography.

The analysis of the metabolic profile revealed three mycotoxins in *P. aurantiogriseum* (terrestric acid, penicillic acid and aurantiamin). The nature and amount of thoses toxins were tightly related to the nature and concentration of carbon source in the artificial rearing medium of *P. aurantiogriseum*. The highest productivity of terrestric acid was obtained on Yeast Extract Sucrose broth and the production of this toxin increased with sucrose concentration in this medium. Penicillic acid was produced in different media (CYA, YES and MB) while the best medium for aurantiamin excretion was glucose-free Medium Base.

Keywords: *Penicillium aurantiogriseum; mycotoxins; thin layer chromatography; carbon sources.*

Introduction

Genus of Penicillium has long been used in food and pharmaceutical industry. However, some species are toxinogenic and, thus, could be very harmful to human health.

Numerous studies have reported that some mycotoxins can be secreted by a huge number of *Penicillium* species **(Lu et al. 1994)** including those used in food processing and pharmaceutical industry, whenever favorable physicochemical and trophic conditions are present.

Penicillium fungi contaminate food during storage. *P. aurantiogriseum* that is frequently isolated from food **(Borjesson,L, Stollman, and Schnurer, 1990; Khaddor et al. 2007; Maouni et al. 2001)** secrets three mycotoxins: terrestric acid, penicillic acid and aurantiamin. On the other hand, it was also found that aurantiamin has an antibacterial effect against *Bacillus subtilis* **(Khaddor et al. 2007)**. Moreover,due to its chemical structure which is similar to phenylahistinand registered activity against tumor cell lines, aurantiamin is considered as a potential substituent to colchicin **(Boulikas and Tsogas 2008)**.

The aim of this work is to study the effects of different culture media compositions on toxinogenesis of *P. aurantiogriseum*, particularly the influence of glucose and sucrose used at different concentrations.

Materials and methods

The *Penicillium* aurantiogriseum strain

The *P. aurantiogriseum* strain used in this study belongs to the collection of EFBRT (Environmental and Food Biotechnology Research Team).
The strain was first cultivated on MEA (Malt Extract Agar) at 25 ° C for 7 days, and the spores were suspended in 0,1 % of tween 80. The density of the suspension was adjusted to 10^7 spores / ml.
Purification was then made on three different media MEA, CYA (Czapeck Yeast Extract Agar) and G25N (Glycerol 25% Nitrate Agar) (table 1). The identification was realiseed according to the determination key of Pitt **(Pitt 1988)**.

Culture conditions

The media used for toxinegesis study were YES (Yeast Extract Sucrose), BM (Base Medium) and G25N. The composition of all media is given in Table 1.
For this study 25 ml of YES and MB liquid media, with different concentration in sucrose or glucose were distributed in 100 ml Erlenmeyer flasks and inoculated with 2ml of spore suspension. All cultures were incubated for 10 days at 25 °C.

Table 1. Media used in this study and the concentrations of glucose and sucrose tested

Basic medium			Carbon source	
Name	Composition	Reference	Nature	Quantities added (g/l)
Media of reactivation and purification of *Penicillium aurantiogriseum*				
CYA (Czapeck Yeast Extract Agar)	Czapeck concentré : (10ml) ; K_2HPO_4 : 1 g ; Yeast extract : 5g ; Sucrose : 30g ; Agar : 15 g ; Distilled water:1000ml.	(Pitt 1988)	Sucrose	
MEA (Malt Extract Agar)	Malt extract agar : 30 g Glucose : 20 g Agar : 10 g ; Distilled water:1000ml	(Pitt 1988)	Glucose	
G25N (Glycerol 25% Nitrate Agar)	Concentrated Czapeck* : 7.5 ml ; K2HPO4 : 0.75g ; Yeast Extract : 3.7g ; Glycerol : 250g ; Agar : 12g ; Distilled water : 750 ml	(Pitt 1988)	Glycerol	
Media inducing toxinogenesis of *Penicillium aurantiogriseum*				
YES (Yeast Extract Sucrose Broth)	Yeast Extract : 20g ; Sucrose : 100g ; Distilled water : 1l	(B. Botton 1990)	Sucrose	0; 100 ; 200 ; 300

BM (Base Medium)	Malt Extract : 130g ; Agar : 15g ; Distilled water : 1l	(Pitt 1988)	Glucose	0; 100 ; 200 ; 300
*Concentrated Czapeck: $NaNO_3$: 30g ; KCl : 5g ; $MgSO_4$:5g ; $FeSO_4$: 0,1g ; $ZnSO_4$: 0,1g ; $CuSO_4$: 0,05g ; Distilled water : 100 ml.				

Research of the Mycotoxins

The study of toxinogenesis was made according to the method reported by Khaddor **(Khaddor et al. 2007)**. The chromatography technique of thin layer which was adopted in this study is described by Mills **(Mills et al. 1995)**. The TLC plates used are 60 Kieselguhr F_{254}, mycotoxins standards used by the reference of migration forehead (Rf) were patulin, citrinin, ochratoxin A, penicillic acid and grisefulvin. 10 ml each of ethanol extract and 10 ml of standard solutions (1 mg / ml) were spotted on TLC plates. Elution systems used are: toluene - ethyl acetate - formic acid (5/4/1, v / v / v) and chloroform - acetone - 2-propanol (85/15/20, v / v / v). The plates were examined in daylight and by ultraviolet 365 and 254 nm after spraying the spots by ANIS: 0.5% (v / v) of p-anisaldehyde solution in absolute ethanol – cold acetic acid and concentrated sulfuric acid (17/2/1, v / v / v), 8 min heating to 120 ° C. Some toxins react specifically with ANIS at this temperature, leading to characteristic colors under daylight, namely blue lilac for penicillic acid, yellow for terrestrique acid and gray for aurantiamine.

Results and discussion

Purification and identification of the *Penicillium aurantiogriseum* strain

The purified strain of *P. aurantiogriseum* had the morphological characters summarized in Table2.

Table 2. The morphological characters of the *P. aurantiogriseum*strain

Colony on CYA (25°C)	30-37 mm diam, radially silcate, moderately deep, texture granular ; reverse pale Reverse colour Yellow
mycelium	white
Pigmentation	soluble, brown.
Exudate	pale brown
Smell	heavy
Conidiophores(on MEA)	borne singly or in fascicles, mostly from subsurface hyphae, smooth to finely roughened bearing terminal terverticillate mostly 7-10 µm long
Metulae	spherical, usually 3 – 4 µm long.
Conidia	blue grey conidia on both CYA and MEA

Mycotoxin Production

The chromatographic analysis of the extracts obtained from different culture media of *P. aurantiogriseum* (YES Broth, YES and MEA agar) allowed highlighting three mycotoxins: penicillic acid, terrestric acid and aurantiamin. These mycotoxins have been reported to be produced by this species in previous works **(Colombo et al. 2003; Frisvad and Samson 2004; Khaddor et al. 2007).**

The effect of culture media on the production of mycotoxins

Results of our study showed a great diversity regarding mycotoxin production by *P. aurantiogriseum* in different culture media (Figure 1). Production of penecillic acid was detected in CYA, BM and YES media, while aurantiamin was produced only in MB medium and terrestric acid in YES Broth. Mills et al **(Mills et al. 1995)** have also found penicillic acid and aurantiamin in CYA. However, they have detected terrestric acid in YES agar. This suggests that the culture medium composition has an influence on *Penicillium* toxinogenesis.Some sugars like glucose which are more favorable for the growth of Penicilliums than others (sucrose and fructose) due to their assimilation which is in agreement with other studies that have shown the effect of culture conditions on the excretion of mycotoxins by some strains of *P. Roqueforti* **(Kristian Fog Nielsen 2002; Piva et al. 1976; Ren, Ahearn, and J 1999)**.

The effect of glucose on the production of mycotoxins

We observed a production of aurantiamin in glucose-free BM medium. This production decreases with the increase of glucose concentration in the medium. On the other hand, penicillic acid production increases according to the concentration of glucose in BM medium (Figure 1) which led to conclusion that aurantiamin production is inhibited by glucose. Similarly, many cases of glucose negative effect in the secondary metabolism have been reported **(Gallo and Katz 1972; Hurley and Bialek 1973; Telma Elita Bertolin et al. 2003)**. For example, glucose has proved to negatively affect Ochratoxin A biosynthesis by suppressing the biosynthetic pathway enzymes **(Muhlencoert et al. 2004)**. It has also been reported that glucose inhibits the production of extracellular enzymes and sporulation **(Shafikhani, Nunez, and Leighton 2003)**. Moreover, the addition of glucose suppresses penicillin production in *P. chrysogenum* **(Sanchez et al. 2010).**Some possible explanation is that glucose excess inhibits the synthesis of extracellular enzymes **(Strauch and Hoch 1993a)**, the expression of the Krebs cycle enzymes **(Fouet, et al. 1990)** and the initiating of sporulation **(Takahashi, and MacKenzie, 1981)**. Furthermore, the glucose inhibitory effect in some microorganisms is due to the acidification resulting from to the accumulation of organic acids such as lactic, acetic, citric and pyruvic acids. The fact that penicillic acid production is not affected by glucose concentration increase in the culture medium is may corroborated by the lack of pH influence on the production of this mycotoxin **(Regassa, Novick, and Betley 1992).**

The effect of sucrose on the production of mycotoxins

We observed terrestric acid production in the YES medium. This production increased proportionally to sucrose concentration in the YES Broth, while it does not occur in YES agar. On the other hand, penicillic acid production is inversely proportional to the concentration of sucrose in YES.

Thus, it seems that terrestric acid production is induced by the sucrose. This corresponds with the results of **(Mills et al. 1995)** who reported that terrestric acid is produced in the YES medium in which sucrose is the only carbon source. In contrast, the production of penicillic acid in the YES has decreased. This could be due to the slower catabolism of sucrose used in YES medium and which is due to the absence of the enzyme invertase into strain compared to the catabolism of glucose which is rapidly hydrolyzed in MB medium. However, neither fructose nor a mixture of glucose and fructose reproduces the stimulating effect of sucrose observed in *Fusarium fujikuroi*, suggesting that the induction signal is the sucrose itself, and not any sucrose derivative metabolite **(Jiao, Kawakami, and Nakajima 2008)**. Similarly, it

has been demonstrated that the production of antibiotics and other secondary metabolites are negatively affected when the carbon source used is rapidly assimilated for growth. However, when the carbon source is slowly introduced into the culture, the secondary metabolite is produced efficiently. Although the regulation of carbon source in the biosynthesis of mycotoxins has been recognized since the 1950s, the mechanisms involved are only known in some cases. For example, in the production of actinomycin, the carbon catabolite repression of an enzyme from secondary metabolism is involved. On the other hand, the production of α-lactams by *Cephalosporium acremonium* seems to be affected by some type of inhibition catabolic **(Aharonowitz and Demain 1978).**

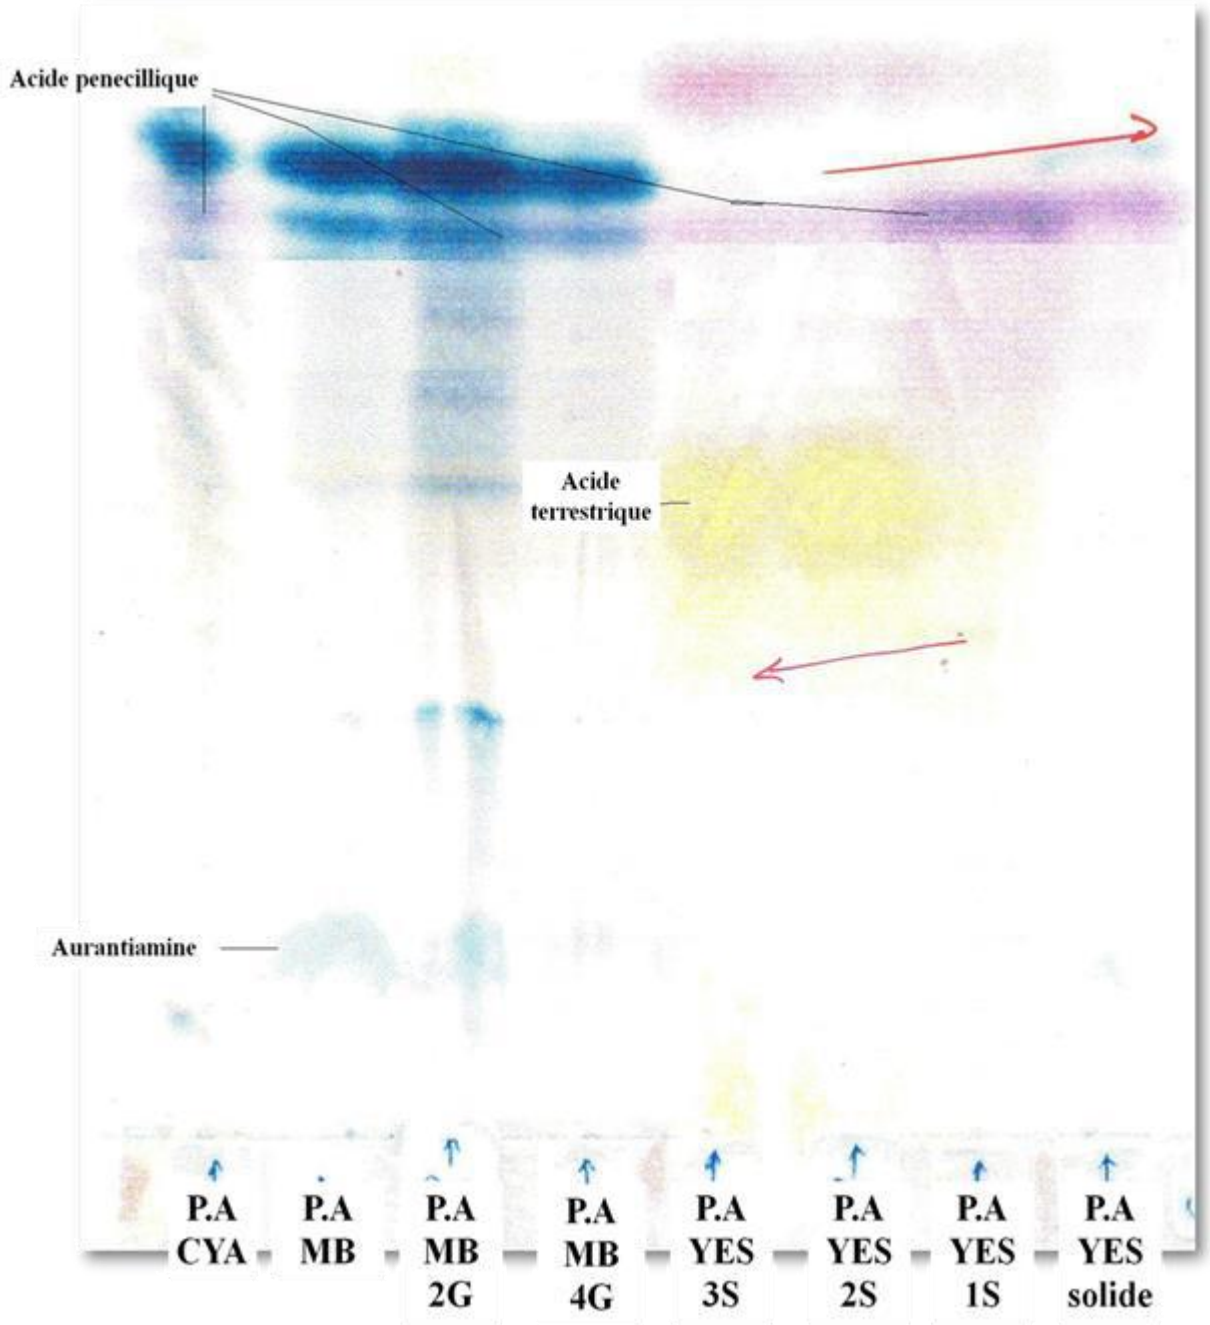

Figure1: mycotoxins on chromatogram *PA* secreted in various culture media and various concentrations of glucose and sucrose (TEF is the migration of solvent)

Conclusions

Several mycotoxins are controlled by carbon sources in culture media. It has been found that the growth of *P. aurantiogriseum* in the medium containing glucose reduced considerably as compared to that observed in the medium containing sucrose **(Oksman et al. 1994).** All this corresponds with our results, where the level of production of metabolites studied in disaccharides was higher than in monosaccharides.

Mycotoxin production by *P. auratiogriseum* is closely dependent on growing conditions. It is difficult to explain metabolically the action of various factors studied.

However, it is interesting to note that factors which could prevent the production of mycotoxins are in the cytoplasm level because all the reactions are reversible. Furthermore, the mycotoxins seem not to be formed if the medium is rich in sugar only, but the production changes with the changes in concentration of the other carbon sources.

Mycotoxin production by *P. aurantiogriseum* also seems to affect the physiological state of its growth and reproduction.

Abstract

Several natural products present in plant extracts have been evaluated for their effectiveness as insecticides. The insecticidal properties of Alliaceae have been reported; among these, Garlic and onion, plants with varied biological properties, which contains benefits molecules responsible for pest potential control of alliaceae. The purpose of this study was to compare the effect of chemical and biopesticide on citrus mites, especially *Tetranychus urticae*, *Panonychus citri* and *Eutetranychus orientalis*. Chemical treatment (Fenazaquin) and biopesticide (Garlic juice+Alcohol) applied on this study to control the various stages of mites, have reduced the proliferation of mobile forms and reducing the number of eggs to acceptable levels. The Fenazaquin product is highly toxic against adults and larvae of mites, but with adverse effects on phytoseiid. Garlic juice + alcohol revealed efficiency from 50 to 57,69% against the mobile forms of *T. urticae*, however, it was effective against the motile forms of *P. citri* and *E. orientalis* with an efficiency of 85,71% and 100% respectively, its action has also reduced the number of eggs of *T. urticae* and *E. orientalis* at low levels. Therefore, this biopesticide is technically and economically conceivable as the infestation by mite is low.

Keywords: *Alliaceae, garlic, mites, Fenazaquin, phytoseiid.*

Introduction

Chemical control, sometimes abusive, and considerable advances in agricultural technology to control pests, contributed, among other things, the destruction of useful auxiliary fauna and outbreaks of new pests which phytophagous mites (Nafide M, 2008). The mixed results are likely due to the fact that studies have been conducted on mites at different levels of exposure to insecticides and therefore different levels of resistance (Ako *and al.*, 2006).

The damage caused by these mites are manifested by premature leaf drop sometimes reaching, in heavy infestations, defoliation of the tree, and therefore, impairment of the quality and quantity losses of production (Vacante, 2010). Lower populations in dry areas, can produce the same effect (CABI et OEPP, 1990).

That is why the search for new organic products as an alternative to harmful chemicals on the auxiliary fauna, could remedy the systematic chemical interventions. In addition, the use of different formulations (e.g. azadirachtin) of these biopesticides can induce delayed effects on spider mites (Mansour *and al.*, 1993)

The insecticidal properties of Alliaceae have been reported; among these, Garlic and onion, plants with varied biological properties, which contains benefits molecules responsible for pest potential control of Alliaceae (Arnault and *al.*, 2005).

This study aims to determine and compare the effect of a chemical and a biopesticide on spider mites on *Citrus*, especially *T. urticae*, *E. orientalis* and *P. citri*.

In order to study the possibility of the feasibility for a future substitution of chemicals with biopesticides which are efficient, and accessible to all citrus growers and not harmful to

beneficial fauna, and also authorized by the set of specifications for organic farming. Therefore, the trial was conducted against spider mites in the Field Gazelle-Delassus in the region of Taroudant (Morocco) to assess the effectiveness of products in different stages of these mites.

Material and methods

1. Plot trial

The trial was conducted on June, 2013 in the S1P3 plot, whose characteristics are presented in the following table:

Table 1 : Characteristics of study plot

Plot	**S1P3**
variety	Nour
area (ha)	1,02
Rootstock	Citrange
Planting year	1994
Number of existing trees	656
irrigation type	Drip

The choice of the plot was based on the rate of infestation was more important compared to the other plots.

2. Tested products

The products used are presented in the table below :

Table 2 : Used products

Specialities	**Active ingredient**	**Formulation**	**Doses**	**Action Type**
PRIDE 200 SC	Fenazaquin	SC	40 cc/hl	Contact
Garlic Juice **+ Alcohol	Sulfur	Liquid	625cc of Garlic Juice+16cc of Alcohol	Contact + inhalation

** : 1L of garlic juice is obtained after maceration of 500 g of garlic in a liter of water.

3. Experimental plan

To perform this test, authors opted for an experimental randomized complete block, consisting of 3 blocks (3 repetitions). Each block is divided into three basic plots. The treatment assignment was made randomly. To avoid the effect of the treatments, the blocks are separated by a passage 4 m, while for basic plots, we opted for a line of trees separating two elementary plots (Figure 1).

Each elementary plot consists of 18 trees, so we treated 72 trees.

The treatments were conducted on June 6 at 7:30 am (this is the week that follows the maximum infestation by mites). In fact, we started with the control treatments (water), then the biopesticide treatment: Garlic Juice**+Alcohol, and chemical treatment: Fenazaquin.

The experimental plan is performed as follows :

: **Trees treated with chemical (Fenazaquin)**

: Trees treated with biopesticide (Garlic juice+Alcohol)

: Control trees (water)

Figure 1 : Experimental plan of test

4. Treatment equipment

Applications made on citrus were applied with a sprayer towed with projected jets, with a 2000L cistern and two spears. Spraying was done with a pressure of 30 bar. The porridge used is 12 liters per tree, allowing the wetting of all the parts of the tree.

5. Sampling technique and notations

Sampling consist to assess the number of living mites on 30 leaves for each treatment. In each elementary plot, a single tree and a number of leaves have were the object of our sampling. The sampling method in each elementary plot is as follows: 6 leaves per tree, 2 within the canopy on twig and 4 to the different cardinal points of the tree.

The evaluation is to determine the level of infestation of each elementary plot, to count individuals per species per stage and determine the effects on acariphage fauna. The Calculating of the effectiveness of tested products, in the various control dates was performed using the ABBOT's method :

$$\text{Effectiveness\_ABBOT} = 100 \times (T_0 - T_t)/T_0$$

T_t= Number of mites in the treated plot

T_0= Number of mites in the control plot

We can classify the products from the values of the effectiveness of each product as follows :

Table 3 : Effectiveness class

% EFFECTIVENESS	CLASS
95 à 100%	very good efficacy
80 à 95%	good efficacy
60 à 80%	average efficacy
40 à 60%	low efficacy
40%	Efficacy with no practical interest

6. Frequency

Samples taken before and after treatment are seven, spread over time, as shown in the following table :

Table 4 : Frequency of samples collection

Counting	Frequency
1	just before the treatment
2	3 days after treatment
3	7 days after treatment
4	10 days after treatment
5	13 days after treatment
6	16 days after treatment
7	19 days after treatment

Results and discussion

1. Infestation rate and demographic structure of the mites population

T. urticae

Situation before treatment

Just before the treatment, the infestation rate of leaves was about 12%, the statistical analysis of the data after the angular transformation, showed no significant effect between the elementary plots receiving the various treatments applied in terms of infestation rates. Analysis of the variance of the density of mobile forms and Eggs has also showed no significant effect at the 5% level between the different treatments. Furthermore, statistical analysis of the density of larvae and eggs of *T. urticae* revealed no significant effect at the 5% level between the different treatments.

3 days after treatment

Statistical analysis of the data collected revealed a significant effect of treatment applied ($p = 0.001 < 0.05$).

The statistical processing of the variable number of mites per leaf, did not record a significant treatment effect ($p = 0.419 > 0.05$). Garlic has registered the lowest rate of infestation with 0%. The fenazaquin recorded 3.33% as infestation rate. For control treatment, the rate infestation was 6.67%. Analysis of variance of the variable number of *T. urticae* larvae showed no significant effect of treatment at 5% level ($p = 0.328 > 0.05$). The analysis of variance of the variable number of eggs of *T. urticae* reported no significant effect of treatment ($p = 0.256 > 0.05$).

7 days after treatment

The statistical data processing of the variable the infestation rate of leaves showed a highly significant effect of treatment at 5% level ($p = 0.000 < 0.05$).

The comparison of averages with the SNK test identified two homogeneous groups. Indeed, the first group containing the fenazaquin with law infestation rate of 0% and the second group containing the control treatment and garlic with an infestation rate of 3.33% and 6.67% respectively.

Nevertheless, the comparison of averages by SNK test at 5% of the number of mobile forms (adults and larvae) and eggs of *T. urticae* revealed a single homogenous group.

10 days after treatment

The statistical data processing of this sampling, reported a highly significant effect of treatment ($p = 0.000 < 0.05$).

Garlic marked the lowest rate of infestation with 0%, while fenazaquin recorded an infestation rate of 3.33%, and finally the control treatment whose infestation rate was 6.67%.

13 days after treatment

During the sampling, analysis of the data collected revealed a significant effect of treatment at 5% level ($p = 0.000 < 0.05$). The infestation rate of fenazaquin and garlic was 0%, and 6.67% for control treatment.

16 days after treatment

During this sampling, statistical analysis of the infestation rate variable showed a significant effect of the treatment at 5% level ($p=0.000<0.05$). The infestation rate of fenazaquin, garlic and control treatment was respectively 0%, 3.00% and 10%.

Statistical analyzes of the variables number of adults, number of larvae and number of eggs/30 leaves reported a significant effect of treatment for only the variable number of adults/30 leaves ($p=0.041<0.05$).

P. citri

Situation before treatment

Statistical analysis of the infestation rate and density of mobile forms of *P. citri* showed no significant effect at the 5% level between the 4 treatments. The infestation rate was 5%.

3 days after treatment

The analysis of variance showed that there was a highly significant effect of treatment ($p = 0.000 < 0.05$). During the sampling, 0% was noted for garlic juice and fenazaquin as infestation rate, while 10% was recorded for the control treatment.

However, the data processing of the number of mobile forms on infested leaves showed that there was no significant effect of treatment ($p = 0.186 > 0.05$).

7 days after treatment

During this control, the infestation rate was 0% for each treatments applied.

The comparison of averages by SNK test at 5% of number of mobile forms of *P. citri* has unveiled a single homogeneous group.

10 days after treatment

The analysis of statistical data by SNK test of the variable infestation rate of *P. citri* was almost similar to that of *T. urticae*.

Garlic recorded 0% as infestation rate, while the fenazaquin and the control treatment noted an infestation rate of 3.33%.

13 days after treatment

The analysis of variance of the variable rate of infection for the species of *P. citri* showed a highly significant effect of treatment at 5% level ($p = 0.000 < 0.05$).

On the other hand, the analysis of variance of the variable number of mobile forms/30 leaves demonstrated that the treatment has no significant effect at 5% on the number of mobile forms of *P. citri* ($p = 0.053 > 0.05$). In addition, the comparison of averages by the test revealed a significant difference between the fenazaquin and the control treatment ($p = 0.031 < 0.05$).

16 days after treatment

The analysis of variance of the variable infestation rate of *P. citri* noted a significant effect of treatment ($p=0.000<0.05$). Indeed, the rate of infestation in the control treatment was 6.67%, but, other treatments reported 0% as infestation rate.

The table 5 shows the average densities of mobile forms for different treatments, and therefore, we find that Garlic recorded the lowest average density, followed by fenazaquin, and the control treatment which the average density is higher compared to other treatments. That reveals the toxic effect of garlic on mobile forms, those results are concorded with those obtained by El Hardouni (2006).

E. orientalis

Situation before treatment

Before applying treatment, statistical analysis showed no significant effect at 5% for mobile forms and eggs, the infestation rate was 2%. Therefore, the number of *E. orientalis* appears too low compared to other species.

3 days after treatment

During this control, the analysis of variance of the variable infestation rate of leaves showed a highly significant effect of treatment ($p = 0.001 < 0.05$). Therefore, the comparison of averages by SNK test revealed two homogeneous groups. The first group containing the fenazaquin with an infestation rate of 0% and the second group with Garlic and control treatment with an infestation rate of 3.33% and 6.67% respectively.

The analysis of variance of the variable number of mobile forms and eggs showed no significant effect of treatment at 5% level ($p = 0.431 > 0.05$, $p = 0.108 > 0.05$; $p = 0.691 > 0.05$).

7 days after treatment

The analysis of variance of the variable rate of infestation noted a highly significant effect of treatment ($p = 0.000 < 0.05$).

Nevertheless, by the analysis of variance densities adults, larvae and eggs showed no significant effect of treatment at 5%. For biopesticide, the rate of infection was 3.33%. For fenazaquin and the control treatment, 0% is recorded as infestation rate.

10 days after treatment

The infestation rate of *E. orientalis* was 0% for all treatments, the plots treated with the fenazaquin, no activity of mobile forms or eggs have been reported on samples.

13 days after treatment

The infestation rate of *E. orientalis* was the lowest compared to other species, with an average of 0% for all treatments. Furthermore, analysis of variance of the variable number of mobile forms (adults and larvae) per 30 leaves reported no significant effect of treatment [(p (adults) $=0.534>0.05$) ; (p (larvae) $=0.574>0.05$)]. However, analysis of variance of the variable number of eggs per 30 leaves noted a significant effect of treatment ($p=0.029<0.05$).

The samples examined from the plots treated by fenazaquin, revealed no presence of *E. orientalis*.

16 days after treatment

The samples including the control treatment didn't detected presence of mobile forms of *E. orientalis*, it may be due to the high temperature caused mortality of mobile forms during this sampling day (36 ° C).

19 days after treatment

During the last sampling, the infestation rate of species *T. urticae*, *P. citri* and *E. orientalis* was 0% for all treatments including the control treatment because of the high temperature (38 ° C) whose thermal effect was unfavourable for the evolution of the population of mites.

Table 5 : Average densities of each stage of mite species collected during the test period

2. Comparison of the products tested efficacy

Te examination of Figure 2 allows that the evolution of the effectiveness of the tow products is increasing from the application of the treatment. Indeed, the effect of the products evolves gradually from 77.27% and 72.72%, recorded on J + 3, respectively for Garlic and fenazaquin to 57.69% and 96.15% considered on J + 16. This biopesticide was tested and reduced the average level of the population of *T. urticae* in peach orchard (Sagouti, 2007). As for *T. urticae* larvae (Figure 3), the efficacy of product follows a fluctuating evolution, However, the effect increased from 100% to 100% on J + 3 for Garlic and fenazaquin until 50% and 100% on J + 16. In addition, garlic has shown an average efficacy against adult and very effective against the larvae, while fenazaquin was very effective against mobile forms almost along the trial period.

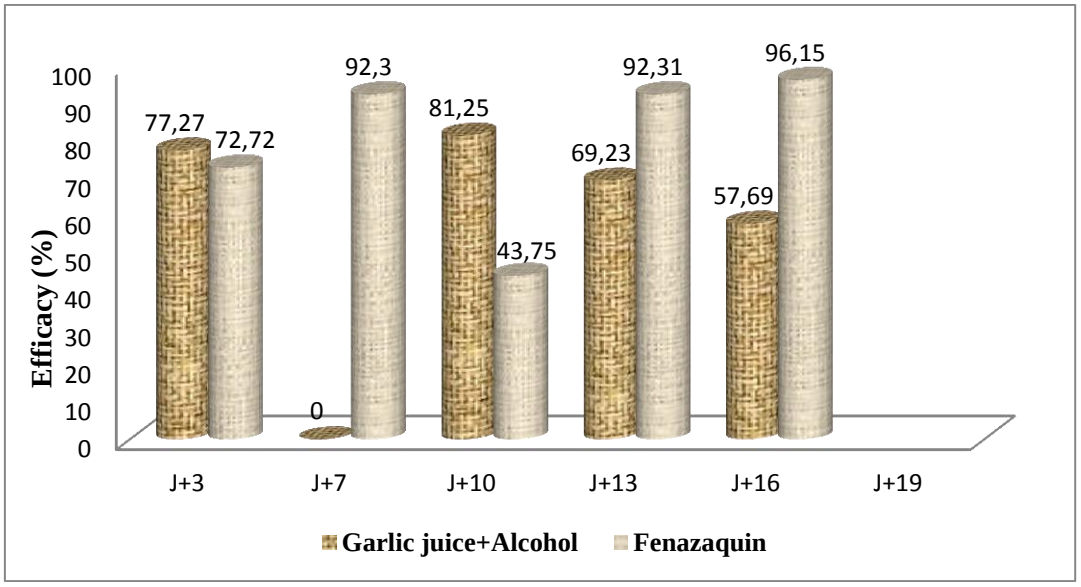

Figure 2 : Evolution the effectiveness of the products tested on adults of *T. urticae*

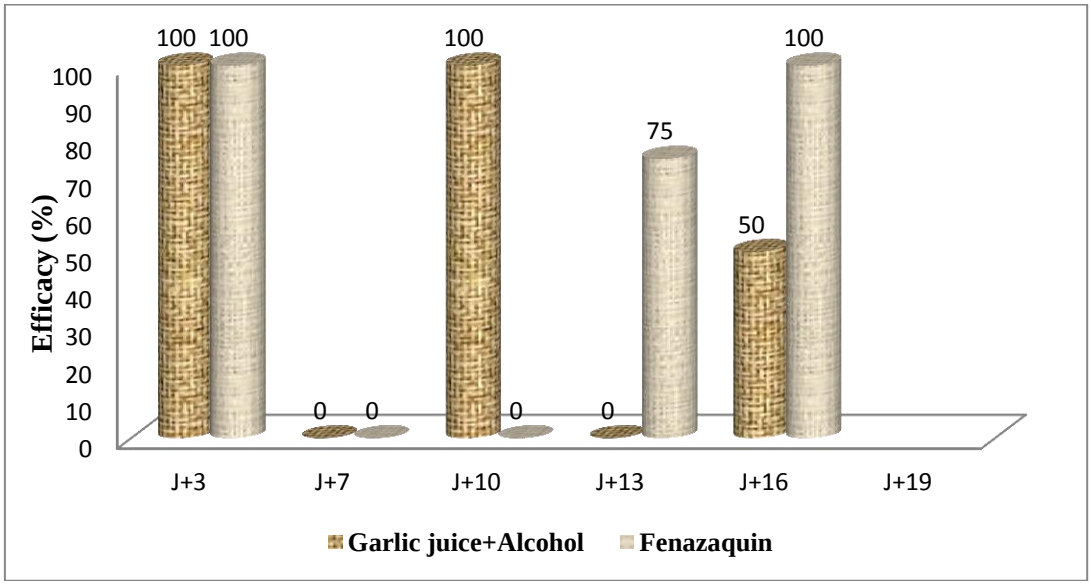

Figure 3 : Evolution the effectiveness of the products tested on larvae of *T. urticae*

Regarding the species *P. citri* (Figure 4), Garlic unveiled an efficacy of 85.71% in the 1st day of sampling after treatment (J + 3) and J + 16, and therefore, it is good efficacy against the

mobile forms of *P. citri*. The fenazaquin has good efficacy, since it reached 100% in the last day of sampling (J + 19). Studies in the Gharb region (Morocco), have indicated that the use of garlic juice and alcohol can replace the chemicals to treat against spider mites (*T. urticae* and *P. citri*) on citrus, knowing that biopesticide is conceivable in technical and economic perspective, authorized by the specifications of organic farming (El Hardouni, 2006; Boutaleb, 2011).

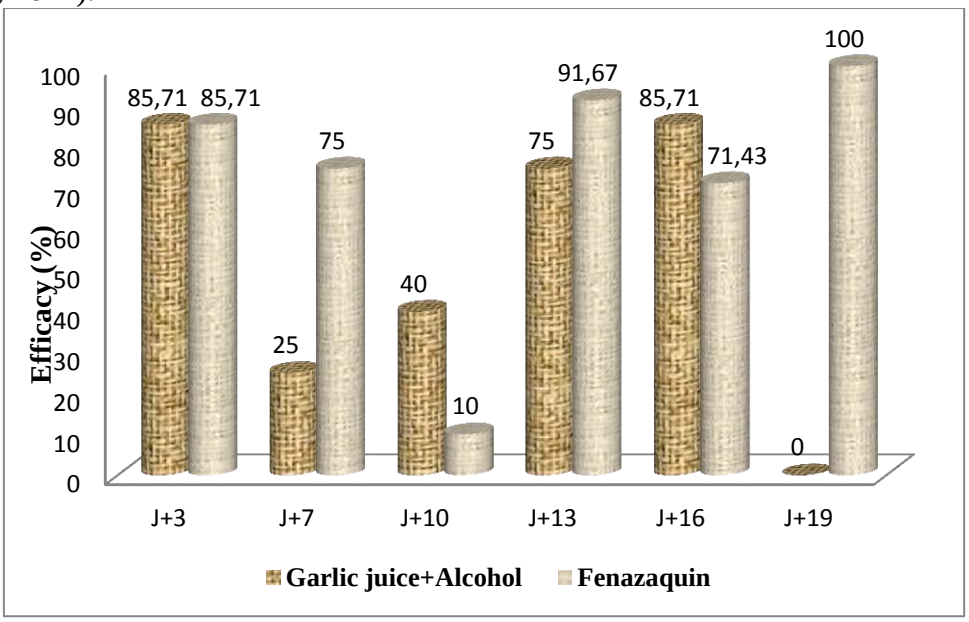

Figure 4 : Evolution the effectiveness of the products tested on *P. citri*

The figure below illustrates the effectiveness of both products against *E. orientalis*, the fenazaquin has noted very good efficacy, which is increased from 83.33% (J + 3) to 100% (J + 19). These results are in agreement with those found by Abbasi (2011), he noted that fenazaquin has an average or very good efficacy, and suggested washing the trees with water + potassium soap (repeat according to the infestation level).

As for garlic, the effectiveness of this biopesticide was very low on J + 3 (16.67%), but it revealed a very good effect on the last sample (100%).

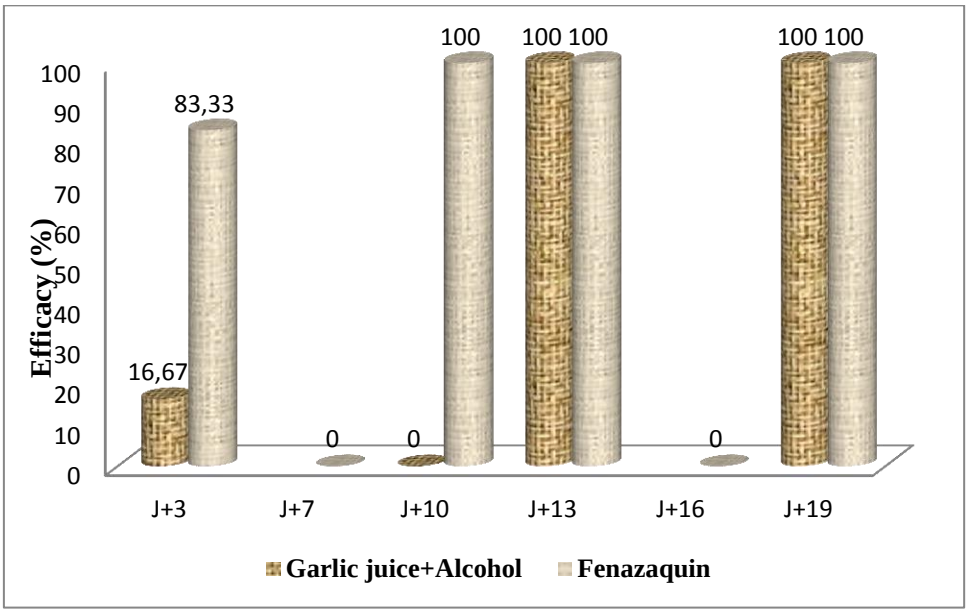

Figure 5 : Evolution the effectiveness of the products tested on *E. orientalis*

Conclusion

Chemical treatment (fenazaquin) and biopesticide (Garlic + alcohol) applied in the test, against the different stages of mites namely *T. urticae*, *P. citri* and *E. orientalis*, have reduced the proliferation of mobile forms and reducing the number of eggs at low levels compared with the control treatment. The fenazaquin assured very good control (100%) of adults and larvae of mites, with adverse effects on auxiliary fauna. The garlic juice showed a weak effect against the mobile forms of *T. urticae*, but, it appears effective against mobile forms of *P. citri* and *E. orientalis*. In the other hand, it's action reduced also the number of eggs of *T. urticae* and *E. orientalis* at low levels. Garlic juice + alcohol provides an average efficiency against mobile forms of *E. orientalis*, but with weak effect on the mite eggs in heavy infestations.

The application of biopesticides treatment is recommended for low infestations of mites for better control, and therefore, they can be used as an alternative means of control to chemicals, knowing that biopesticides are biodegradable in nature, and also technically and economically conceivable. In addition, other biological controls are possible and may be associated with the biopesticides such releases of predators.

Abstract

The duty of the integrated protection of plants was introduced in Poland in 2014 and it is related with the application of biological and other non chemical methods of plant protection. Health and quality of seed is extremely important, especially in organic farming. Seeds treatments before sowing e.g. dressing with the microorganisms can stimulate their germination, the health of the seedlings and to improve the development of young plants. The search for alternative means and methods to seeds dressing was the purpose of this research. A seed dressing in dry and wet way was also evaluated for finding the most effective one. The experiments were conducted in greenhouse and field conditions with pea (*Pisum sativum* L.) seeds. Commercial products based on *Pythium oligandrum* Drechsler, *Trichoderma asperellum* Samuels, Liechfeldt et Nirenberg and *Saccharomyces cerevisiae* Meyen ex E.C. Hansen in doses of 10 g/1 kg of seeds were used. Also the product containing a complex of microorganisms (EM Farm) in dose 1 ml/100 ml of water was included. The number of seedlings, health and development of plants according to microbial dressing was evaluated. In glasshouses conditions it was found that *T. asperellum* and *P. oligandrum* the most improved the number of plants emergence, healthiness and development of pea seedlings. Dry seed treatment was more effective compared to wet dressing way. In the field conditions *T. asperellum* was the most effective. *P. oligandrum* had slightly positive effect only on number of leaves and development of the root. *S. cerevisiae* was the least effective in the promotion of development of the seedlings.

Keywords: *organic farming, Pythium oligandrum, seed dressing, Trichoderma asperellum, yeast*

Introduction

The soil environment is the habitat of a lot of microorganisms. The research on the application of antagonistic microorganisms and organic compounds in controlling plant diseases was developed worldwide (Martin and Hancock 1987, Orlikowski and Skrzypczak 2003, Pięta et al. 1998). Introducing biopreparations in plant protection can contribute to reduced use of fungicides, and – as a result – less contamination of the natural environment (Pięta et al., 2005). Plant biostimulants include diverse substances and microorganisms that can enhance plant growth. The global market for biostimulants has been projected to reach $2.241million by 2018 and to have a compound annual growth rate of 12.5 % from 2013 to 2018 (Anonymous, 2013). According to the same study, the largest market for biostimulants in 2012 was Europe. The European biostimulants industry council (EBIC) reported that in 2012 over 6.2 million hectares were treated with biostimulants (European Biostimulants Industry Council 2013). (Calvo et al., 2014).

Biological control of plant diseases is the utilization of one or more living organisms which have antagonistic effect against various plant pathogens to achieve the suppression of plant diseases. Health and quality of seed is extremely important. Seed treatment can stimulate their germination, emergence and improve the health parameters of development of young plants. It is a necessary condition for obtaining high plant productivity, and thus one of the cheapest means of determining the good performance of crops. The most important enriching

treatments should be dressing (Orzeszko-Rywka et al. 2011). In organic farming chemical seed treatments that are very effective in the protection of seeds and seedlings are not permitted. Sowing seeds without dressing is quite risky, may lead to a mass loss of plants in the early stages of development and consequently, to lower yield and deterioration of its quality. Therefore, in many research centers are developed methods of alternative and acceptable in the organic farming ways of dressing seeds (Orzeszko-Rywka, 2011). The aim of the study was to choose methods of microbiological pea seed treatment to accelerate the emergence and improve the development seedlings and young plants. The glasshouse trials were performed in 2014, the field experiments were conducted in 2015.

Materials and methods

The glasshouse is located near institute in Poznan, the Field Experimental Station of IPP-NRI is located in the Western part of Poland. Commercial products based on *Pythium oligandrum* (Polyversum), *Trichoderma asperellum* (Trifender), *Saccharomyces cerevisiae* (baker's yeast) in doses of 10 g/1 kg of seeds were used. Each experimental combination included 4 repetitions (big plots). Product Polyversum is registered in Poland as biological plant product and one gram of it consists $1x10^6$ of zoospores *P. oligandrum*. Trifender WP (product of Biovéd, Hungary) is used in Poland as microbial plant growth promoter. One gram of the product contained $5x10^8$ of conidium isolate T1. As source of *S. cerevisiae* trade bakery product with lyophilized fungus in concentrate $11x10^6$ of *S. cerevisae*in in one gram was used.

Glasshouse conditions

Combinations with each microorganism were made with 100 seeds (5 seeds in 20 pots), which were sown in the sterile perlit or soil. Pots sowed seeds were kept in a greenhouse at 20 ° C giving optimal growth of seedlings. For dry dressing seeds were placed in a Petri dish and mixed with microbial product in accurate dose in relation to weight of seeds. Petri dishes were shaken by 10 s and after next 5 minutes seeds were sown. In way of wet dressing the fixed dose of Polyversum was mixed with warm water (100 ml). Seeds were put into solution for 0.5 h. EM Farm in dose 1 ml/100 ml water was also used. Dressed seeds were out and slightly drained on paper towel by 24 hrs. Two varieties of pea were used, “Sześciotygodniowy” and “Cud Kelvedonu”. In glasshouse conditions the number of health and dead seedlings (infected by *Fusarium* spp., *Rhizoctonia solani*) during 2 weeks after sowing was evaluated. After 4 weeks, the seedlings were measured (fresh weight of the total plant, weight of the roots and number of leaves).

Field conditions

The experiment was established using the random block design on plots of 400 m^2 area where pea cv. Milwa was sown. The field experiments were performed in 2015. Date of sowing was 7 April, number of plant emergence was calculated in 16 April, on 1 m in four locations in each combination. Seeds were treated with powder of each used microbial product, only EM was used as water treatment. These same doses as in glasshouse were used.

Statistical methods

Differences between treated and untreated were determined using Tukey’s multiple range test at $P \leq 0.05$ for selected combination. The data are presented as untransformed means.

Results and discussion

Trichoderma isolates are known for their ability to control plant pathogens and have been used in different fields of production and protection in agriculture (Howell, 2003; Kowalska, 2010). *Trichoderma* is able not only to produce toxic compounds with a direct antimicrobial activity against pathogens, but also generates fungal substances which are able to stimulate

plant to produce its own defense metabolites. An additional category of inoculants is the product referred as EM “effective microorganisms.” EM consist of around 70 species of microorganisms belonging to five groups, namely lactic acid bacteria, photosynthetic bacteria, actinomycetes, yeast fungi and filamentous fungi (Valarini et al. 2003). The application of EM has a beneficial effect on soil texture and quality (Khaliq et al. 2006). In Poland the biopreparation EM is registered as a soil enhancer recommended for use in organic farming (Okorski et al. 2008). As described by Hu and Qi (2013), the inoculant called EM was first described in non-refereed presentations in the early 1900s. The contents of EM were subsequently summarized (Hu and Qi 2013) The microbes are fermented together in the presence of organic wastes and molasses (Khaliq et al. 2006). Field experiments with cotton showed that EM increased the efficiency of mineral and organic fertilizers, and the combination of EM with organic matter increased yields 23 % compared to treatment with organic matter alone (Khaliq et al. 2006). In contrast, (Mayer et al. 2010) found that EM did not increase yield or soil quality in trials conducted over 4 years in Central Europe. On the basis of data included in table 1 can be stated that that positive effect on number of emergence was confirmed in EM combination inof conducted trials in the glasshouse.

Table 1. Pea seed wet dressing with EM – impact on plants emergence, cv. „Sześciotygodniowy” in glasshouses conditions

Sowing into pots with soil	Treated with EM Number of seedlings	Untreated Number of seedlings
5th day after	29	19
6th day after	39	27
7th day after	54	38
8th day after	61	45
9th day after	62	47

Comparing two methods of dressing can be decided that dry seed treatments were more effective than wet dressing, especially in influence on increase number of seedlings. Our results are presented in Table 2.

Table 2. Pea seed dressing with fungus P. *oligandrum* in different ways, cv. “Cud Kelvedonu” in glasshouses conditions

Sowing into pots with soil	Product Polyversum (10 g/1 kg of seeds)	
	Dry dressing	Wet dressing
number of plants emergence	82 pcs	69 pcs

Fungi of the genus *Trichoderma* are often used as seed treatments influencing favorably the characteristics of seedlings (Sadowski et al., 2005; Mastouri et al., 2010). It is believed that such treatments are favorably only short time and few further reports of Trichoderma impact on plants during their development are available. Our results presented in table 3 clearly points out that effects of seed treatments are more visible in the experiments with soil than in the perlit. The best effect for development of young plants was observed for *T. asperellum* and *P. oligandrum*.
Seed microbial dressing was factor which determined the number of plant emergence in the field conditions. The highest number was noted after treatments with *T. asperellum* and *S. cerevisiae*, (av. 16 pcs/1m). After EM and in plot with untreated seeds were noted 15 pcs/ m, respectively. The lowest number was observed in case of *P. oligandrum* (13 pcs/ m). Effect of dressing seeds compared to untreated seeds is not clear visible and significant.

In field conditions was evaluated the influence of selected microbial products on the development of seedlings. Statistically a confirmation of the effectiveness of certain products was done. Data are presented in the Table 4.

Table 4. Mean values of development parameters of plants collected from different combination in the field conditions

Microbial dressing	weight of whole plant [g]	weight of roots [g]	number of leaves [pcs]
Trichoderma asperellum	**1.28 a**	**0.30 a**	**5.25 a**
Pythium oligandrum	1.05 b	0.10 b	**5.30 a**
Effective microorganisms (EM)	1.20 a	0.25 a	**5.45 a**
S. cerevisae	0.66 c	0.11 b	**4.50 b**
untreated	1.07 b	0.22 a	4.25 b

Values with letters are statistical different within column

In the field conditions seed treatments with *T. asperellum* had the most positive effect on development of seedlings and young plants for all evaluated parameters. EM increased the development of the root part. All microbial except yeast treatments were influencing on increase of number of leaves. In combination with *S. cerevisae* some parameters of

development were worst than in untreated plants. The studies conducted by Pięta et al. (2005) in a growth chamber showed the protective effect of Polyversum used as seed dressing for common bean and pea. Eight fungi species were considered for pea. The seeds were dressed with Polyversum in the dose of 1 g/100 seeds. Five weeks after the experiment was established the number of plants and their healthiness. Fact was confirmed that antagonistic microorganism (*P.oligandrum*) has protective effect. Sobolewski et al. (2013) showed that the carrot seed dressing with selected isolates of the fungus *Trichoderma* spp. against damping-off seedlings significantly reduced the infection of germinating seeds and carrots seedlings by the pathogenic fungus species *Pythium* spp. The use of *Trichoderma* spp. was more efficiently affected the height and weight of the tested carrot seedlings as compared to untreated seed. No effect of phytotoxicity of *Trichoderma* spp. isolates was observed (Sobolewski et al., 2013).

In other tests symptoms of downy mildew (*Peronospora viciae*) on pea leaf, Ascochyta pod spot and Fusarium root significantly was affected by dressing of seeds with EM in 0.2% concentration of solution. (Okorski et al. 2008). EM reduced the incidence of pea diseases. Foliar application of EM significantly increased the rate of photosynthesis in pea. Soil application of EM, seed dressing and chemical control decreased the rate of photosynthesis in pea. Seed dressing with EM and chemical products caused a significant decrease in molar transpiration values in pea. The occurrence of downy mildew of peas significantly reduced the rate of photosynthesis. In studies of Zbroszczyk and Kordas (2012) was the assessment of a potential effect of tillage systems and EM treatments (seed dressing and soil application) on reduction of plant diseases infection. The three-year studies did not show any explicit positive effects of EM on health status of spring wheat grown in a short-term monoculture. Dłużniewska (2006) was conducted the study on the effect of fungicides in concentrations 10 ppm and *T. harzianum, T. pseudokoningii* and *T. viride* usability for biological pea seed treatment against diseases. It was found that seed dressing with *Trichoderma* fungi improved healthiness of pea seedlings threated with diseases. Fungicides have a negative effect on the protective activity of the studied antagonistic fungi (Mastouri et al.,2010). The efficacy of application of Trichoderma was evaluated against wet root rot of chickpea. Seed treatment formulations of Trichoderma species was more effective than soil application for all the parameters. Both soil application and seed treatment formulations enhanced the growth of the plants indicating growth promoting ability of the isolates used for development of the formulations. (Dubey et al., 2012). Polyversum was used among others products in the tests conducted by Horoszkiewicz et al. (2012) to dressing seeds of different varieties of blue lupine, yellow lupine, and pea. Grapefruit extract, garlic pulp and a synthetic seed dressing Vitavax 200 FS were used. No significant differences in the number of infected plants of lupine and the level of infestation between tested biopreparations and control were found. Antagonistic fungi such as *Trichoderma harzianum*, *T.* v*iride* and *T. hamatum, Bacillus subtilis, Pseudomonas fluorescens* and *Saccharomyces cerevisiae* were tested in dose $2x10^4$cfu/mL by El-Mougy et al. (2012). All used seed dressing treatments reduced significantly root rot incidence at both pre-, and post-emergence growth stages of cucumber, cantaloupe, tomato and pepper plants comparing with untreated check control.

On basis gained results we can conclude that in the glasshouses conditions *Trichoderma asperellum* and *Pythium oligandrum* the most improved the number of plants emergence, healthiness and development of pea seedlings, especially in the soil compared to the perlit. Dry seed treatment was more effective compared to wet dressing way. In the field conditions *T. asperellum* was the most effective. *P. oligandrum* had slightly positive effect only on number of leaves and development of the root. *S. cerevisiae* was the less effective in the promotion of development of the seedlings.

EFFICIENCY OF REGULATORS OF GROWTH AND MICROFERTILIZERS ON THE LETTUCE A GRADE GEYSER CULTIVATED BY METHOD OF A FLOWING HYDROPONICS

Ludmila V. DERBENEVA, A.D. BOYARSHINOVA

Department of Agrochemistry, Perm state agricultural academy, Perm, Russia
*Corresponding author: nata020880@mail.ru

Abstract

In the protected ground use of regulators of growth and microfertilizers is mandatory agronomic reception at cultivation of vegetable cultures. In recent years, the market of agrochemical production is filled up annually by new natural and synthetic agrochemical preparations: regulators of growth and microfertilizer, the direction of action and which efficiency aren't always justified in production. Purpose of researches: to study efficiency of regulators of growth (Narcissus, Zircon) and microfertilizers (Siliplant and Rexolin of APN) on productivity, removal of elements and some indicators of quality of on the lettuce a grade Geyser cultivated by method of a flowing hydroponics. Researches on use of regulators of growth and microfertilizers on plants of salad were carried out under production conditions by LLC "Tchaikovsky greenhouses" of Tchaikovsky of the region of Perm Krai in 2010. Lettuce cultivated by method of a flowing hydroponics. It was established that the strait of substrate solution of the drug Narcissus, Zircon, Rexolin APN increases of the salad productivity on 5.20, 10.8 and 3.60 g with five plants, respectively. Effective action from use of microfertilizer of Siliplant on salad it isn't revealed, on the contrary established that the strait of substrate solution led to essential decrease in productivity. A regulator of growth and microfertilizer has no essential impact on the content of nitrogen, phosphorus, calcium, magnesium, ashes (Ffact. < Ftheor.) and on carrying out of removal of elements salad. When using regulators of growth is noted the tendency to decrease in nitrates in sheet lettuce a grade Geyser.

Keywords: *Growth stimulants, micronutrient fertilizers, lettuce a grade Geyser, yield, elemental composition*

Introduction

Protected ground is currently developing as a dynamic and competitive agriculture industry capable of year-round supplying the population with fresh vitamin-rich vegetables. Growing of vegetables by flowing hydroponics method using a complex of chemistry, biology and electronics is a cutting edge direction in a glasshouse industry (Antipova, 2003, 2010).

It is well known, that certain chemical substances used in low concentrations show the positive effect on plant resistance to diseases and stress situations, the seed germination and plant establishment, the stimulation of growth and hasten ripening, the yield and quality of cultivated plants. In protected ground, the use of growth regulators and microfertilizers is mandatory (Antipova, 2003, 2010). In recent years, the market for agrochemical products is annually replenished with new natural and synthetic agrochemical formulations such as growth regulators and microfertilizers, the direction of action and the effectiveness of which are not always justified for production.

The purpose of the research is to study effectiveness of action of growth regulators Narcissus and Zircon and microfertilizers Siliplant and Rexolin APN on yield, removal of the fertilizer elements, and some indicators of the quality of Geyser lettuce grown by method of flowing hydroponics.

Materials and methods

The method of the research: Studies on the use of growth regulators and microfertilizers in plants of lettuce were conducted under production conditions of "Tchaikovsky greenhouse" LLC in Tchaikovsky district of the Perm Krai (Fig. 1)

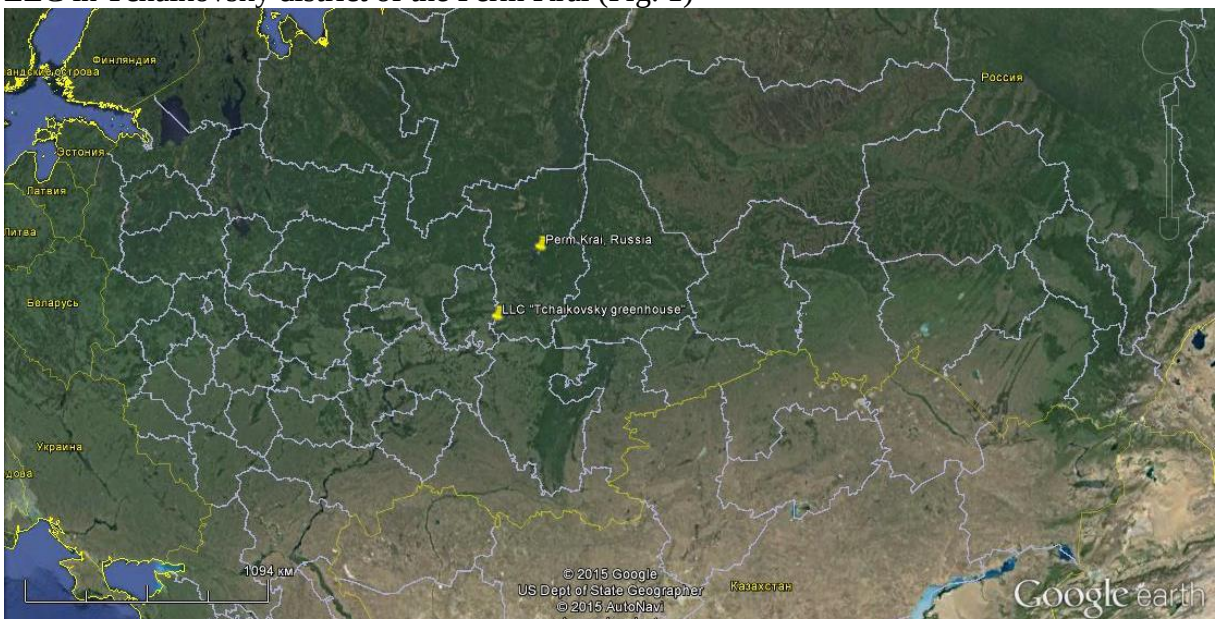

Figure 1. Location of the experiment in Perm, Russia

In the experiment, the following growth regulators were used: Narcissus and Zircon; and the following microfertilizers: Siliplant and Rexolin APN in chelated form. After seeding of lettuce, the substrate was poured with warm water to achieve a moisture content of 65% of full moisture (FM), then with water solutions of study formulations at doses indicated on the label of their packages.

The experiment was using the following scheme:

1. Water (control)
2. Narcissus 0.25 %
3. Zircon 0.01 %
4. Siliplant 0.20 %
5. Rexolin of APN 0.02 %

There was eightfold replication of the experiment variants.

The Geyser lettuce is grown in protected ground year-round. When choosing the lettuce for testing, attention was paid to early ripening, shade tolerance, resistance to bolting and root rot, to the rapid formation of leaf apparatus and healthy appearance of the leaf. Growing season of the lettuce in perfusion culture is about 30 days. Plants were grown in plastic pots (PR-306) with a diameter and a height of 5 cm and perforated bottom. The pots were installed into a cassette. The lettuce seeding was carried out manually on June 7, harvesting on July 14. Before emergence (June 9) cassettes with pots were kept in germination chamber. Then the lettuce was checked and lined out, the number of plants in each pot was set to 5. After 2-4 true leaves appeared, the lettuce plants were placed in special "inserts" cassettes and carried to the work area.

Calcified wood shavings with mineral fertilizers (ammonium nitrate, double superphosphate, potassium sulphate, magnesium sulphate and agrochulk) were used as a substrate: $N\text{-}NO_3$ – 250 mg, P_{water} – 70 mg, K – 350 mg, Mg – 80 mg/l. The substrate was held for 10 days. Agrochemical characteristics of the substrate on the day of seeding are presented in Table 1.

Table 1. Agrochemical characteristics of the substrate

Substratum	EC, mS/cm	Water pH	$N\text{-}NO_3$	K	Ca	P	Mg
			mg/l				
Sawdust on the day of sowing lettuce	0.95	5.60	265.0	302.5	158.0	5.0	90.5

After holding, the substrate had low electrical conductivity of 0.95 mS/cm, which is close to neutral pH 5.60. The content of nitrate nitrogen in the substrate was higher than the required (265 mg), potassium not high enough (302.5 mg), phosphorus very low compared to the required (5.0 mg) and magnesium content slightly above the required (90.5 mg/l).
Lettuce grown in the nutrient solution constantly recycling through the channels and pipes. When preparing the solution, the quality of water was taken into account and readily soluble fertilizers were used: akvarin-12, magnesium sulfate, potassium sulfate, and 50 % nitric acid.
The climatic conditions in the greenhouse have been violated during the experiment. The air temperature in the summer months in 2010 reached 40 °C, and in the greenhouse, especially during the day, it was about 60-70 °C. The ventilation system at the production was not designed for these conditions.

Results and discussion

The yield of green crops in the protected ground is a basis for providing the population with fresh vegetables all year round. It depends on the climatic, biological, agrotechnical, organizational and economic conditions and the properties of the substrate. The average yield of lettuce in the experiment is shown in Table 2.

Table 2. Yields lettuce, depending on the applied growth regulators and microfertilizers, g/ 5 plants

Variant	Average productivity	Increase to control
Water (control)	34.25	-
Narcissus 0.25 %	39.45	+5.20
Zircon 0.01 %	45.05	+10.80
Siliplant 0.2 %	29.10	-5.15
Rexolin of APN 0.02 %	37.85	+3.60
$LSD_{0.95}$	3.09	

The yield of lettuce in the experiment is low and ranges from 29.10 g to 45.05 g from five plants. One of the reasons for low yields is the high air temperature during the growing season of the lettuce. Antipova (2003) points out that the temperature of 18-19 °C is optimal to obtain a high yield of lettuce in greenhouses. Overheating lettuce leaves leads to the closure of stomata, reduces CO_2 intake and reduces photosynthesis. The warm nutrient solution and substrate contributed to increased evaporation of water by plants and non-proportional absorption of ions from the solution, which led to disruption of metabolic processes in plants.
To be sold in the retail network, the lettuce should have 6-7 true leaves and the average weight about 100 g (Antipova, 2010). Growth regulators Narcissus at a dose of 0.25 % and Zircon at a dose of 0.01 % of the solutions had a positive impact on the yield of lettuce, which was 39.45 g and 45.05 g from five plants. The highest yield increase of 10.80 was observed in the Zircon. Apparently at high air temperature Zircon enhanced the enzymatic and hormonal activity creating a more favourable environment for cell division and protecting plants from UV radiation. Peregudov (2010) notes that Zircon is also involved in the regulation of gas exchange and increment of photosynthetic activity affecting the nutrition of plants and yield. When pouring the substrate with 0.25 % aqueous solution of Narcissus a smaller, but still significant increase of 5.20 g was achieved (least significant difference $LSD_{0,95}$ = 3.09 g/5

plants). Shevlyagin (2010) writes that Narcissus penetrates into plant cells and activates an enzyme complex improving the immune system and the work of leaf apparatus. Due to the enhanced plant immunity and metabolism followed by lower severity of pathogens, there is a stable growth of plants and the formation of a high yield.

There was not achieved any effective action of the Siliplant fertilizer on the lettuce, on the contrary, pouring the substrate with it leads to a significant reduction of yield (29.10 g). Siliplant is a mixture of macro and micronutrients: silicon, potassium, iron, magnesium, copper, zinc, manganese, molybdenum, cobalt and boron. The absence of increase with Siliplanta is probably due to lettuce insensibility to silicon, as well as accumulation of a large number of nutrients available to plants at different values of pH of the medium, and their possible antagonistic action. The Rexolin APN microfertilizer contains practically the same micro elements in chelated form. Such nutrients are readily available for the plants. The average yield of lettuce with Rexolin APN is 37.85 g from five plants. There is a significant increase of 3.60 g compared to the control.

The dynamics of mass gain of the lettuce for four control periods shows that the smallest mass was noted in the version with water, which in the last observation period rose sharply to 9.09 g and reached 34.25 g (fig. 2).

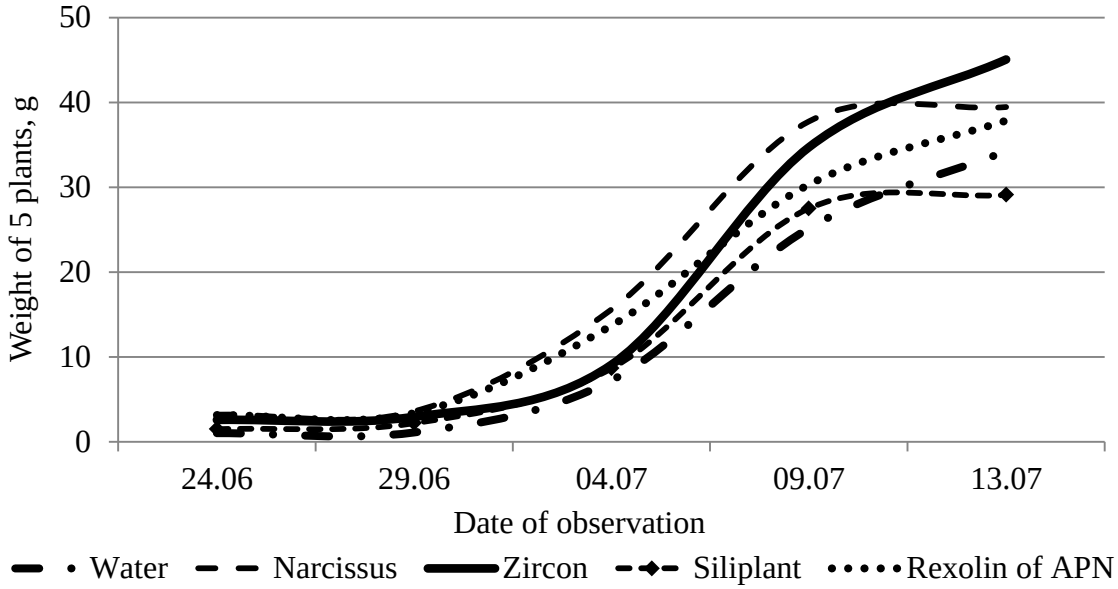

Figure 2. The dynamics of mass gain of the Geyser lettuce depending on applied growth regulators and microfertilizers, g/5 plants

With Zircon mass of plants in the initial period increased slowly, then a sharp increase up to 45.05 appeared. With Siliplant and Narcissus a sharp increase of vegetative mass was noted in the middle of the observations, yet it was then suspended. Slight lettuce mass gain at all observation periods was noted with the use of Siliplant.

Figure 3 shows the dynamics of the growth of lettuce from June 15 to July 13.

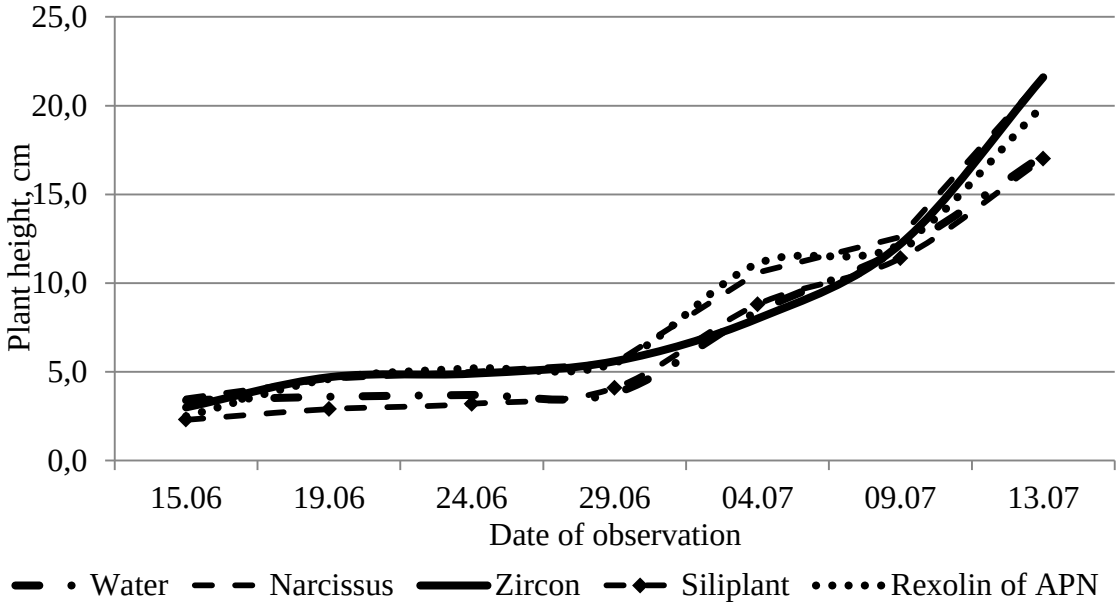

Figure 3. The dynamics of growth of the Geyser lettuce depending on applied growth regulators and microfertilizers, cm

Through the growing season, plants showed growth retardation in the version with Siliplant. Plants using Zircon and Narcissus had the largest increase. However by the end of the growing season all the plants had specified height which according to Antipova (2003) must be 16 to 20 cm average.

Leaf area per plant is shown in Figure 4. The largest area was observed in lettuce leaves with Zircon. By the end of growing season it was 476.25 cm^2. The smallest area of 304.37 cm^2 was observed with Narcissus. Rexolin APN contributed to intensive growth of leaf area during the second half of the growing season and by the end of vegetation the leaf area was 428.75 cm^2.

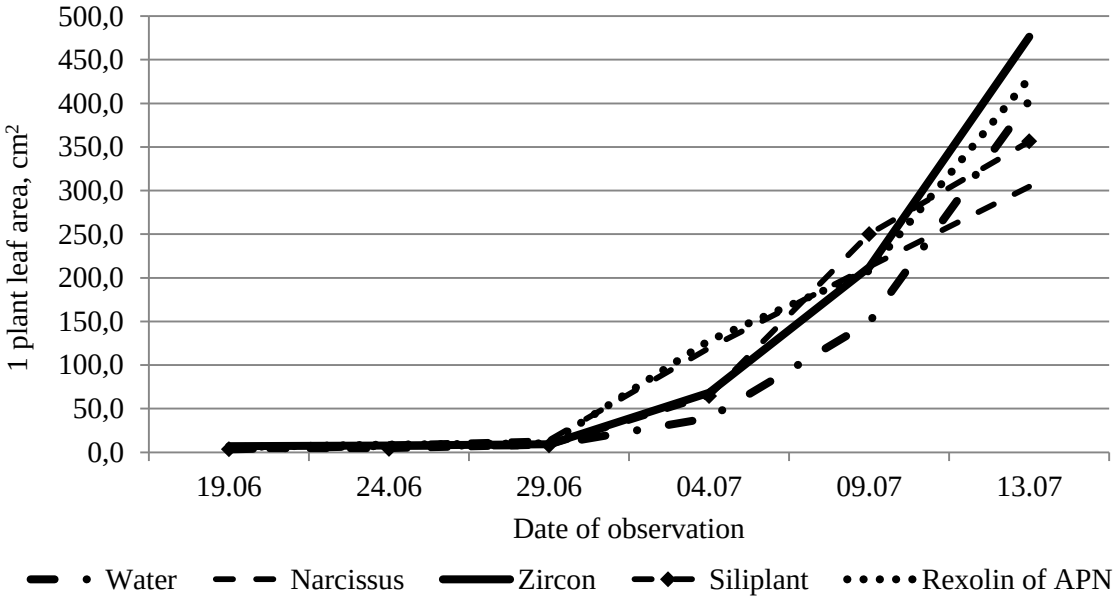

Figure 4. The dynamics of leaf area gain of the Geyser lettuce depending on applied growth regulators and microfertilizers, cm^2

Lettuce as well as other vegetables have a high water content which ranged from 85.4 to 90.0 %. The use of growth regulators contributed to the accumulation of water in plants up to

88.8-90.0 %. In variants with the use of fertilizers a tendency to accumulate dry matter up to 13.2-14.6 % appeared.
The elemental composition of the lettuce is given in Table 3.

Table 3. The elemental composition of lettuce grades Geyser, % on dry matter

Variant	N	P	K	Ca	Mg	Ashes
Water (control)	3.84	0.23	1.86	0.12	1.36	11.65
Narcissus 0.25 %	4.38	0.30	2.07	0.18	1.32	11.90
Zircon 0.01 %	4.81	0.24	2.08	0.24	1.25	11.97
Siliplant 0.20 %	4.57	0.28	2.07	0.23	1.19	11.60
Rexolin of APN 0.02 %	4.58	0.29	2.07	0.31	1.29	11.82
$LSD_{0.99}$	Ffact. < Ftheor.		0.05	Ffact. < Ftheor.		

The total amount of nitrogen compounds in the lettuce is high, ranging from 3.84 to 4.81 %. Growth regulators and microfertilizers had no influence on the content of total nitrogen in plants ($F_{fact.} < F_{theor.}$), however there is a tendency to its increase. Of nitrogen compounds, the lettuce accumulated large amounts of nitrate from 3250 to 4899 mg/kg of crude product, which in all cases exceeded MPC (3000 mg/kg of crude product. Practical Course…, 2001). High levels of nitrates in the lettuce are caused by the use of nitrate fertilizers and high temperature of the nutrient solution. The high plant density resulting in poorer lighting conditions could also contribute to the accumulation of nitrate (Belyaeva, 2008). Puchalskaya (2009) notes that the increase of proportion of potassium in the amount of cations in the solution has a positive effect on nitrate uptake by plants. The highest nitrate concentration in the lettuce was gained in the version with fertilizers: Siliplant – 4899 mg, which 1.63 times exceeds the maximum permissible concentration; Rexolin APN – 3787 mg (1.26 times more than the MPC). The lowest nitrate concentration in the lettuce was gained in the version with growth regulators: Zircon – 3250 mg, Narcissus – 3405 mg/kg (1.08 and 1.13 times, respectively).
The lettuce accumulated ash elements – potassium and magnesium. The potassium content in the lettuce in the variant with water was 1.86 %. Growth regulators, as well as fertilizer equally influenced the content of potassium in the lettuce – 2.07-2.08 % ($LSD_{0.99}$ = 0.05 %). Puchalskaya (2009) in her researches shows that the nitrate nutrition increases the intensity of the potassium absorption by roots of plants and there is a rapid movement of potassium ions with ascending stream. Plants in all variants, along with nitrate nitrogen, had a high content of magnesium of 1.19-1.32 %, which is not connected with the use of growth regulators and fertilizers.
We have calculated the economic removal of nitrogen, phosphorus, potassium, calcium and magnesium with lettuce harvest (Table 4).

Table 4. Carrying out of removal of element of lettuce grades Geyser, mg/ 5 plants

Variant	N	P	K	Ca	Mg
Water (control)	163.2	9.8	79.1	5.1	57.8
Narcissus 0.25 %	193.6	13.3	91.5	8.0	58.3
Zircon 0.01 %	221.3	11.1	95.7	11.0	57.5
Siliplant 0.20 %	194.2	11.9	88.0	9.8	50.6
Rexolin of APN 0.02 %	229.0	14.5	103.5	15.5	64.5

Lettuce characterized by high nitrogen (163.2-229.0 mg), potassium (79.1-88.0 mg), and magnesium (57.8-64.5 mg/5 plants) removal. The value of the elements removal from the substrate is associated with lettuce dry matter yield and concentration of elements in it.

Conclusion

On the basis of conducted studies we can conclude the following:

1. Siliplant can't be recommended for growing lettuce in greenhouses because formed a low level of productivity with a high content of nitrates.

2.When growing leaf lettuce in greenhouses can recommend Pouring of substrate with 0.01% Zircon solution, 0.25 % Narcissus solution, or 0.02 % solution of Rexolin APN microfertilizer.

Abstract

It has been shown that the presence of weeds can signifficantly affect the yield of winter rapeseed, especially during years with high humidity. The weed species *Sinapis arvensis*, *Raphanus raphanistrum*, *Stellaria media*, *Solanum nigrum* and *Chenopodium hybridum* are particularly harmful because of their fast development. The study was carried out in 2011/12 (Crvenka, Novi Sad) and 2013/14 (Kovilj, Novi Sad). 14 herbicides and their combinations were applied, to assess the possibility of controlling the weeds in the rapeseed plots and the impact of weed control on the amount of proteins and oils.

The active substance and their combinations: metazachlor and clomazone showed the highest efficacy on annual broadleaf weeds, except on *Sinapis arvensis*, *Solanum nigrum* and *Chenopodium hybridum*. The differences in the quality and quantity parameters of rapeseed, although observed, were not statistically signifficant. The spring application of active substance metazachlor did not show fitotoxicity effects on rapeseed plants.

A higher percentage of oils in the rapeseed was determined at the site Novi Sad in 2011/12, when compared to the site Crvenka. Data analysis of the oil and protein contents in the studied sites in 2013/14 has shown no signifficant differences between the sites.

Therefore, it can be concluded that the observed differences in the oil and protein contents are the result of the effects of climatic factors, the presence of weed species, on which the herbicides weren't efficient enough, edaphic factors, etc.

Keywords: *weeds*, *herbicides*, *rapeseed*, *oil content*, *protein content*

Introduction

Brassica napus, commonly known as rapeseed, is the dominant biofuel crop in the European Union (EU) (van der Velde et al., 2009), with its economic significance increasing worldwide (Kachel-Jakubowska and Szpryngiel, 2008). It is the fourth most important crop by area in the EU, after wheat, maize and barley (Ollier & Utz, 2007), its main producing countries being France, Germany, Poland and the Czech Republic (van der Velde et al., 2009). Further increases in the area covered by rapeseed in the EU are to be expected in the near future (Ollier & Utz, 2007). Rapeseed was sown in Serbia on 6273 ha in year 2000, 13 965 ha in 2006 (with 13133 ha in Vojvodina province), 15000 ha in 2010 and 9686 ha in 2013 (Stat. Yearb. Serb, 2014). The median production of rapeseed for France is estimated to be 22057 t and for Italy 62500 t (FAO, 2013), while for Serbia it is 26992 t (2,8 t/ha) (Stat. Yearb. Serb, 2014). Traditionally, rapeseed has been grown primarily for food, e.g. vegetable oil (40-45%), and for feeding purposes, as a high-protein (25%) animal feed (van der Velde et al., 2009, Roshdy, et al., 2008).

There is ample evidence of the harmful effect of weeds on crop plants, as a result of the competition for light, water, nutrients and space, or as a result of allelopathic interactions between weed species and the crop plants (Rose and Bell, 1982; Roshdy et al., 2008). Many weeds can, in addition to direct damage, also cause indirect damage as vectors of harmful fungi and insects, e.g. weed species *Capsella bursa pastoris* is host to a fungus *Albugo*

candida (Leino, 2006; Antonijević and Mitrović, 2007). Furthermore, the presence of weed seeds in the harvested rapeseed crops can reduce the total yield of oils and proteins (Klaaßen, 2006; Davies, 2005).

Rapeseed, as a slow-growing plant, is particularly vulnerable to the severe competition of weeds. The faster development of weed plants causes shading of the rapeseed, thereby reducing its photosynthetic efficiency and subsequently lowering the final yield and crop quality. Furthermore, weeds with vigorous, highly branched root systems can also deprive the rapeseed of the necessary soil nutrients, thereby inhibiting its development (Roshdy et al., 2008). Longterm agricultural practice has shown that *Sinapis arvensis*, *Raphanus raphanistrum, Stellaria media, Solanum nigrum* and *Chenopodium hybridum* are particularly harmful to rapeseed yield and quality due to their fast development (pers. obs.).

It is important to assess the efficiency of weed control on the reduction of losses in the yield and quality parameters of rapeseed. Therefore, the purpose of this paper is to present the results of an initial study of the effects of herbicide weed control on the yield and quality parameters of rapeseed. The results are based on the yield samples taken from the infested rapeseed fields in two study sites, with the aim to assess the effect of these weed species on the rapeseed yield and quality parameters.

Materials and methods

Weed control in spring rapeseed was carried out in 2011/2012 (loc. Novi Sad and Crvenka) and 2013/2014 (loc. N. Sad and Kovilj), using the standard method for testing the efficiency of herbicides in rapeseed crops (Anonymus, 2007; Table 1). The experiment was set up as a randomized block design with three replicates. Applied herbicides were based on active substances metazachlor and clomazone. Samples for assessment were taken from each treatment (3 times) and compared using the *t-test*. Rapeseed yield and quality were determined by measuring and analyzing the following parameters: grain yield (kg/plot ($30m^2$)), oil content (%) and protein content (%) in the seeds.

Results and discussion

Observed results have shown that the changes in the oil and protein content (depending on the herbicides applied and the presence of weed species) did not significantly affect the rapeseed yield in all of the tested sites (Table 2a).

Also, no effect of climate factors on the rapeseed yield was evident in the locality Novi Sad, when observed in two consecutive growing seasons (results not shown). Peltonen et al. (2008) have concluded that in their experiment the changes observed in the yield were linked to the yield-associated changes in the rapeseed quality. Furthermore, oil yields increased due to both higher oil content and higher yields, while increases in protein yield only resulted from higher seed yields (Peltonen et al., 2008).

Table 2a. Rapeseed yield based on the oil and protein content

locality	year	T value		P value		St.dev

p<0.05*, p<0.01**, p<0.001***

The analysis of the weed species presence and abundance has indicated that the applied herbicides have shown low efficacy on *Raphanus raphanistrum, Stellaria media, Solanum nigrum* and *Chenopodium hybridum*. Very low efficacy was detected for the species *Sinapis arvensis* (loc. Crvenka). Regrowth of plants (10-15%) in the spring has caused the yield reduction (with statistical signifficance, Table 2b). In the locality N. Sad low efficacy was observed on the species *Solanum nigrum* and *Chenopodium hybridum.* Similar conclusions were made by Rose and Bell (1982), who pointed out that growth of some of the weed species such as *Sinapis arvensis* and *Thlaspi arvensis* in rapeseed fields reduced the *B. napus* seed quality, by increasing the level of erucic acid in the extracted oils and the glucosinolates content of the remaining meal. The application of herbicides in the spring, especially those based on the a.s. metazachlor, did not cause the reduction in the grain yield, and oil and protein content. Our results of different methods of weed control testing: 1) chemical and 2) non-chemical method of eradicating weeds by manual hoeing, concur with those obtained by Tanveer et al. (2005). They have concluded that manual hoeing as a method of weed control is not feasible and has become too expensive due to the costs of manual labor. Bearing that in mind, chemical weed control is the best alternative, being less laborious, time saving and more effective.

Table 2b. Comparison of rapeseed yealds from different localities

p<0.05*, p<0.01**, p<0.001***

Using the t-test and obtained data from all locations, there was no statistical significance in the differences between the tested localities, based on the oil content (with the exception of loc. N.Sad, p=0,014, Table 3), and proteins (with the exception of loc. N.Sad and Kovilj, p=0,039, Table 4). Contrary to this, the results of RajabLarijani and Alikhani (2011) indicate that rapeseed yield, yield components and oil percentage decreased significantly due to weed interference.

Table 3. Oil content changes in rapeseed plants

locality	year	Means			T value			P value		
		I	II	III	I	II	III	I	II	III
N. Sad	2011/12	45,90	45,20	45,46	16,96	9,55	8,32	0,000	0,000	0,000

Kovilj		44,06	43,75	42,35						
N. Sad	2011/12	45,90	45,22	45,46	5,42	3,52	2,61	0,000	0,000	**0,014**
N. Sad	2013/14	44,09	43,56	44,22						

p<0.05*, p<0.01**, p<0.001***

Our results (Tables 3, 4) can be explained by the conclusions of Peltonen et al. (2008). Their findings indicate that relatively low variations in seed oil content are strongly determined by the oilseed genotype. This is further supported by the findings that the seed number per square meter also does not correlate with the seed oil content, while the variation in single seed weight is quite similar to that in oil content (Peltonen et al., 2008).

Table 4. Protein content changes in rapeseed plants

locality	year	Means			T value			P value		
		I	II	III	I	II	III	I	II	III
N. Sad	2011/12	17,94	17,56	18,29	-14,43	-5,56	-4,19	0,000	0,000	0,000
Crvenka		22,38	20.56	19,93						
N. Sad	2013/14	21,98	22,00	21,22	4,02	4,25	-2,16	0,000	0,000	**0,039***
Kovilj		20,83	21,45	22,00

N. Sad	2013/14	22,00	21,33	21,21						

p<0.05*, p<0.01**, p<0.001***

The hectoliter weight of seed ranged from 69,0 to 70,2 g in the loc. of Kovilj, from 67,5 to 68,8 g (in 2013/14) and from 67,4 to 69,0 g (in 2011/12) in the loc. N. Sad and from 67,6 to 69,0 g in the loc. Crvenka. In our study, the 1000 seeds weight in all of the localities was between 4,27 (recorded in the weedy check) and 5,40 g, while Khan et al. (2003) have previously documented a stronger effect of weeds on the 1000 seeds weight - 2,27 g.

Conclusions

The results of this research have shown that the changes in the oil and protein content did not affect the yield of the rapeseed. Also there were no statistically significant differences observed in the oil and protein contents in the seeds between locations. Furthermore, the application of the tested herbicides in the early spring has not caused a reduction in either the grain yield or the oil and protein content of the rapeseed, hence it can be said that no effects on yield were registered due to the good effects of tested herbicides.

MORPHOLOGICAL AND MOLECULAR IDENTIFICATION OF FUSARIUM SUBGLUTINANS, PATHOGEN OF ANISE SEED IN SERBIA

Danijela RISTIĆ[1]*, Snezana PAVLOVIĆ[1], Nenad TRKULJA[1], Milica AĆIMOVIĆ[2], Erika PFAF-DOLOVAC[1], Nenad DOLOVAC[1], Mira STAROVIĆ[1]

Abstract

During 2012 and 2013 aniseeds were collected in three localities in the province of Vojvodina (Mošorin, Veliki Radinci and Ostojićevo). Conventional mycological seed testing revealed significant seed infection with *Fusarium* spp. ranging from 2-18%. From the infected anise seed, monosporial cultures, based on morphology, were identified as *Fusarium subglutinans*, and their pathogenicity proved on artificially inoculated anise seedlings. Molecular identificaton was performed utilizing polimerase chain reaction (PCR) with primer pair EF1/EF2 and by amplification of the translation elongation factor-1 alpha (*tef-1α*) gene. The sequence analysis of *tef-1α* region revealed that Serbian isolate A5 (GenBank Accession No. KP126606) shared 100% nt identity of with sequences of seven *F. subglutinans* isolates deposited in the GenBank. The presence of a large number of phytopathogenic fungi on anise seed should be further investigated in order to clarify their relationships and relative significance.

Key words: anise seed, *Fusarium subglutinans*, molecular identification, morphological features, pathogenicity test

Introduction

Anise (*Pimpinella anisum* L.) is an annual important spice and medicinal plant belonging to the family *Apiaceae*. Aniseed is cultivated in Turkey, Asia, South Africa, Europe and America. The anis fruit oil is used in the pharmaceutical industry to mask odors and for flavoring. The aniseed has economical importance as a flavoring agent also in food and perfumery industries (Baser, 2002; Tabanca et al. 2007). Since anise is an attractive ornamental and medicinal species, with seeds rich in essential oils, its production in Serbia has increased over the last decade. Recently, an increasing interest in the cultivation and production of medicinal and aromatic plants has been noticed (Mahmoud, 1996), but the farmers are facing a significant low productivity and low content of active ingredients in these plants because of fungal diseases and also the synthetic chemicals which are employed as fungicides in crop protection (Fiori et al. 2000; Hashem et al. 2010).

The genus *Fusarium* is widely found in plant debris and crop plants worldwide (Marasas et al. 1984). Several species from this genus are economically relevant because, apart from their ability to infect and cause tissue destruction on important crops such as corn, wheat and other small grains on the field, they produce mycotoxins on the crops in the field and in storage grains (Dambolena et al. 2010; Whang et al. 2011). Diseases that are reported on anise are being intensivly studied in many countries worldwide, while in Serbia published literature data about anise pathogens are scarse although disesases cause major problems to anise production. *Fusarium* spp. were common pathogens on anise seed during 2012 and 2013 at the cultivating plantation of the Institute for Medicinal Plants Research “Dr Josif Pančić”, Belgrade (Serbia).

Consequently, the objectives of this study were to identify the *Fusarium* species of anise seeds for the first time in Serbia based on morphological and molecular characteristics.

Material and methods

Identification of *Fusarium* species

During 2012 and 2013 aniseeds were collected in three localities in the province of Vojvodina (Mošorin, Veliki Radinci and Ostojićevo). A hundred aniseeds were randomly chosen from every sample in 4 replications. For agar plate method, the aniseeds after surface sterilization with 2% NaOCl for 2 min, were rinsed twice in sterile distilled water and dried on sterile filter paper in a laminar flow cabinet. Aniseeds from each sample were placed on PDA and the Petri dishes were incubated for 7 days at 25°C with a 12 h dark ⁄ light cycle (Singh et al. 1991). The fungal species present on each seed were recorded and the percentage incidence of each fungus per sample was computed.
The morphology of macroconidia, microconidia, conidiogenous cells and the chlamydospores was assessed from cultures grown on Spezieller Nahrstoffarmer Agar (SNA) and carnation leaf agar (CLA). Colony color and colony diameter were recorded after 7 days of growth on PDA (Burgess et al. 1994). Morphological identifications of isolates were made using the criteria of Gerlach and Nirenberg (1982) and Leslie and Summerell (2006).

Pathogenicity

Pathogenicity tests were conducted on five healthy, 1-month-old seedlings of anise in a moist chamber. Plants were separately inoculated in pots with sterilized soil and 10 ml of *Fusarium* sp. isolate spore suspension (1×10^6 conidia/ml). Control plants were inoculated with sterile soil without spore suspension. After inoculation, the plants were placed in a humidity chamber for 24h and then transferred to a greenhouse maintained at 27°C. The development of symptoms on inoculated and control seedlings were observed for 10 days. The inoculated fungi were re-isolated from the infected plants to prove the Koch's postulates.

PCR detection and sequencing

Total DNA was extracted from fungal mycelium with a DNeasy Plant Mini Kit (Qiagen, Hilden, Germany) following the manufacturer's instructions. PCR was carried out for the identification of *Fusarium* species by amplifying the translation elongation factor-1α gene (*tef-1α*) using the primer pairs EF1 and EF2 as described in O'Donnell et al. (1998). PCR was performed in a 25 µl l final reaction mixture containing 12.5 µl 2 X PCR Master mix (K071, Fermentas, Lithuania), 9 µl RNase-free water, 1.25 µl each of both forward and reverse primers (100 pmol/µl, Metabion International, Deutschland) and 1 µl template DNA. DNA amplification was performed in a Thermal Cycler PCR system 2720 (Applied Biosystems).
Amplified products were analyzed by 1% agarose gel electrophoresis, stained with Midori Green DNA Stain (Nippon Genetics), and visualized under a UV transilluminator. Sequencing in both directions was performed on an automated sequencer (ABI 3730XL Automatic Sequencer Macrogen, Korea). Sequence generated in this study was deposited in the National Center of Biotechnology Information (NCBI) GenBank database. Sequence of Serbian representative isolate (A5) was compared with sequences of *Fusarium* species available in the GenBank database (http://www.ncbi.nlm.nih.gov/BLAST/) using the ClustalW program (Thompson et al. 1994) and MEGA5 software (Tamura et al. 2011).

Results and discussion

Conventional mycological seed testing revealed significant seed infection with *Fusarium* spp. ranging from 2-18%. In this study, a total of eight *Fusarium* isolates were obtained from aniseeds, collected in three different localities in the province of Vojvodina. Based on their morphological characteristics, these isolates were identified as *F. subglutinans*. After 7 days of incubation at 25°C under 12 h of dark ⁄ light cycle, eight monoconidial isolates formed colonies with white aerial mycelium, purple pigment in agar and orange sporodochia on the surface of PDA (Fig.1a,b). Within the colony, microconidia were hyaline, non-septate and ovoid, and ranged from 12.5 to 16.5 × 3 to 3.5 µm (Fig.1d). On CLA colonies produced thin-walled macroconidia with 3 to 5 septa, a foot-shaped basal cell and a curved apical cell (33-51 x 2.5-3.6 µm from 100 measured) (Fig.1c). The morphological characteristics of the pathogen correspond with the records for *F. subglutinans* described by Leslie and Summerell (2006).

A total of eight isolates of *F. subglutinans* obtained from naturally infected seedlings of anise were tested for pathogenicity. Within 10 days, inoculated plants developed leaf wilt, stunted growth, discolored vascular tissue on stems, and finally died. No symptoms were observed on any of the control seedlings.

The amplification of *tef-1α* produced a sequence of 629 bp (Fig. 2) for *F. subglutinans*. The sequence analysis of *tef-1α* region revealed that the representative Serbian isolate A5 (GenBank Accession No. KP126606) shared 100% nt identity of with seven *F. subglutinans* isolates deposited in the GenBank from China (JX456582 to 83, KC964122 to 23 and JQ639211), and USA (JF270302 and JF270288).

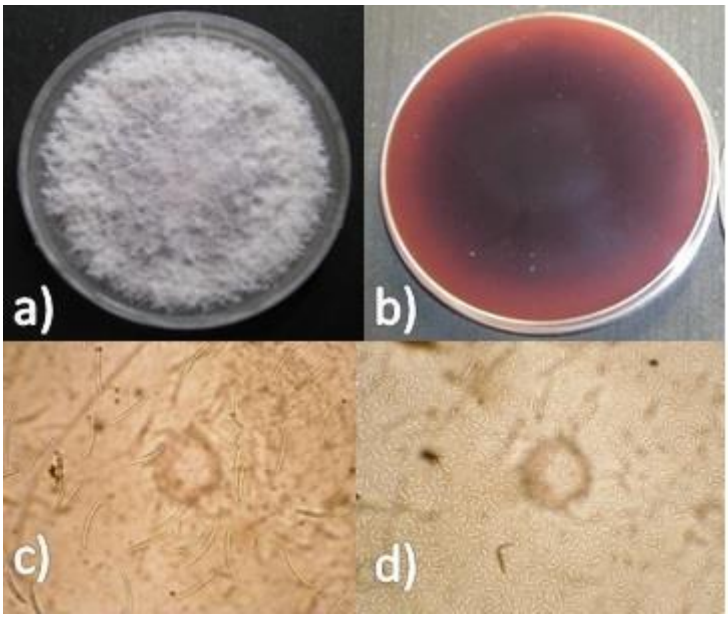

Fig. 1. *F. subglutinans:* a) surface side after 10 days of grown on PDA. b) reverse side. c) macroconidia. d) microconidia

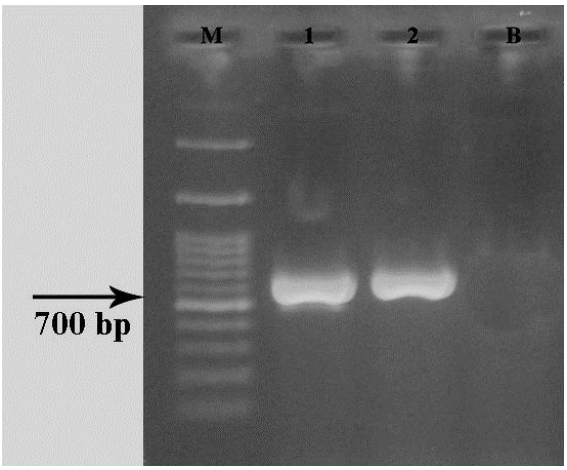

Fig. 2. Electrophoretic analysis of PCR products obtained using primer pair EF1/EF2. Lanes: M - Mass-Ruler^{TM}DNA ladder, Mix (Fermentas Life Sciences GmgH, Lithuania); 1 - isolate A5; 2 - positive control (*F. proliferatum*); 3 - negative control (PCR mix with Rnase-free water)

This study represents the first report which identifies pathogens of *F. subglutinans* in anise seeds in Serbia. This pathogen identification was based on the morphological pathogenicity and molecular identification. Because *F. subglutinans* can cause further losses through the contamination of crops with mycotoxins, these infected seeds are of poor quality reducing the market value of the produce. The obtained results are of great importance as they support the reliable and quick protocol for molecular identification of this pathogen, as a prerequisite for implementing efficient control measures. Previous studies of mycopopulation of anise seeds showed only *Bipolaris sorokiniana* (Pavlović et al. unpublished data) and *Alternaria alternata* presence (Stanojković-Sebić et al. 2014) in Serbia.

Conclusions

From the results obtained in this study, based on the cultural, macroscopic, microscopic and molecular characteristics, selected isolates from anise seeds were identified as *F. sublutinans*. The representative isolates A5 showed the highest nt homology of 100% with seven *F. subglutinans* isolates from China and USA. To our knowledge, this is the first report of natural infection of anise seeds by *F. sublutinans* in Serbia.

Abstract

Charcoal root rot, caused by *Macrophomina phaseolina* is potentially the most destructive sugar beet pathogen in Serbia, especially during extremely warm and dry season. Reaction of eleven sugar beet genotypes (G1-G11) was tested to *M. phaseolina* using artificial inoculations in controlled, laboratory conditions. The aim of this research was to optimize methods of testing pathogenicity of *M. phaseolina* on sugar beet. Development of such methods would enable testing a large number of commercial genotypes which are grown in Serbia in order to improve control measures against this pathogen, but also to test different sugar beet germplasms for the purpose of breeding for resistance. Three week old plants were inoculated with *M. phaseolina* grown on sorghum seed. Root rot intensity was evaluated after seven days using scale from 0 (healthy plant) to 4 (complete necrosis of hypocotil and root). Results of this research showed that sugar beet genotypes reacted significantly different to this pathogen – root rot intensity in average varied from 1.5 to 3.3. These results showed that more resistant sugar beets can be recommended for planting in areas with high density of *M. phaseolina* inoculum in soil.

Key words: *Macrophomina phaseolina, charcoal root rot, sugar beet, pathogenicity, resistance*

Introduction

Charcoal root rot, caused by *Macrophomina phaseolina* is economically the most important and the most damaging sugar beet root disease in Serbia. Infections are favored by dry and warm conditions, especially those in which sugar beet are grown without irrigation. The disease is most evident at the end of the season, although the fungus can be isolated from beet roots through the growing season (unpublished data). Symptoms are similar as reported on soybean and most apparent under conditions that reduce plant vitality (Kendig et al., 2000), such as high soil temperature, drought, reduced fertility, inadequate cultivation practices, poor soil structure and root injuries from root pests, such as sugar beet root aphids (*Pemphigus fuscicornis*) and other (Stojšin et al., 2012a).

Primarily wilt and subsequently leaf decay occur on individual plants. Later, severely affected roots become rotten while leaves are completely dry. Internally, roots are spongy and dehydrated whereas the color of the inner root tissue can vary from lemon yellow, light or dark brown to black, depending on sugar beet variety, environmental conditions and soil moisture (Stojšin et al., 2012b) – Figure 1.

Figure 1. Symptoms of charcoal root rot on sugar beet root

The parasite survives in plant remains in the field as mycelia and microsclerotia-overwintering structures. Microsclerotia may survive in soil for many years and they are always present in soil in sufficient amount. Infection may occur on young roots, after which parasite spreads through vascular system, while characteristic symptoms appear after plants are being stressed due to drought (Stojšin et al., 1999).

Together with climate changes, which will eventually lead to warmer and drier parts of vegetative season, it is expected that in future charcoal root rot becomes even more significant problem in sugar beet production. Given that *M. phaseolina* is very virulent and polyphagous, the most effective control measure would be use of disease resistant cultivars (Stojšin et al., 2012a).

Therefore, the aim of this research was to test a reaction of 11 sugar beet cultivars and germplasms to inoculations with *Macrophomina phaseolina*. It is expected that results of this research contribute to optimization of pathogenicity tests which will be used for detection of resistance genes in sugar beet cultivars.

Material and methods

Isolate ŠR 62/4 which was used for artificial inoculations was isolated from sugar beet root with severe symptoms of charcoal root rot in 2009. Sugar beet at the locality of isolate's origin suffered great damages during 2009 (locality Ečka, Vojvodina province, Serbia). Inoculum was prepared by colonizing sorghum seed (Omar et al., 2007).

Eleven sugar beet cultivars (G1-G11) were tested. Plants at the two leaf stage were replanted in 500cm³ pots in homogenous containing mixture of sterile sand and inoculum in volume a ratio 3:1 ratio (v/v) (sand:sorghum seed). For the negative control, plants were grown in non inoculated sterile sand. Plants were incubated in a growth chamber at 30°C with a photoperiod of 16h/8h light/dark and watered daily. Symptom development on leaves was assessed daily, while final evaluation of root and hypocotyl necrosis was performed after 7 days, when over 80% of leaves of most susceptible cultivar showed symptoms of irreversible wilting.

Root and hypocotyl necrosis was rated using a scale from 0 to 4 which is explained in Table 1 and Figure 2. Based on average pathogenicity isolates were grouped into three groups: i) low pathogenic 0-1, ii) moderately pathogenic 1-2, iii) highly pathogenic 2-4.

Table 1. Scale for evaluation of symptom development on hypocotil and root.

Grade	Symptom
0	Healthy plant
1	Individual lesions on hypocotyl and root
2	Merging of lesions on hypocotyl and root
3	Section necrosis on hypocotyl and root
4	Complete necrosis of hypocotyls and root

Figure 2. Scale for disease intensity evaluation on sugar beet hypocotil and root (from right to left: 0-healthy plant, 4- complete necrosis of hypocotyls and root).

In order to fulfill Koch's postulates, reisolation of *M. phaseolina* from inoculated plants was performed on standard PDA (Potato Dextrose Agar) with addition of 50µg/ml of streptomycin sulphate. Reisolations were done from 10 plants rated 2 and 3 per cultivar.
Statistical analysis was performed in Statistica 12 software (StatSoft, Tulsa, OK) using ANOVA and Fisher LSD test at p=0.05.

Results and discussion

Seven days after inoculation, 83% of leaves of sugar beet cultivar G4 irreversibly wilted or decayed (Chart 1). At that moment, all plants were pulled out and intensity of charcoal rot on hypocotils and roots was evaluated. Disease severity on root and hypocotil of 11 sugar beet genotypes are shown in Chart 2.

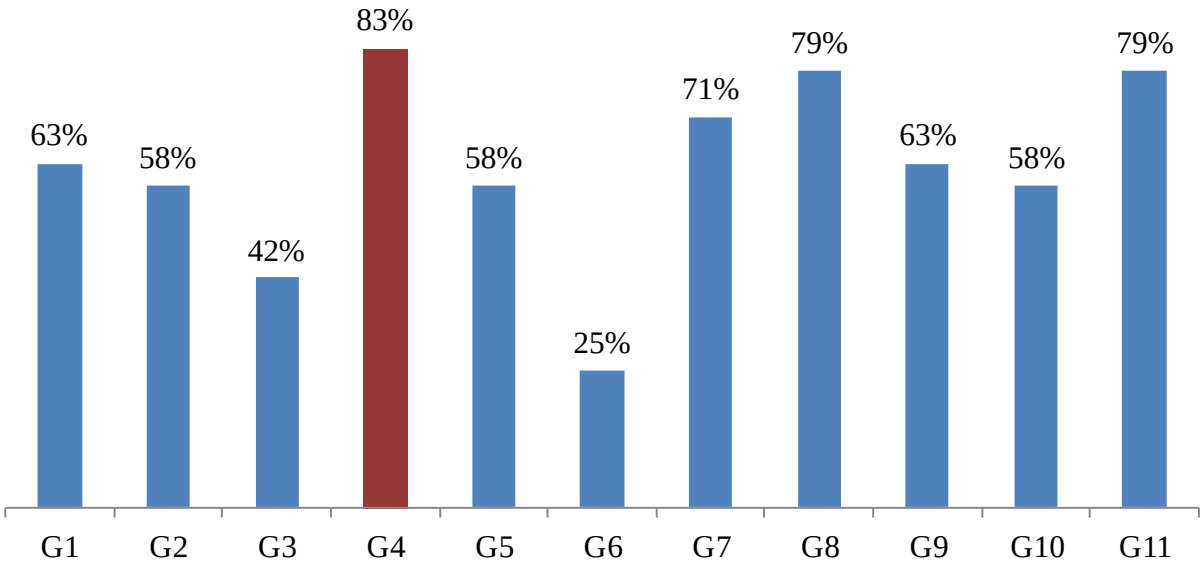

Chart 1. Decay and wilting registered seven days after inoculation (%)

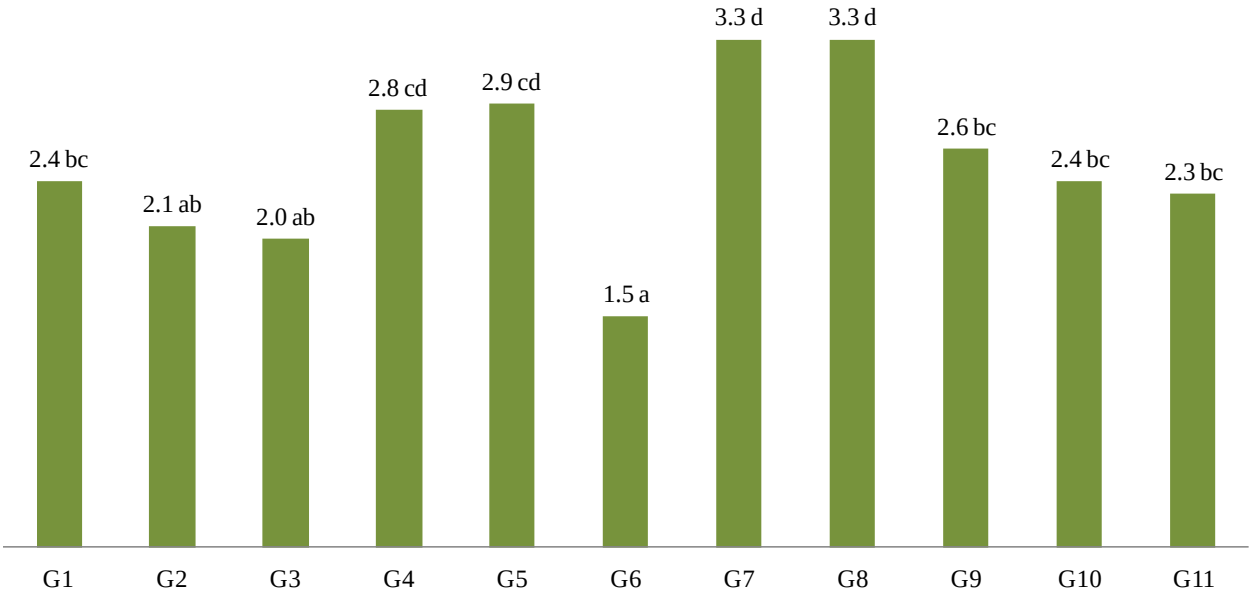

Chart 2. Disease intensity on hypocotils and roots of 11 sugar beet genotypes. Values not connected by the same letter are significantly different at $p<0.05$.

According to leaf ratings, G4 reached 83%, whereas G8 and G11 showed 79% of irreversible wilting and decay 7 days after inoculation (Chart 1). Symptoms on roots and hypocotil corresponded to wilting and decay in case of cultivars G4 (2.8) and G8 (3.3), which belonged to the group of the most susceptible cultivars (Chart 2). As most resistant to charcoal root rot was G6, which showed slowest leaf decay after 7 days (25%) and lowest intensity of root and hypocotil necrosis (1.5).

All cultivars in non-inoculated control were healthy, no wilting or decay was noted and hypocotil and roots were rated 0 (Figure 3).

In order to fulfill Koch’s postulates, reisolation of fungus from infected root with typical simptoms was performed. Results showed that *Macrophomina phaseolina* was isolated in 100% of cases.

Figure 3. Non-inoculated plants (upper row) and inoculated G4 (lower row).

Macrophomina phaseolina is a soil-borne plant pathogen which causes charcoal root rot in different crops including sugar beet. Variations in morphological, cultural, pathogenic and genetic characteristics among isolates are present and well investigated (Sharma et al., 2003; Purkayastha et al., 2006; Iqbal and Mukhtar, 2014). However, the main challenges considering this parasite are means of control. Different measures were described and tested including biological control using *Bacillus subtilis* (Singh et al., 2008), *Trichoderma* species (Ramezani, 2008), fluorescent *Pseudomonas* and *Bacillus* strains (Pal et al., 2001), which all showed potent in control of *M. phaseolina*. Fungicide applications were also tested (Cohen et al., 2012), however, their utilization and cost effectiveness in sugar beet production in Serbia are yet to be investigated. According to Stojšin et al. (2012a), since sugar beet in Serbia is mostly produced without irrigation, environmental conditions have primary significance in disease incidence. Therefore, the most suitable disease control would be breeding sugar beet for resistance similarly as in common bean (Hernández-Delgado et al., 2009) and soybean (Smith and Carvil, 1997).

Conclusions

Significant differences in response of cultivars to infection with *Macrophomina phaseolina* exist. This implies that genes that have an effect on susceptibility of plants during infections with this pathogen could be targeted in order to breed sugar beet for resistance to charcoal root rot. This method should be used for further testing of larger number of cultivars with different response to infections with *Macrophomina phaseolina* in the field.

Abstract

The production of healthy food and preserving the environment is a fundamental objective of modern agricultural production. Proper chemical protection is important for preventive crop protection against diseases, pesticides control, protection against disease and controlling weeds. In Serbia in the category "attachable unit" there was a total of 138.084 sprayers and 17.281 atomizers. Percentage of sprayers more of ten years old in the Republic of Serbia is 82%. This data points out to the fact that protection, as well as agro-technical measures, in Serbia are performed with the unreliable devices that may seriously undermine production. Plant protection department of the Ministry of agriculture and environment of the Republic of Serbia in accordance with the Directive of the European Parliament 2009/128 EC establishes a framework for the control systems of sprayers and atomizers. According to the standards of the European Union (EU) is necessary to optimize the consumption of pesticides and reduce their harmful impact on the environment and human health. Testing of working machines is in accordance with the European norms EN 13790 which prescribes methods and equipment used to perform inspections. This allows agricultural producers to export their products to the EU market which need to fulfill all the conditions prescribed by the "Global G.A.P." standard. This directive becomes current in our country, so that the adoption of relevant legislation in this field is expected in the future, together with Serbian joining in EU.

Key words: *technical control, pesticides, sprayers, atomizers*

Introduction

The main task of modern agriculture is the production of safe food. Regular and agro-technical measures inevitable in the process of agricultural production is the care and protection of crops from diseases, pests and weeds. The chemical method of protection is now the primary means of plant protection. Pesticides are intended to prevent, destroy or control pests, but their remains in food, water, soil and animal feed have resulted in poisoning of wildlife and domestic livestock, environmental pollution and disruption of ecological balance (Bugarin et al., 2010; Srivastava, 2014).

Using the correct techniques and controlled application of pesticides, in favorable weather conditions, increases the effect of protection, and reduce losses of toxic pesticides and soil pollution, as well as surface and ground water. According to research on the effectiveness of pesticide application has been shown to phytotherapeutic effect of pesticides and economy of the process depends to 70% of high-quality applications where 40% depends on the condition and safety of machinery and 30% is professionalism user machines for the application of pesticides. The remaining 30% relates to the use of appropriate pesticides, timeliness of application of protective agents, resistance and others. (Urosevic, 2001).

In Serbia, the use of pesticides is further complicated by inadequate technical level of the application device; testing new machines in operation are generally not enforced, and often

operate machines insufficiently trained persons. (Sedlar et al., 2007; Sedlar et al., 2014). The quality of treatment machines for application in connection with the correctness, adjustability, technical solutions and contemporaneity of machines affect the accuracy of distribution, dosing accuracy and size of the losses (Bugarin et al., 2008).
The introduction of HACCP and "Global GAP" standards in agricultural production guarantees the health safety of products, and the absence of pesticide residues, especially in fresh vegetables and fruits (Koprivica et al., 2015).
Suppression of pathogens and pests is based on the fast and precise distribution and application working fluid, pesticides, respecting working conditions (Višacki et al., 2014). The most important factor spraying machines represent nozzles. They perform important functions such as leakage given amount of liquid per unit time, making disperse liquid droplets of appropriate size and form a stream of appropriate shape (Tadic et al., 2014, Bajkin et al., 2014). Defective nozzles that give higher or lower flow rate due to worn or clogged need to be replaced with new ones.
The EU introduced regulations required inspection of technical means of plant protection directive 2009/128 / EC and 2006/42 / EC, which is the basis of the standard EN 13790 (Banaj et al., 2014). To agricultural producers could export their products to the EU market need to fulfill all the conditions laid down by the "Global GAP" standard (GAP - Good Agricultural Production). This covers the protection of consumers' health, measures to control and limit the use of pesticides and certification of products. Within this standard have significant role nozzles and sprayers that are commonly used as a machine for the application of pesticides in crop farming, orchards and vineyards.
In Serbia in the category "attachable unit" there was a total of 138.084 sprayers and 17.281 atomizers (Radivojevic, 2014). The Republic of Serbia is legally required since 1999 to inspect sprayers and air assisted sprayers. Testing the proper working of machines is carried out in accordance with grading EN 13790 which prescribes methods and equipment used to perform control. Control stations (31 on the territory of Serbia) are equipped with the latest technology to control. The equipment for testing is from a Belgian manufacturer AAMS-Salvarani.
There are two central laboratories in the Faculties of Agriculture in Belgrade and Novi Sad, and other regional laboratories in institutes, agricultural stations and schools. Among the accredited laboratories and the laboratories of the Institute for forage crops in Globoder-Krusevac and is responsible for testing the machines for plant protection in the Rasina district.
The aim of this study was to carry out practical testing of nozzles and the pressure gauges to several types of agricultural sprayer to determine the accuracy and uniformity of flow measurement and flow to nozzles.

Material and method

In July 2015, in a control station in Institute for forage crops in Krusevac-Globoder (Serbia) technical testing of plant protection products was carried out. This is taken to the testing of nozzles and the pressure gauges to six types of agricultural sprayer and determines the correctness and uniformity of flow measurement and flow to nozzles.
Since the equipment was used Nozzle Flow Rate Tester S001 (Figure 1) and controller manometer (Figure 2). Flow measurement is performed at a pressure of 3 bar and rpm PTO 540 min^{-1}. Faulty nozzles represent the biggest problem for the proper functioning of machines for plant protection. In practice, it often happens that the openings in the nozzles clog due to mechanical impurities or water quality or worn during prolonged use, which significantly affects the quality of spraying.
AAMS Salvarani Nozzle Flow Rate Tester is a handheld portable device designed for fast and precise control characteristics and wear nozzles. It is a device that defines the flow of all types

of nozzles mounted sprayers, accuracy class 1%. If it is determined by measuring the flow nozzles deviate by more than ± 10% of Tablet value in a given operating pressure, according to EU standards such nozzles are removed from use.

Figure 1. AAMS-Salvarani Nozzle Flow Rate Tester S001

Control gauge is done by comparing the pressure on the gauge to be tested with the reference pressure gauge manufacturer WIKA. According to European norms gauges that are installed on the machines for plant protection products must have a minimum diameter of 63 mm and the accuracy of the pressure gauge to be tested must be ± 0.2 bar for measuring range up to 2 bar. If it is a larger area measuring deviation may be up to ± 10%.

Slika 2. Tester pressure gauge with "Wika" reference pressure gauge

AAMS Salvarani Pumptester is used to determine the actual capacity of the pump at different pressures. This instrument shows the pressure and flow of liquids.
To check the spraying machine in accordance with EN 13790 is necessary to check about 40 different requests. Some checks are carried out visually, while others need to perform certain tests. Visual inspection is done by reviewing the state hoses, tanks and filters, with the sprayer switched on to work for 1 minute at a pressure of 3 bars. The sprayer is then switched off and check for dripping fluids on nozzles, intestines and anti-drop devices.
Distribution of fluid beneath the wing has a direct impact on the quality of nozzles and distribution of liquid in the operating conditions. The measurement is performed Spray scanner. The spray scanner works automatically under the boom until it performs measurement of the entire length of the boom. To determine the flow of individual nozzles mounted on sprayer used AAMS Salvarani Single Nozzle Tester for atomizer.
Sprayer type A is mounted sprayer manufacturer "Agromehanika" from Kranj, with 19 nozzles. The capacity of the pump sprayer 60 l min^{-1} and the volume of the reservoir for

liquid is 400 l. Sprayer types E is also mounted sprayer "Agromehanika" from Kranj tank volume 330 l, pump capacity 60 l min^{-1}. The sprayer B is driven by volume 400 l Swiss manufacturer "Fischer". Sprayers C, D and F are mounted sprayer 330 l (M 330 Lux) producers "Morava" from Pozarevac. Number of nozzles varied depending on the type of sprayer. Ranged from 16 (C, D, E, F), 19 (A) and 22 (B).

Results and discussion

Faulty nozzles represent the biggest problem for the proper functioning of machines for plant protection. In practice, it often happens that the openings in the nozzles clog due to mechanical impurities or water quality or worn during prolonged use, which significantly affects the quality of spraying.

Test results flow of the working fluid during the test using a sprayer flow meter individual nozzle S001, as shown in Table 1. The table shows the average value of three repetitions. Six different types of sprayer were tested (A, B, C, D, E, and F).

Table 1. The flow of the working fluid crop sprayers

Number of nozzles	The flow of the working fluid crop sprayers (l min^{-1})					
	The type of sprayers					
	A	B	C	D	E	F
1.	1.072	0.824	0.904	1.094	0.545	0.636
2.	0.946	1.242	1.085	1.362	0.632	1.681

19.	1.508	1.089	-	-	-	-
20.	-	1.089	-	-	-	-
21.	-	1.001	-	-	-	-
22.	-	1.178	-	-	-	-
Average	1.258	1.198	0.938	1.411	0.747	1.304
CV (%)	16.209	10.611	5.131	11.714	18.885	5.137

The highest variability of nozzles operation was established for the nozzles E and A (CV% = 18.885% and CV% = 16,209) and the lowest for sprayers C and F (CV% = 5.131 and CV% = 5.137%). This indicates that the sprayer E and A not we allowed using all the nozzles on the nozzles while the C and F use of all nozzles was acceptable.

Minimum flow of the working fluid amounted to 0.444 l min^{-1} in F-type nozzles as a result of malfunctioning nozzles, or clogged nozzle. Maximum flow of the working fluid was 1.746 l min^{-1} nozzles in type A which is due to deterioration of the nozzles. The lowest average flow was 0.747 l min^{-1} in E-type sprayer manufacturer "Agromehanika" from Kranj, which was also the latest of the tested sprayer. The highest average flow of the working fluid amounted to 1.411 l min^{-1} in type sprayers D.

Conclusion

Based on the analysis of the current status of implementation of pesticides for agricultural producers in Serbia in Rasinski district can be concluded that the sprayers are very old, except sprayers type D, which is four years old. The nozzle gauges were defective, there were no gauges or used inappropriate pressure gauges, the nozzles A built-in pressure gauge measuring range much larger than necessary.

It is necessary to replace the corresponding faulty gauges pressure gauges to control the proper operation of the nozzles. In some nozzles do not work regulating valves regulating the working pressure sprayer. It was also revealed that the nozzles are not working valves which are used for closing the liquid flow through the boom.

On the sprayer type D membrane air bells at the pump was not correct, causing uneven spray of working liquid. There are significant variations in the flow of the working fluid as a result of wear or nozzles were closed on orifice nozzles. Such nozzles should be replaced with new nozzles respective hole. When working with the correct and well-tuned devices for the application of pesticides manufacturers can realize profit.

Abstract

It has been showed that apple is host of *Venturia inaequalis*, a very aggressive phytopathogenic fungus known for production scab. In search for ecological ways for prevention and reduction of disease symptoms, biological control using indigenous fluorescent *Pseudomonas* isolates has been offered as a possible solution. The aim of this study was to examine the activity of some indigenous isolates of the genus *Pseudomonas* (B25, Q16) to prevent ascospores germination and pseudothecia forming of pathogenic fungi *V. inaequalis*, in order to minimize the infection potential of pathogens and prevent apple infection. In this experiment we used a series of concentrations of B25 and Q16 isolates of the genus *Pseudomonas* as a biological agent that has shown good antagonistic effect. Copper hydroxide was used as a standard treatment and non-treated plants as a control. Ascospores, which are exempt from the pseudothecia maceration, isolated from samples of owervintering apple leaves, were exposed to the mentioned agents. Readings of results were carried out after 24 and 48 hours.

The obtained results showed that the complete inhibition of ascospores germination achieved at a concentration of 10^8 $CFUml^{-1}$of isolate B25, while a high percentage of inhibition relative to the standard was achieved at a concentration of 10^7 $CFUml^{-1}$of the same isolate.

In prevent of pseudothecia forming best results showed Q16 isolate (24.4% formed pseudothecia), followed by B25 isolate (68.3%) comparing to the cooper hydroxide as a standard with 78.0% formed pseudothecia and control (100%).

Keywords: *antagonisme, apple scab, ascospores*

Introduction

Plant diseases caused by phytopathogenic fungi are one of the major problems in orchard plants in Serbia. Apple scab caused by *Venturia inaequalis* (Cooke) Winter (anamorph *Spilocaea pomi* Fr.) is the most important apple disease. Chemical control with fungicides has been the main measure of disease control (Ivanović, 2001). During the growing season, in order to keep the trees scab free, more than 20 fungicide treatments may be needed (MacHardy, 1996; Ivanović, 2001). In order to protect apple trees from the apple scab, a wide spectrum of different chemical preparations is used from different chemical groups, with different modes of action (preventative, preventative-curative, curative and eradicative) which are often combined in order to enhance their effectiveness or to avoid the development of resistance. Unfortunately, fungicide resistance has been observed in some orchards. Turechek *et al.* (2004) as well as many other researchers warn about the strobilurin fungicides resistance for example.

Therefore, the application of natural microbial antagonists to control apple scab could be a promising alternative to the application of synthetic fungicides (Hossain *et al*. 2009). Biological control represents an efficient alternative or an additional plant protection method which and reduces the need for chemical agents (Postma *et al*., 2003; Welbaum *et al*., 2004).

The agents which are used in biological control are numerous microorganisms, including a special group of rhizospheric bacteria also known as a plant growth promoting rhizobacteria (PGPR) (Cattelan *et al*., 1999; Zehnder *et al*., 2001). Bacteria from the genus *Pseudomonas* represents one of the most widespread and efficient PGPR in biological control of different plant pathogens - fungi, bacteria and viruses (Cattelan *et al*., 1999; Gerhardson, 2002). *Pseudomonas* spp. produce various secondary metabolites with antagonistic effects: antibiotics (phenazine, 2,4-diacetylphloroglucinol, pyoluteorin, pyrrolnitrin), siderophore, cyanohydrin, tensin, homoserine lactone, cyclic lipopeptide, (Nielsen *et al*., 2002; Raaijmakers *et al*., 2002; de Souza, 2003; Nielsen and Sørensen, 2003). This is the reason why they can be used in the plant protection formulations.

When investigating suitable ecological ways for prevention and reduction of disease symptoms, biological control using indigenous fluorescent *Pseudomonas* isolates has been presented as a possible solution. The key purpose of the biological control is to reduce the inoculum density and the activity of the pathogens that cause disease (Baker and Cook 1974). Therefore, identifying naturally occurring harmless and/or beneficial microorganisms and a subsequent analysis of their biocontrol potential is still a focus of current research (Hyakumachi, 2013).

The aim of this study was to examine the activity of some indigenous isolates of the genus *Pseudomonas* (B25, Q16) in preventing the germination of ascospores and formation of pseudothecia of the pathogenic fungi *V. inaequalis*, in order to minimize the infection potential of this pathogen and prevent apple infection. In this paper, both the germination of ascospores and the formation and maturation (ripening) of pseudothecia were examined.

Material and methods

The *in vitro* conditions were used for the examination of three bacterial isolates of genus *Pseudomonas* (Q16p, Q16L and B25) in order to determine inhibition of *V. inaequalis* ascospores germination. Ascospores were released by maceration of the pathogen's pseudothecia which were extracted from the tissue of overwintered infected apple leaves. Pseudothecia were extracted according to the Aleksić (2006) and Aleksić *et al* (2014) method. These pseudothecia were transferred to the microscopic slide in the drop of suspension of the *Pseudomonas* isolate.

V.inaequalis pseudothecia were further macerated in order to release the ascospores, then covered with a **cover slide** and transferred to the Petri dish with a moist filter paper. These slides were left in darkness to incubate at a temperature of 20°C for 24 to 48 hours, after which the counting of the ascospores' germination was performed. This set up was repeated five times. In order to ascertain germination, 100 ascospores per repetition were examined under the microscope, magnified 400 times. The preparation Funguran OH (copper hydroxide) was used as a standard as well as the untreated control. Three bacterial isolates of the genus *Pseudomonas* (Q16p, Q16L and B25) were used for the examination in a series of five concentrations in the intervals from 10^9 to 10^4 whereas the standard was used in five concentrations of application (0.8; 0.4; 0.2; 0.1 and 0.05%). 0.4% and 0.2% are recommended commercial concentrations. *Pseudomonas* isolates are cultivated on a liquid Waxman medium at 26°C using orbital shaking incubator at 100rpm for 24h, then optimized to 5 x 10^6 $CFUml^{-1}$.

The field experiments were conducted at the start of the vegetative growth in the period from February to April 2014 in an apple orchard PKB-Agroekonomik-Padinska Skela, Belgrade. A Polyvinyl chloride (PVC) net of $1m^2$ was placed tightly over the overwintered leaves, on the orchard floor, under the apple trees of the Golden Delicious cultivar. After that, the three treatments spaced over time, were performed using the following suspensions of bacterial isolates: 2ml x 10^9 $CFUml^{-1}$ of Q16L or 2ml x 10^8 $CFUml^{-1}$ of B25 with a hand sprayer using

100ml of water/m^2 (1000 l/ha). Treatments were carried out on 22 February, 9 March and 25 March. Funguran OH at a concentration of 0.4% (50% copper-hydroxide) and an untreated control were used for comparison.
Following the application of the suspensions, the samples of overwintered leaves were collected on 10 April. From every combination, 50 leaves were sampled after which the pseudothecia were extracted using a binocular lens. Pseudothecia from the sample were transferred to a drop of water on the microscopic slide, macerated and examined under the microscope to determine the stage of pseudothecia formation and maturity according to the Aleksić (2006) and Aleksić *et al*(2014) method. The prepared pseudothecia were examined under the light microscope and categorized in 5 categories (0-K4) according to the scale Aleksić (2006).
The forming and maturation of pseudothecia were calculated using the following formula:

$$P = \frac{K_1 + 2K_2 + 3K_3 + 4K_4}{U * 4} * 100$$

P- percentage of pseudothecia ripening
K- category of pseudothecia ripening
U – total number of examined pseudothecia

The results were analyzed by the variance method and the statistical significance calculated by the Duncan’s test.

Results and discussion

The obtained results showed that the complete inhibition of ascospores germination was achieved at a concentration of 10^8 $CFUml^{-1}$ of the *Pseudomonas* isolate B25, while a high percentage of inhibition relative to the standard was achieved at a concentration of 10^7 $CFUml^{-1}$ of the same isolate (Tab.1; Fig.1).
The isolate Q16p demonstrated the complete inhibition of germination of ascospores in higher concentration of bacteria (10^9 $CFUml^{-1}$), whereas the isolate Q16L has not showed the complete inhibition of germination of ascospores *V. inaequalis* even at the highest concentration of bacterial suspension (tab.1)

* concentration in $CFUml^{-1}$

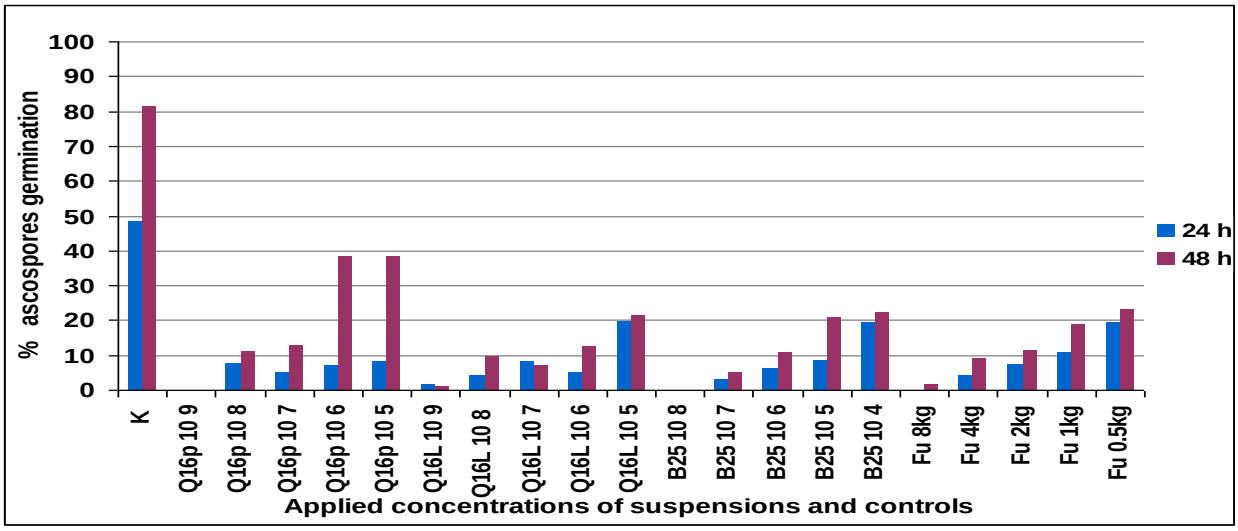

Fig.1 Percentage ascospore germination in different concentrations of *Pseudomonas* suspensions (in $CFUml^{-1}$) and controls after 24 and 48h

Based on achieved results, it can be concluded that the indigenous rhizospheric bacterial isolates of the *Pseudomonas* genus have demonstrated a high level of inhibition of ascospores' germination of phytopathogenic fungi *V.inaequalis*, especially when applied in high concentration of suspensions (10^9 and 10^8 $CFUml^{-1}$) after 24 and 48 hours of activity.
Generally, the isolates B25 and Q16L have shown a sufficient level of inhibition of ascospores' germination in all of the applied concentrations and time exposure, whereas the isolate Q16p which was applied in lower concentrations (10^6 and 10^5) showed the lower level of inhibition of ascospores' germination after 48 hours (Fig.1). Similar results of inhibition of *V. inaequalis* conidia germination were obtained by Hossain *et al*. (2009). These authors determined that the level of inhibition was 73-100% by examining the inhibition of conidia germination with the extracellular protein fractions of antagonistic bacteria *Pseudomonas fluorescens* Bk3.
In the experiment examining the pseudothecia formation, the Q16L isolate showed the best results (24,4% of formed pseudothecia), followed by B25 isolate (68,3%) compared to the cooper hydroxide as a standard with 78,0% formed pseudothecia and a control (100%) (tab.2.).

These results are the first reported and very encouraging results of the inhibitory effect of rhizospheric bacteria on the *Venturia inaequalis* pathogen. Scientific research on the use of biological control for the purpose of preventing apple scab infection or as a contributor to the integral plant protection control is limited. Only a few authors have found some antagonistic effect on *Venturia* of epiphytic *Pseudomonas* bacteria (Singh et al, 2004). Köhl *et al.* (2009) showed that an application of conidial suspensions of *Cladosporium cladosporioides* caused a reduction in the production of *Venturia inaequalis* conidia.

Further research could include the effect of *Pseudomonas* suspensions on the ripening of pseudothecia as well as their formation and whether this can reduce the level of infection even more. On a larger scale, measuring the effect of the bacterial suspension in field conditions over a longer period of time would show if the use of biocontrol is a truly feasible alternative to chemical control of *Venturia inaequalis*.

Abstract

Alumina powders were obtained by auto combustion method and calcined for 1 h at temperatures ranging from 1000ºC to 1200ºC. X-ray powder diffraction analysis revealed an overwhelming presence of γ–Al_2O_3 for the powder calcined at 1000ºC, while at 1200ºC only the presence of α–Al_2O_3 was detected. Insecticide properties of these powders were investigated on bean weevil (*Acanthoscelides obtectus* Say). Mortality of treated and untreated male and female adults was checked in a period of 7 days. The powder calcined at 1200ºC was the most efficient, and 100% mortality of both male and female insects were reached after 7 days of exposure. It was also observed that insecticide efficiency increased with the increase of α–Al_2O_3 phase present in the powders and the female insects were less susceptible to the powders' toxicity in general. Scanning electron microscope analysis of the treated adults with Al_2O_3 indicated that mortality of bean weevils can be related to adsorption of the powders onto their exoskeleton. Development of F_1 progeny was similar for all the powders and the number of hatched larvae was significantly reduced in comparison with the untreated seeds, while the percentage of damaged seeds dropped from 70% to 15%. These results suggest that relatively cheap and non-toxic α–Al_2O_3 powders can be considered for use in pest control, especially in organic seed production.

Keywords: alumina; pest control; bean weevil, *Acanthoscelides obtectus*.

Introduction

The bean weevil (*Acanthoscelides obtectus* Say) is considered as one of the most serious stored bean pests worldwide (Jovanović et al., 2007). Its oviposition and growth are continuous, and the larvae feed on the seeds. After emergence from the seeds, the adults reproduce either in the field or in the stored seeds in a continuous cycle (Ayvaz et al., 2010). Since bean is one of the most important nutritive sources in developing countries, its protection in stored conditions has been attracting much attention in past decades. Protection of agricultural stored products against insect pests is of utmost importance to secure a continuous and safe food supply all over the world (Pemonfe et al., 1997). Conventional treatments have been used for this purpose, but for the last decades there have been numerous reports of environmental contamination by use of toxic pesticides, mostly organophosphorous and pyrethroid compounds (Nikpay, 2006). Their use has been constantly challenged by resistance of insects, consumer's demand for pesticide-free products and restrictive governmental regulations (Subramanyam et al., 1994). This led to replacement of the existing chemical insecticides by a new class of non-toxic, nanostructured inorganic compounds, such as silica, alumina, diatomaceous earth and inert dusts (Barik et al., 2012; Reynolds et al., 2009; Stadler et al., 2010; Stadler et al., 2012). Especially these compounds have been reported to be effective in control of stored product insects (Nikpay et al., 2006; Stadler et al., 2010; Stadler et al., 2012). This approach was successfully demonstrated in pest control of

rice weevil (*Sitophilus oryzae* L.) and lesser grain borer (*Rhyzopertha dominica* F.) by nanostructured alumina (Stadler et al., 2010; Stadler et al., 2012).
The cause of mortality of insects by applying these inert inorganic powders has not yet been fully clarified. However, this approach being cost effective and environmentally friendly is worth further investigations and optimization of the existing formulations. Thus, in this study, Al_2O_3 powders obtained after calcination at different temperatures were tested as potential insecticides against *A. obtectus*. The comparison of insecticidal properties was observed for male and female adults and F_1 progeny.

Materials and methods

Synthesis and characterization of alumina powders: 0.03 moles of aluminium-nitrate nonahydrate ($Al(NO_3)_3 \cdot 9H_2O$, "Centrochem", Serbia) was dissolved with citric acid monhydrate ($C_6H_8O_7 \cdot H_2O$, „Lachner", Czech Republic) in minimal amount of distilled water, whereas the citrate to nitrate molar ratio was set at 0.8. pH value was kept at 8 by adding ammonium hydroxide (NH_4OH, „Lachner", Czech Republic) into the solution. First, the solution was heated at 80 ºC with constant stirring until a viscous gel was formed. Then, the temperature was raised up to 200ºC to start the autocombustion reaction. The resulting black precursor powder was collected and calcined at 1000ºC, 1100ºC and 1200ºC for 1 h in a chamber oven. Phase content of the powders was determined by X-ray diffraction (XRD, RIGAKU® RINT 2000) analysis using a CuK_α radiation ($\lambda_{CuK\alpha} = 1.54178 \times 10^{-10}$ m) from 20º to 80º 2θ angle.
Test insects: Male and female insects of *A. obtectus* were reared separately under controlled conditions (27ºC±1ºC, relative humidity 65%±5% and photoperiod L16:D8) and were 48 h old prior to testing. The insects were provided from the Institute for Biological Research "Siniša Stanković" (Belgrade, Serbia).
Lethal effect of the alumina powders: Al_2O_3 powders were mixed with 40 g bean grains by rotary shaker (Multifix GmbH, Germany) for 10 min, to form 1% mass concentration. The mixtures were further divided into four smaller portions of 10 treated grains with 10 male, or 10 female insects placed separately in a 90/14 mm Petri dish. Additional four control portions contained only untreated grains with insects. All tests were carried out simultaneously under controlled conditions and mortality rate was tracked after each day, during 7 days.
Effectiveness of powders on reduction of number of individuals in F1 progeny: Al_2O_3 powders were mixed with 40 g bean seeds in 200 ml glass jars by rotary shaker (Multifix GmbH, Germany) for 10 min, to form 1% mass concentration. Each batch was divided into four smaller samples with 10 g treated seeds, which were placed in 90/14 mm Petri dishes together with 10 female and 10 male insects. Control sample was prepared in the same way, but contained only untreated seeds. Each testing was repeated four times. After 15 days dead insects were removed from the Petri dishes and the development of F_1 progeny was investigated. The number of F1 progeny produced was recorded after 30 days. The experiments were carried out under controlled laboratory conditions (T=27ºC ± 0.5ºC, RH= 65%, L16:D8).
SEM analysis: In order to determine any changes of the exoskeleton, the tested insects were analyzed by scanning electron microscopy (SEM, TESCAN Vega TS5130MM).

Results and discussion

XRD analysis of the powders calcined at different temperatures was presented in Figure 1. The changes in diffraction patterns indicated a gradual transformation from γ–Al_2O_3 to α–Al_2O_3 as the calcination temperature increased from 1000ºC to 1200ºC.

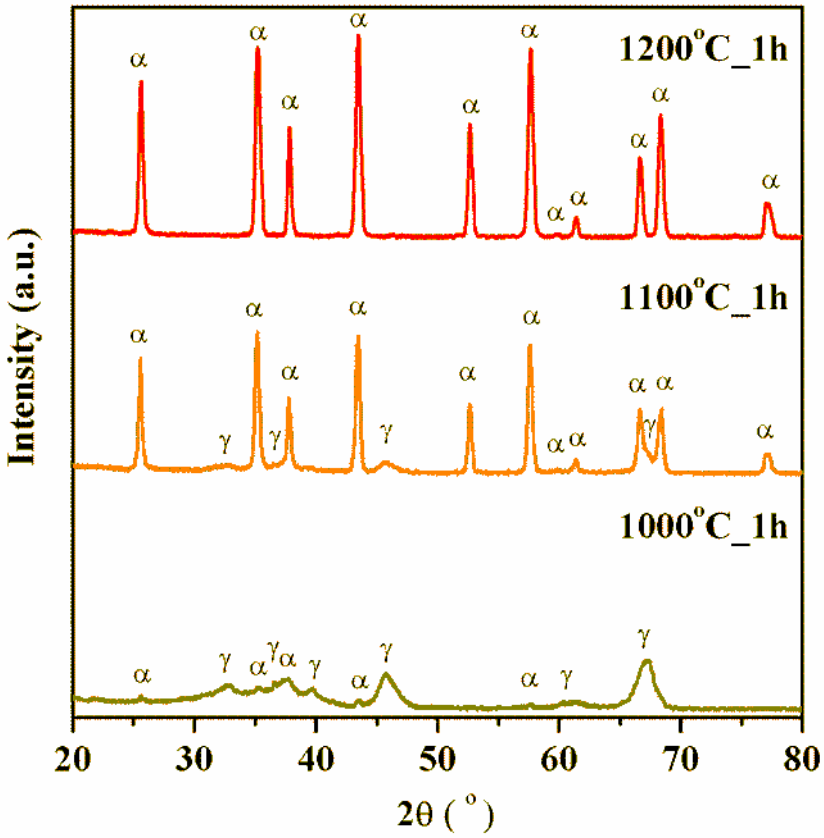

Figure 1. XRD patterns of alumina powders calcined at 1000–1200ºC for 1h.

The results of the lethal effect of the alumina powders on treated and untreated male and female adults in a period of 7 days were presented in Figure 2. After 24 hours all insects were alive, only after 48 h the first mortality cases were observed. Al_2O_3 powder calcined at 1200ºC began to be lethal against male adults after 48 h. After 72 h, mortality was 40%, after 96 h, more than 60%, after 120 h, 70% and after 144 h, mortality reached 100%. In the case of females Al_2O_3 powder calcined at 1200ºC began to be lethal after 72 h, with mortality of 20%. The maximal lethal effect of almost 100% was reached after 168 h. Al_2O_3 powders calcined at 1100ºC and 1000ºC showed their lethal effect on male adults after 72 h and 96 h. They showed maximal lethal effect after 168 h, 100% and 97.5%, respectively. These powders exhibited lethal effect on female adults first after 120 h and maximal lethal effect they showed was after 168 h, 92,5% and 62,5%.

It was clear that pure α–Al_2O_3 powder obtained after calcination at 1200ºC was the most lethal against both male and female adult insects. Taking into account untreated adult insects, it is clear that female insects live a bit longer, probably due to their final role in laying eggs that were previously fertilized. This trend is also observed for treated insects, leading to a conclusion that females are less overall susceptible to alumina powders. Furthermore, lethal effect decreased almost monotonously with the increase of γ–Al_2O_3 content in the powders for female insects, while the powders calcined at 1000ºC and 1100ºC showed no significant difference in their insecticidal activity against male insects.

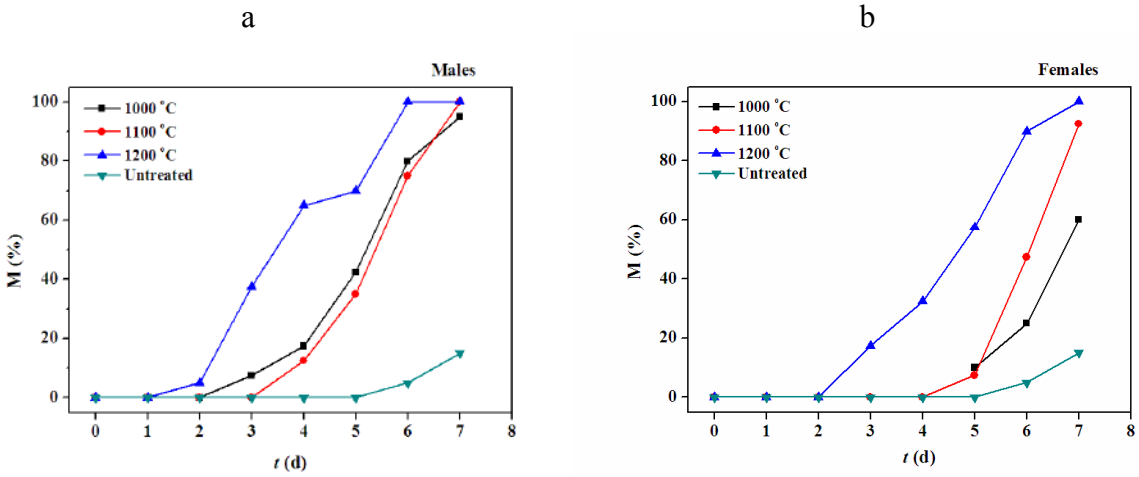

Figure 2. Lethal effect of powders against male (a) and female insects (b) in a period of 7 days.

Compounds like α–Al_2O_3 powder, if attached to an exoskeleton of insects, are able to adsorb cuticular lipids, which can cause dehydration of insects and their death, consequently (Stadler et al., 2012). SEM analysis of untreated and insect treated with Al_2O_3 was presented in Figure 3 and it is easy to notice how Al_2O_3 particles adhere to the exoskeleton of the treated imago. Thus, mortality rate is certainly related to a degree of adhesion of these particles onto the insect exoskeleton, keeping in mind that α–Al_2O_3 are inert and non-toxic. Degree of powder adhesion depends on factors such asspecific surface area and concentration of powders, humidity, temperature and insect pubescence (Fields et al., 2000; Stadler et al., 2012). On the other hand, by optimizing these parameters it is possible to raise efficiency of alumina powders, and accordingly, even lower concentrations could provide satisfying efficiency. Thus, these results suggest that α–Al_2O_3 powders, being the most effictive against *A. obtectus*, can be considered as an alternative in pest control of the stored products and in organic seed production, as well (Krnjajić, 2003; Obradović and Krnjajić, 2003).

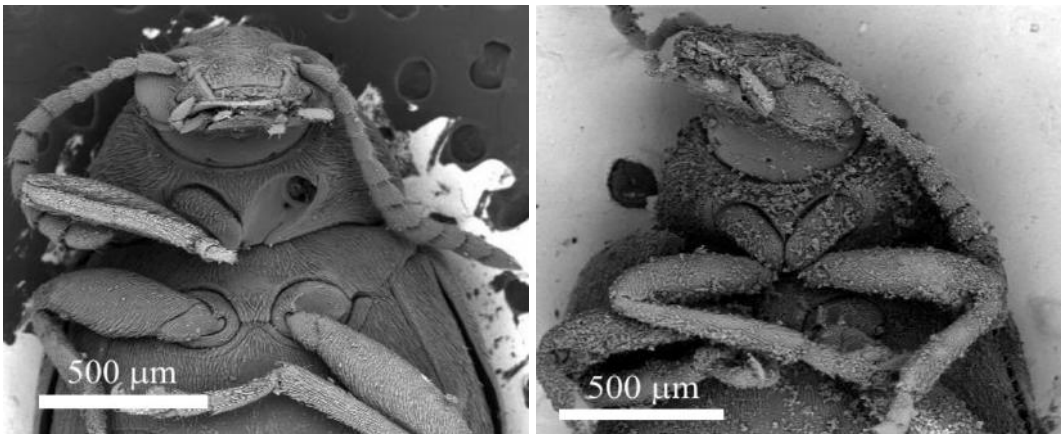

Figure 3. SEM images of untreated (left) and treated insect with Al_2O_3 (right).

When it comes to the lethal effect of alumina powders on F_1 progeny, again the powder calcined at 1200ºC exhibited the highest efficiency (Figure 4), but there is a slight difference in their efficiency. The number of larvae hatched from eggs under treated conditions was

reduced about 75%. The percentage of damaged seeds as a consequence of larval activity is also significantly reduced (dropped from 70% to 15%), which confirmed the pesticide effect of alumina powders against *A. obtectus*. These results clearly serve as both qualitative and quantitative indicators of pest control efficiency of the stored products. This efficiency can be ehanced by increasing powder concentration, since 1% is probably too low for more robust *A. obtectus* compared with *Sitophilus oryzae* (L.), or *Rhyzopertha dominica* (F.), whereas this concentration was used as maximal (Stadler et al., 2010; Stadler et al., 2012).

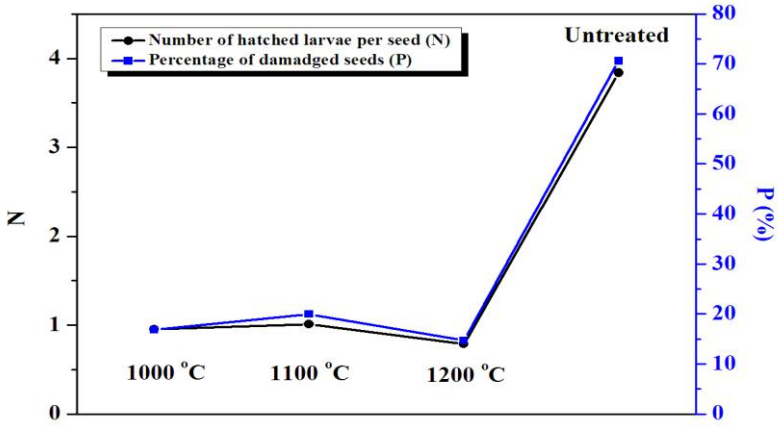

Figure 4. Development of F_1 progeny (a) and percentage of damaged seeds (b).

Conclusions

In this study comparative lethal effect of various Al_2O_3 powders calcined at different temperatures, 1000ºC, 1100ºC and 1200ºC for *Acanthoscelides obtectus* was successfully carried out. Al_2O_3 powder calcined at 1200ºC was the most efficient against adult insects, reaching 100% mortality after 6 days of exposure for males and 7 days for females, compared with 17,5% (males) and 12,5% (females) mortality of the untreated insects after 7 days. On the other hand, all the Al_2O_3 powders exhibit similar lethal effect level against larvae insects in F1 generation and percentage of the damaged seeds was significantly reduced. Al_2O_3 is also promising due to its cost-effectiveness and solid effeciency against *A. obtectus*. Their efficiency can be enhanced by increasing their concentration and/or by optimizing synthesis parameters with aim to obtain powders with appropriate particle size and increased specific surface area.

Abstract

Fennel (*Foeniculum vulgare* Mill.) is a medicinal plant as well asa flavoring agent in food, cosmetics and pharmaceutical products. There are two commercial types: sweet fennel (var. *dulce*) and bitter fennel (var. *vulgare*). These two fennel types were cultivated in Serbia during 2014, on an experimental field in Mošorin (Vojvodina province, Serbia). Fatty oil content was determined by Soxhlet extraction, while fatty acid composition was determined by esterification and GC analysis. Essential oil content was determined by hydrodistillation, whereas the composition of obtained essential oils was investigated using Gas Chromatography and Mass Spectrometry analysis.

Oil content in seeds of sweet and bitter fennel was3.97% and 6.39%, respectively. The major compound in both fennel oils was saturated myristic fatty acid (64.85% and 47.86%, respectively), followed by unsaturated C18:1 (21.71% and 25.03%, respectively). In sweet fennel these two fatty acids participated with 86.56%, and other five fatty acids (C4:0, C10:0, C12:0, C16:0 and C18:22) were present from 1.45 to 4.22%. In bitter fennel C14:0 and C18:1 fatty acid participated with 72.89%. Another significant fatty acid was capric acid (17.83%), followed by polyunsaturated C18:2 (4.41%),while other four fatty acids (C4:0, C6:0, C12:0 and C16:0) were present from 0.35 to 1.97%.Essential oil content in sweet and bitter fennel was 7.1% and 8.0%, respectively. The major compound in both fennel essential oils was *trans*-anethole (80.0% and 67.1%, respectively). In sweet fennel the second major compound was limonene (11.4%), followed by fenchone (3.9%) and methyl chavicol (2.7%), while in bitter fennel that was fenchone (22.6%) followed by *α*-pinene (3.3%).

Key words: *Foeniculum vulgare*, myristic acid, *trans*-anethole

Introduction

Fennel (*Foeniculum vulgare* Mill.) is a medicinal and aromatic plant from Apiaceae family. Essential oil of fennel fruits is used as a flavoring agent in food products such as beverages, bread, pickles, pastries and cheese because of its aroma (Shahat et al., 2011). Apart from essential oil, plants from this family are rich in fatty oils, which also have great biological potential (Öztürk et al., 2014).

Fennel fruits are used as raw material in cosmetic and pharmaceutical industry (Kooti et al., 2015). It is used in traditional medicine worldwide, but it is also a very popular plant in modern phytotherapy (Rahimiand and Ardekani, 2013), because of its antioxidative (Oktay et al., 2003; Chang et al., 2013), hepatoprotective (Özbek et al., 2003, Rabeh and Aboraya, 2014) and anticancer activity (Mohamad et al., 2011). It is also known that fennel can reduce cholesterol levels (Rezq, 2013), and the seed extracts can be successfully used in the treatment of obesity (Garg et al., 2011). Fennel also posses hypoglycemic effect (Dongare et al., 2010), and it can be used as a natural antidiabetic drug in the pharmaceutical industry (El-Soud et al., 2011).

The objective of the present work was to determine the fatty acid and essential oil composition of two fennel varieties grown in Serbia.

Material and method

Plant material. Sweet fennel (*Foeniculum vulgare* var. *dulce*) variety “Fino”(Austrosaat AG, Austria) and bitter fennel (*Foeniculum vulgare* var. *vulgare*) variety “Vojvodjanski” (Institute for medicinal plant research “Dr Josif Pančić”, Serbia) were grown during 2014 at an experimental field in Mošorin (45°18' N, 20°09' E, altitude 111m), Vojvodina province (Serbia).

Fatty acids analysis. Fatty oil content was determined by Soxhlet extraction. Fatty acid methyl esters were prepared from the extracted lipids using the method based on 14% boron trifluoride/methanol solution, as the recommended method for this type of substrates (Verešbaranji, 1996). Nitrogen gas was used for drying and removing solvents from fatty acid methyl esters. Obtained samples were analyzed by a GC Agilent 7890A system with FID, autoinjection module for liquid, equipped with fused silica capillary column (SP-2560, 100m x 0.25mm, I.D., 0.20µm). Helium was used as the carrier gas (purity >99.9997 vol%, flow rate =1.26ml/min). The fatty acids peaks were identified by comparison of retention times with retention times of standards from Supelco 37 component fatty acid methyl esters mix and with data from internal data library, based on previous experiments. Results were expressed as mass of fatty acid or fatty acid group (g) in 100g of fatty acids.

Essential oil analysis. Essential oil was obtained by hydrodistillation using the Clevenger-type apparatus from crushed mature fruits. The oil quality was assessed through analysis by combined Gas Chromatography and Mass Spectrometry. GC-MS analysis was performed by using an Agilent 6890 gas chromatograph coupled with an Agilent 5973 Network mass selective detector (MSD), in positive ion electron impact (EI) mode. The separation was achieved by using Agilent 19091S-433 HP-5MS fused silica capillary column, 30m x 0.25mm i.d., 0.25µm film thickness. The GC oven temperature was programmed from 60°C to 285°C at a rate of 4.3°C/min. Helium was used as the carrier gas; inlet pressure was 25 kPa; linear velocity was 1ml/min at 210°C. Injector temperature: 250°C; injection mode: splitless. MS scan conditions: source temperature, 200°C; interface temperature, 250°C; energy, 70 eV; mass scan range, 40-350 amu. Identification of components was done on the basis of retention index (RI), their retention times (RT) and by comparison with reference spectra (Wiley and NIST databases).

Results and disscusion

Oil content in seeds of sweet and bitter fennels was 3.97% and 6.39%, respectively (Table 1). The major compound in both fennel oils was saturated myristic fatty acid (64.85% and 47.86%, respectively), followed by unsaturated C18:1 (21.71% and 25.03%, respectively). In sweet fennel these two fatty acids participated with 86.56%, and other five fatty acids (C4:0, C10:0, C12:0, C16:0 and C18:22) were present from 1.45 to 4.22%. In bitter fennel C14:0 and C18:1 fatty acid participated with 72.89%. Another significant fatty acid was capric acid (17.83%), followed by polyunsaturated C18:2 (4.41%), while other four fatty acids (C4:0, C6:0, C12:0 and C16:0) were present from 0.35 to 1.97%.

In Turkey, the obtained oil content in sweet and bitter fennel was 12.22% and 14.41%, respectively (Coşge et al., 2008). The C18:1, C18:2, and C16:0 were the principal fatty acids which constituted around 97% of the total oil content. The ratios of essential oil from sweet and bitter fennel were found similar (average 3.00%).

Table 1 Fennel fatty acids

Fatty acid	R.t. (min)	sweet fennel	bitter fennel
C4:0	10.102	1.55	1.24
C6:0	10.546	nd	0.35
C10:0	13.874	3.85	17.83
C12:0	17.041	2.37	1.97
C14:0	21.073	64.85	47.86
C16:0	25.526	1.45	1.31
C18:1	30.985	21.71	25.03
C18:2	32.692	4.22	4.41
Fatty oil content		**3.97**	**6.39**

R.t. – Retention time; nd – not detected

Essential oil content in sweet and bitter fennels was 7.1% and 8.0%, respectively (Table 2). According to our Pharmacopeia, essential oil content in fruits of sweet fennel need to be more than 2%, while in bitter fennel fruits more than 4% (Ph. Jug V, 2001).
The major compound in both fennel essential oils was *trans*-anethole (80.0% and 67.1%, respectively). In sweet fennel the second major compound was limonene (11.4%), followed by fenchone (3.9%) and methyl chavicol (2.7%), while in bitter fennel that was fenchone (22.6%) followed by *α*-pinene (3.3%).

Table 2 Fennel essential oil

Compounds	R.t. (min)	RI	sweet fennel	bitter fennel
α-pinene	5.816	936	1.0	3.3

Essential oil content			**7.1**	**8.0**

R.t. – Retention time; RI – Retention indices on HP-5 MS capillary column; tr – compound present in traces (less than 0.1%); nd – not detected

The compound with the highest value in the sweet and bitter fennel from Turkey was *trans*-anethole as 95.25% and 75.13%, respectively (Coşge et al., 2008). While methyl chavicol was found in bitter fennel oil in a remarkable amount (15.51%), sweet fennel oil contained small amounts of methyl chavicol (2.87%). Fenchone was found in less than 1% in sweet and around 5% in bitter fennel.
There are a lot of factors which can influence the essential oil content and composition. Growing technology such as date of sowing, plant density, apply fertilizers etc. have a

significant influence on essential oil content (Mohamed and Abdu, 2004; Ayub et al., 2008; Khorshidi et al., 2010). Alternatively, very important factors are the environmental and ecological characteristics of the particular growing region (Shahat et al., 2012). However, the content of *trans*-anethole in essential oil from fennel grown in Romania varied between 60.4-77.6%, while fenchone was present from 8.6-13.1%, and methyl chavicol 2.5-8.3% depending on the year of cultivation (Aprotosoaie et al., 2010).

Conclusion

Fatty oil and essential oil content in bitter fennel seed is higher than in the sweet variety. The major compound in both fatty oils was saturated myristic acid, followed by unsaturated C18:1, while the major compound in both essential oils was *trans*-anethole, followed by limonene in sweet fennel, and fenchone in bitter fennel.

Abstract

This study investigates the possibility of biological control of fungal species isolated from marigold seeds using essential oils from medicinal plants: mint (*Mentha spicata* L.), sage (*Salvia fruticosa* L.), rosemary (*Rosmarinu sofficinalis* L.), anise (*Pimpinella anisum* L.), bitter fennel (*Foeniculum vulgare spp. piperituum* L.) and myrtle (*Myrtus communis* L.).

Two fungal species isolated from marigold seeds: *Botritiscinerea* and *Sordaria fumicola*, were used in this experiment. The minimum inhibitory concentrations (MIC) were determined by micro-dilution method using selected essential oils (EOs). MIC was determined by a modified micro-dilution method in 96 well microtiter plates. Spores were added to each well with 90 μL potato dextrose medium with appropriate dilutions of the EO 10 μL fungal inoculum ($1.0x10^5$-$5.0x10^5$). All experiments were performed in duplicates and repeated four times. The microplates were incubated for 72h at 28°C. The MIC was defined as the lowest concentration of essential oils (EO) which completely inhibited the visible fungal growth. Fluconazole was used as positive control.

Essential oils MIC values were in the range of 0.00325-7.75.0 mg/mL. Among thetestedoils *Salvia fructicosa* EO proved to be the best inhibitor of *B.cinerea* (MIC 0.003mg/mL) and *Myrtus communis* EO to the *Sordaria fumicola* (MIC=0.032mg/mL). The tested fungi were observed to have a susceptibility to all selected essential oils. These results suggest the possibility for application of the EOs in biological control of marigold production.

Key words: *Antifungal activity, Essential oils, MIC, marigold*

Introduction

The plant disease control in agriculture using the antimicrobial chemicals is very often associated with serious problems: toxicity, carcinogenic and teratogenic effect on people and fungal resistance to the fungicide, justifying the search for new strategies in plant protection (Rapp, 2004). The essential oils and other products of especially medicinal plants become a potential antifungal agents in recent years (Bouchra et al. 2003; Carmo et al. 2008; Tavassoli et al. 2011). The phytopatological fungi are very often a casual agents of numerous diseases during the cultivation of medicinal plants. The presence of the fungi in medicinal plants reduces their quality (Essono et al. 2007). On the other hand the medicinal plants are a very rich source of a biologically active compounds including antifungal activity (Kumar et al. 2007; Carmo et al. 2008; Arrebola et al.2010; Bouzennaans Krichen, 2013; Stević et al. 2014). The antimicrobial activity of selected species has already been demonstrated (Maksimovic et al. 2005; Carmo et al. 2008; Tawassoli et al. 2011; Cosic et al. 2010; Istianto and Emilda, 2011; Vitoratos et al. 2013; Mahilrajan et al. 2014).Therefore, the application of essential oils is an alternative, biological control measure.

This study was undertaken to investigate the inhibitory effects of a number of essential oils (EOs), against two phytopathogenic fungi isolated from marigold seeds.

Material and methods

Essential oils

EOs of selected plants (listed in Table 1.), were obtained by hydro-distillation in a Clevenger-type apparatus. The obtained essential oils were stored in sealed glass bottles, protected from the light by wrapping in aluminium foil and storing at -18^{o}C.

Table 1. Essential oils

No	Essential oil	Plant origin	Origin	Used Parts
1	Mint	*Mentha spicata* L.	Mersin (Turkey)	leaves
2	Sage	*Salvia officinalis* L.	Mersin (Turkey)	Leaves+flowers
3	Sage	*Salvia fruticosa* L.	Sarajevo (BIH)	Leaves
4	Rosemary	*Rosmarinus officinalis* L.	Mersin (Turkey)	Leaves
5	Anise	*Pimpinella anisum* L.	Mersin (Turkey)	Fruit
6	Bitter (fennel)	*Foeniculum vulgare* spp. *piperituum* L.	Mersin (Turkey)	Fruit
7	Myrtle	*Myrtus communis* L.	Mersin (Turkey)	Leaves

Fungi

Antifungal activity was tested using two fungal species isolated from marigold seeds during 2014 identified as: *Botritis cinerea* and *Sordaria fumicola*.

Antifungal assay in vitro

To investigate the antifungal activity of essential oil, modified micro-dilution method was used. A minimum inhibitory concentration (MIC) was determined using 96 well microtiter plates (Douk et al. 1995; Nikolić, 2014). The fungal spores were washed from the surface of agar plates with sterile 0.75% saline containing 0.1% Tween 80 (vol/vol), filtered and adjusted to a concentration of approximately $1.0x10^5$ - $5.0x10^5$ spores per ml using a hemocytometer. Fungal inoculum was added to each well with 90 µL potato dextrose medium with appropriate dilutions of the EO 10 µL. All experiments were performed in duplicates and repeated four times. The microplates were incubated for 72 h at 28 °C. The MIC was defined as the lowest concentration of essential oils (EO) which completely inhibited the visible fungal growth. Fluconazole was used as positive control.

Statistical analysis

The results of the minimal inhibitory concentrations (MIC) were processedby Duncan’s multiple range tests. Analysis of the variance was performed on MIC data of seven oils on 2 pathogenic fungi. Significance was evaluated at $p<0.05$ for all tests. Statistical analyses were done by procedures of STATISTICA v.7 (StatSoft, Inc.) and IBMSPSS Statistics v.20 (SPSS, Inc.).

Results and discussion

The obtained results according to the micro-dilution method referring the antifungal activity of the essential oils are shown in Table 2. and Fig. 1.

The essential oils demonstrated varying levels of antifungal effects against fungal pathogens. Essential oils MIC values were in the range of 0.003-10 mg/mL. Among the oils tested, myrtle EO proved to be the best inhibitor of the both tested fungal isolates in concentrations between 0.0325 and 0.775 mg/mL.

Tab. 2 Antifungal activity of the essential oils expressed through the minimal inhibitory concentration

Essential oil	*Botritis cinerea*	*Sordaria fujicola*
Mentha spicata L.	1d*	0,55d
Salvia officinalis L.	10a	0,55d
Salvia fruticosa L.	0,00325d	5,5bc
Rosmarinus officinalis L.	0,325d	7,75ab
Pimpinella anisum L.	0,2555d	5,5bc
Foeniculum vulgare spp. *piperituum* L.	1d	3,25cd
Myrtus communis L.	0,775d	0,0325d
Fluconazole	3,825cd	4,175bcd

*Values of MIC, followed by the same letter are most significantly different ($p<0,05$), according to Duncan's multiple range test.

Salvia fructiocosa EO showed the strongest inhibitory effect on the species *Sordaria fujicola* (MIC: 0,55mg/mL, and low to the *Botrytis cinerea* (MIC: 10 mg/mL). *Botritis cinerea* was more sensitive (average MIC: 1.91 mg/mL) than *Sordaria fujicola* (average MIC: 3.30mg/mL) to the tested EOs.

The antifungal activity of selected oils to the *B.cinerea* referred to in this paper, are in agreement with results of the other researchers. According to the data from Combrinck et al. (2011) an essential oil from *Mentha spicata* has demonstrated antifungal activity to the numerous fungal species, especially to the *Botrytis cinerea.*

EOs used in this study have already shown high inhibitory effect against more fungal species, e.g. anise oil was found to inhibit the growth of *Fusarium* species in concentrations between 0.7 and 2.2 mg/mL (Stevic et al. 2014), bitter fennel EO has high inhibitory effect against *F. oxysporum* (Özcan et al. 2006). In our study, the MIC values of anis EO was 0,2555 to 5,5 mg/mL to the *B.cinerea* and *S.fumicola* respectively.

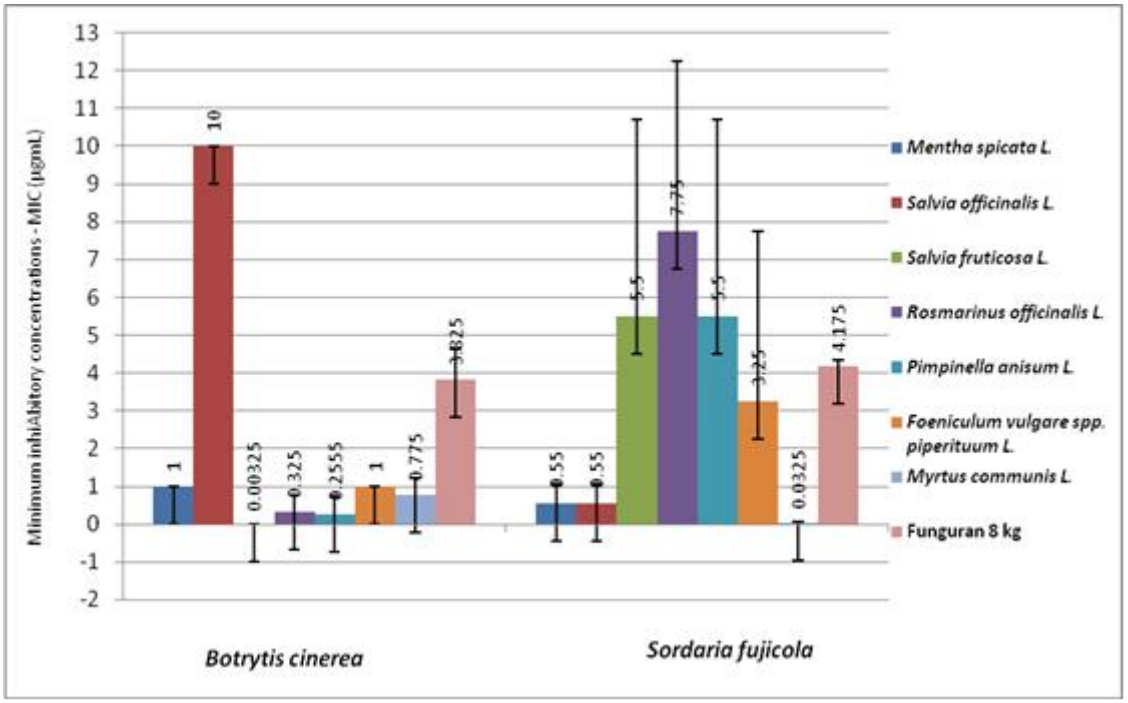

Fig. 1. Antifungal activity of the essential oils is expressed through the minimal inhibitory concentrations (mg/mL) to the *Botrytis cinerea* and *Sordaria fujicola*

This present study provides scientific evidence that different medicinal species EOs can be used as potential sources of bioactive substances. The obtained results could be useful from the practical point of view. An opportunity to test these results *in vivo*, by seed dressing with EOs investigated here, can lead to better monitoring of seedlings' health.

Conclusions

The essential oils of mint, sage, rosemary, anise, bitter fennel and myrtle exhibited good antifungal activity against both tested organisms, known as marigold pathogens. The obtained results in this work suggested that specified essential oils can be applied to prevent growth of phytopathogenic fungi. Further studies on the combined effects of many local plant essential oils could lead to better protection the marigold seeds.

Abstract

Contaminated soil represents a serious environmental problem as the pesticides can be transported to other environmental systems such as surface and ground water, as well as they can cause phytotoxicity on the following crops. Length of pesticide persistence in the environment depends on numerous factors. This paper presents results of nicosulfuron dissipation rate studies in soil of the chernozem type, carried out under field conditions. Field trial was conducted according to OEPP standard methods for experimental design and data analysis. Nicosulfuron OD 40 g/l has been applied post-emergence on a corn crop at the BBCH 12-18 corn growth stage, at the manufacturer's recommended concentration of 44 g/l. Soil samples were collected before and immediately after pesticide application, and every two weeks till harvest, from the surface soil layer of 0-30 cm. Nicosulfuron in soil samples was determined by HPLC-DAD. For the extraction of nicosulfuron, QuEChERS original method EN 15662 was modified. The validation study was performed according to SANCO/825/00 rev.8.1 16/11/2010. The average value of the recoveries at 0.05 mg/kg and 1.0 mg/kg was 83.9%, with the relative standard deviation of 1.5%. The LOD of the analytical method was 0.01 mg/kg and the LOQ was 0.05 mg/kg. In the first two weeks after application, nicosulfuron dissipation was the most rapid (37.9%). Calculation of the results show that nicosulfuron half-life ($t_{1/2}$) in the field soil under corn was 6.93 days.

Key words*: HPLC, nicosulfuron, dissipation,* $t_{1/2}$

Introduction

Residues of some herbicides in the soil can be beneficial during the season of application for control of later flushes of target weeds, thereby reducing potential competition with the crop being grown (Geisel, 2007). However, soil residual herbicides have been found to persist in the soil into the following year, potentially reducing yields of sensitive crops grown in rotation (Cobucci et al., 1998; Johnson et al., 1993). The amount of herbicide that sorbs to the soil and the rate it can desorb back into the soil solution determines the overall phytotoxicity of herbicide (Geisel, 2007).

Stability of herbicides in soil depends on many factors, physical and chemical properties of herbicides, climatic conditions and soil properties during the vegetation period. Microorganisms activity, constant temperature and soil moisture changes have a great influence on herbicide fate in the soil (Vicari et al., 1994). Very important parameter that defines herbicide potential of persistence in the soil is ($t_{1/2}$), i.e. half-life period. One of the factors by which the potential herbicide mobility in the soil is valuated is relative mobility index of herbicides (Rf) (Helling and Turner, 1968). At very low dose, sulfonylurea herbicides have high herbicidal potency, which significantly reduces the amount of the applied chemical to the field in comparison with conventional ones (Brown, 1990). However, the application of low levels of these herbicides does not guarantee high levels of environmental tolerance. In some cases, sensitive plants suffer damages by dosages lower than 1% of the initial application rate (Beyer et al., 1987). For most herbicides, the content of

soil organic matter and soil texture are the major factors affecting their phytotoxicity and persistence in the soil (Rahman et al., 2011).
High mobility of sulfonylurea herbicides in the soil environment (K_{oc}<100 ml/g), weak acid nature, pKa values ranging from 3.3 to 5.2 (Brown, 1990; Hay, 1990) and high value of GUS index, classify them into the herbicide with a potential phytotoxic action. Stability of these residual herbicides and their metabolites can affect sensitive plants species negatively during crop rotations. Sorption of sulfonylureas is low in all soils and they persist long enough in the environment to be ranked as leaches in all soils ($t_{1/2}$≥16.5 d). They are degraded in soil as a result of both microbiological and chemical processes, with the latter being particularly important in acid soils (Brown, 1990). Sulfonylurea herbicides, such as nicosulfuron, are more mobile in alkaline soils and in soils with lower organic matter content. The most applicable sulfonylurea herbicide in corn for successful control of annual and perennial weeds is nicosulfuron (Table 1).

Table 1.Nicosulfuron

IUPAC name	Structural formula	Molecular formula	Molecular mass	p*Ka*
2-[(4,6-dimethoxypyrimidine-2-ylcarbamoyl)sulfamoyl]-N,N-dimethylnicotinamide		$C_{15}H_{18}N_6O_6S$	410.4 g/mol	4.6 (25°C)

At the request of the European Commission, EFSA Panel on Plant Protection Products and their Residues developed guidance on how to derive the half-life for degradation in the top 30 cm of soil at reference temperature and moisture conditions. This half-life is an important input parameter in model simulations of the exposure of organisms in soil for annual crops under conventional and reduced tillage, and therefore this guidance is an important part of this revised methodology. They recommend the evaluation of field dissipation studies taking to represent degradation in the soil matrix from the soil surface, into account for estimating half-life (EFSA, 2012). The studies performed in the last 30 years showed that about 90% of the applied herbicide rates degrade during the season in which they were used. However, the large differences in the persistence of herbicides during the season had temperature, moisture and soil pH. This is especially important when the following crops in crop rotation are legumes that may be susceptible to sulfonylurea herbicide residues present in an amount of only 1% of the applied quantity (Ferris, 1993). The phytotoxic effect of nicosulfuron and its soil metabolites on dicotyledonous plants leads to a self-limitation in the re-planting period. After sowing, in 27-30 days interval since pesticide application, phytotoxic effects are obvious on cereals, sugar beet, canola and clover. The listed crops should not be sown on land previously treated by nicosulfuron before next spring, when the expected level of herbicide residues and their degradation products is <0.001 mg/kg.
For those reasons, numerous tools have been developed to predict the relative persistence and risk of damage from these herbicide residues. In this study, field experiments were designed to investigate the dissipation dynamics and final residues of nicosulfuron in soil. Modified QuEChERS procedures and high performance liquid chromatography (HPLC)-UV detection method were used to detect nicosulfuron residues. This study provides the basis to assess environmental risks. These results would be significant in providing guidance on the proper and safe use of nicosulfuron in field application.

Material and methods

Field experiment design;

The experiment conducted in this research includes the dissipation study and final residues study. The supervised field trial was carried out on a chernozem soil, in the surrounding of Novi Sad. Field trial was conducted according to OEPP standard methods for experimental design and data analysis. In the corn field, nicosulfuron (OD, 40 g/l) was applied at the recommended dose of 44 g/l. The nicosulfuron was sprayed post-emergence at the corn growth stage of BBCH 12-18. Soil samples were collected before and immediately after the pesticide application, and every two weeks till harvest, from surface soil layer, of 0-30 cm.

Chemicals and solutions;

The analytical standard of nicosulfuron (97%, purity) was purchased from Dr Ehrenstorfer (Augsburg, Germany). Nicosulfuron 40 g/l oil-dispersion (OD) was purchased from Galenika Fitofarmacija AD. Acetonitrile (ACN, HPLC grade), formic acid and acetic acid purchased from J.T. Baker (Germany). Purified water was prepared by using Milli-Q water purification system (TKA, Germany). For the soil sample extraction, a ready-to-use QuEChERS dispersive SP extraction (Cat. No. 5982-5650) kit was purchased (Agilent Technologies, USA). Nicosulfuron stock standard solution (1000 µg/mL) was prepared in acetonitrile (HPLC-grade) and stored at -20 °C. The working standard solutions (0.5–10.0 µg/mL) for calibration and quantitation were prepared immediately before analysis through dilution with acetonitrile.

Chromatographic Parameters;

Chromatographic analysis and extraction procedure were described in our previous publication (Lazić et al., 2014). For the chromatographic analysis, an Agilent 1100 Series system with DAD detector and Zorbax SB-C18 column (5 µm, 250mm ×3 mm internal diameter) were used. The mobile phases, which were composed of acetonitrile (A) and 0.1% (V/V) acetic acid in water (B), were pumped at a flow rate of 1.0 ml/min. The following gradient profile was used: 0–10 min linear from 52% to 47% (A). The external standard and calibration on five levels were used.

Extraction Procedure;

Soil samples were dried at room temperature, milled and sieved. After that, 10.0 g of soil sample was weighted into polypropylene tube of 50 ml volume, 3 ml of deionized water and 10 ml of acidified acetonitrile were added. The tube was shaken and vortexed for a 1 min. A mix of buffered salts from separate pouches was added, shaken for 1 min and vortexed 1 min. The tube was placed in an ultrasonic bath for 10 min and centrifuged at 4000 rpm for 5 min. The supernatant was filtered through a 0.45 µm membrane filter and transferred into an autosampler vial for HPLC-DAD analyses.

Results and discussion

The results for determination of nicosulfuron in trace amount were presented in the paper of Lazić et al., 2014. The validation study was performed according to SANCO/825/00 rev. 8.1 16/11/2010. Satisfactory linearity was obtained when the correlation coefficient (r^2) was 0.9999, based on measurement of the analyte peak areas in the soil. The limit of detection LOD and limit of quantification LOQ for nicosulfuron in soil were 0.01 and 0.05 mg/kg respectively. Recovery studies were performed, to validate the HPLC method, by spiking the blank samples at two concentration levels (0.05 mg/kg and 1.0 mg/kg) showed satisfactory result with average recovery of 83.9%, with the relative standard deviation of 1.5%. The precision of the method was 1.83%.

As shown in Figure 1, the results of dissipation demonstrated a gradual and continuous decrease of nicosulfuron content in soil. The initial deposit of nicosulfuron in soil was 0.95

mg/kg. Herbicide concentration decreased over time to 0.59, 0.29 and 0.12 mg/kg in five months period.
The dissipation curve of nicosulfuron in soil was fitted with first order kinetics and the degradation rate constant. Half-life was calculated using the equation (1)

$C_t=C_0e^{kt}$ (1)

where C_t represents the concentration of the pesticide residue at the time of t, C_0 represents the initial concentration after application and k is the dissipation degradation rate constant (days). The half-life of nicosulfuron in soil was calculated from the k value, $t_{1/2}$=ln2/k. The dissipation equation for nicosulfuron, achieved in this experiment was $C=0.839e^{-0.10x}$, with the half-life of 6.93 days (Table 2).

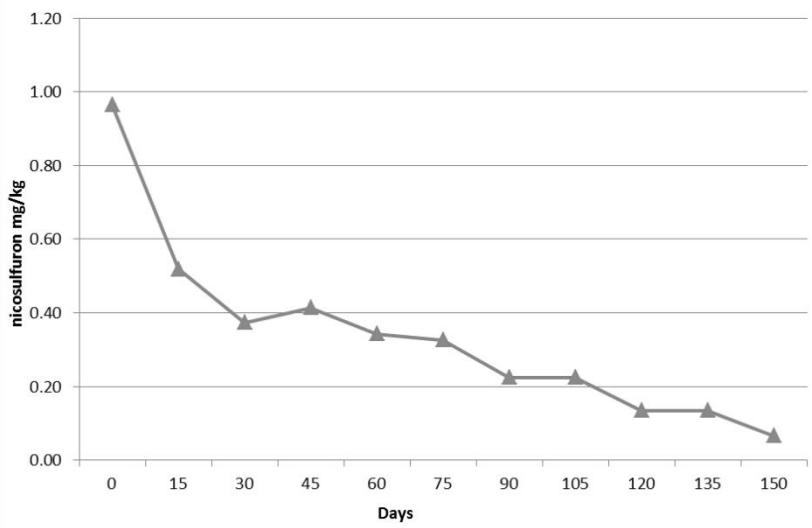

Figure 1. Dissipation curve of nicosulfuron in soil

Table 2. Half-life and data parameters for nicosulfuron dissipation in soil

Sample	Regression equation	Degradation constant (days)	Determination coefficient (R^2)	Half-life (days)
Soil	$y=0.839e^{-0.10x}$	0.10	0.864	6.93

Acetolactate synthase inhibitors (ALS) herbicides have been shown to vary widely in their degradation rates in response to soil pH, organic matter content and temperature (James et al. 1999). The cation-exchange capacity, principally a function of clay type and organic-matter content, is directly involved in herbicide adsorption. The content of organic matter in chernozem soil type, on which the trial was set up, determined by the method of wet incineration (Simakov, 1957) was 3.05-3.47% (Ćirić et al., 2013). With the increase of organic matter content, nicosulfuron adsorption also increases. Herbicide molecules from the soil solution are removed by adsorption, therefore decreasing its phytotoxicity but also making it unavailable for degradation (Loux and Reese, 1993). In this research pH of the soil is also evaluated. pH value of 7.54, indicates weakly alkaline soil. Generally, the rate of degradation of sulfonylurea herbicides in soil is fastest in warm, moist, light-texture and low pH soils, and slowest in cold, dry, heavy and high pH soils (Rao, 2000). It appeared that soil

organic matter followed by soil pH had the greatest effect in reducing herbicide residue phytotoxicity in the soil.

Ashburn et al., 2002 established that nicosulfuron half-life in soils is 5.3 and 4.2 days, when it is applied alone and in a mixture with rimsulfuron. Studies of Azcarate et al. 2015, showed that half-life of nicosulfuron in surface soil layers were 5-7 days. On the other hand, reported DT_{50} values for nicosulfuron in soil were much longer, from 14 to 49 days (Russell et al., 2002). According to EFSA, DT_{90} values of nicosulfuron range between 30 and 210 days.

The dissipation of nicosulfuron in soil in our experiment was slightly faster than that in some of previously conducted researches. It could be the consequence of extreme weather conditions in days after herbicide application. In the region on which the trial was set up during May, in days after the treatment there was more than 200 mm of precipitation, while annually fell the total 821.2 mm of rain. Such conditions could cause intensive nicosulfuron leaching into deeper soil layers, i.e. low herbicide retention in the surface layer. However, as it was mentioned before, half-life is only a rough indication of the potential persistence of herbicide active ingredients in soil (Sekutowski, 2011). In field conditions, herbicide degradation and translocation are slower or more intensive, depending upon the physical and chemical properties of the compound and their interaction with environmental conditions. In such a manner, herbicide persistence and translocation in soil cannot be considered only by one of the named parameters (e.g. $t_{1/2}$, Koc, Rf), but numerous environmental factors are to be included to provide information on herbicide fate in the environment. For the prediction of the mobility of pesticides in the field, the most used index is the Groundwater Ubiquity Score (GUS), (Gustafson, 1989). GUS index is based on the values of $K_{oc,}$ sorption coefficient normalized to soil organic carbon content and on a half-life. According to the literature data, GUS index for nicosulfuron is 3.34, which classifies it into the compounds with high potential of leaching (Pfeiffer, 2010).

Conclusions

In this paper the dissipation rate and residues of nicosulfuron in soil under field conditions were investigated. The final residues of nicosulfuron were ranged from 0.96 to 0.07 mg/kg and nicosulfuron half-life in soil was 6.93 days. Results of the field trial showed that soil properties, as well as climatic conditions have significant influence on nicosulfuron presence in the soil during the season in which it has been applied.

Abstract

Diabrotica virgifera virgifera Le Conte is a significant, introduced harmful species in maize in production conditions of northern Serbia. The aim of this study was to investigate the efficacy of indoxacarb (150 g a.i./l) 0.25 l/ha and bifenthrin (100 g a.i./l) 0.3 l/ha for the control of *D. virgifera virgifera*. The experiments were carried out in 2014 in Parage and Vilovo (Serbia, Vojvodina) according to standard EPPO methods (PP1 / 152; 1/135 and 1/274). Four assessments were made: before the treatment, three, seven and 15 days after the treatment by counting adults on 30 plants/replication. The efficacy (E%) was calculated according to Henderson-Tilton. In Parage the average number of adults of *D. virgifera virgifera* before the treatment was 33-44. Three days after the application of insecticides the number of adults (0 to 2.25) was significantly lower compared to the control (21.5) and insecticide efficacy was 92.5 to 100%, depending on the insecticide. Also the number of adults (0.75 to 4.75) after seven and 15 days (1.75 to 2.75) was significantly lower compared to the control (18.5 to 24.5) and the efficacy ranged from 85.4 to 97.3% i.e. 87.1 to 92.9%, respectively. In Vilovo, before the application of insecticides the number of adults was 24.5-27.5, while three days after (2.5 to 3.75) was significantly lower compared to the control (27.5) and insecticides efficacy was 84.6 to 90%. After seven days the number (1-1.5) was significantly lower compared to the control (24.7) and insecticides efficacy was 93.1 to 95.5%. After 15 days adults of *D. virgifera virgifera* were not recorded in treatments with insecticides.

Keywords: maize, *Diabrotica virgifera virgifera*, indoxacarb, bifenthrin, efficacy

Introduction

Diabrotica virgifera virgifera Le Conte is a significant, introduced pest of maize in production conditions in northern Serbia. The spread of this pest species is favored by the fact that about 40% of arable land is under maize, that the land after property transformation belongs to non-professionals and that the scientific contribution of crop protection was ignored so the areas under maize in monoculture are rapidly increasing. In Serbia, repeat sowing of maize is present in about 30% of the total area and even over 80% in some regions (Stanković et al., 1998). In the 90`s, in Serbia maize was grown in monoculture on about 40% of the state land and about 50% in the private sector, which favored this newly introduced pest and contributed to its rapid expansion in the mentioned area (the collective of authors, 1995). Given the above mentioned, in recent years chemical control is necessary measure in *D. v. virgifera* control. For the control of this pest in Serbia only preparations for seed treatment on the basis of imidacloprid and clothianidin were registered. However, due to problems arising around the intoxication of bees and loss of honey bee colonies, which is attributed to neonicotinoid insecticides, in a number of European and other countries, certain restrictive measures (EU Regulation 485/2013) have been undertaken. Ministry of Agriculture and Environmental Protection of the Republic of Serbia, has also introduced a moratorium on the use of preparations based on imidacloprid and clothianidin for maize seed treatment, so now for the control of *D. v. virgifera* larvae there is only one registered insecticide for seed

treatment –a.i. tefluthrin. For the control of adult *D. v. virgifera* in foliar treatments, for now, there is not a single insecticide registered in Serbia (Savčić-Petrić, 2015).
The aim of this study was to investigate the possibility of adult *D. v. virgifera* control in maize production conditions in Vojvodina, given that there is not a single registered insecticide for this purpose in the Republic of Serbia.

Materials and methods

Experiments were conducted in the localities Parage and Vilovo (at both locations maize was cultivated in monoculture for two consecutive years with the problem of *D. v. virgifera* presence) using standard OEPP methods for experimental design and analysis (Anonymous, 2006), for phytotoxicity (Anonymous, 2006a) and the efficiency of insecticides in the control of adult *D. v. virgifera* (Anonymous, 2011). Sowing of hybrid Pioneer 9911 was conducted on 30.03.2014 in Vilovo, while the sowing of hybrid Pioneer 0412 AQUAMAX was on 08.04.2014 in Parage. Hybrid Aquamax 0412 is a new hybrid of the group 500 and a hybrid Pioneer 9911 is in maturity group 400. Both hybrids have similar characteristics. The stalk is higher with higher position of ears. Kernel is a hard dent type. As all hybrids and from this group, both are adapted to the regions with water deficit and are highly tolerant to prolonged high temperature.
Size of the basic experimental plot was 2500m^2, set in four replications, as randomized block design. In Parage treatment was carried out on 06/07/2014, while in Vilovo on 21.07.2014. Maize was at the stage BBCH 63-65 (beginning of the pollen rejection, visible silk threads, to the upper and lower parts of tassel in flowering, silk fully developed). Preparation Avaunt 15 EC (indoxacarb 150 g / l) was applied at rate 0.25 l / ha, and Fobos-EC (bifenthrin 100 g / l) at 0.3 l / ha, as foliar spraying using tractor sprayer (tractor with a high clearance). The number of adult *D. v. virgifera* was monitored on yellow sticky traps, 3 days before the experiment, as well as after treatment. Efficacy evaluation was performed by monitoring the number of adults on 30 plants (in three places on 10 consecutive randomly chosen plants) per replication. In Parage evaluations were made before the treatment (07.06.2014.), three days after (09.07.2014.), seven days after (07.13.2014.) and 15 days after the treatment (07.21.2014.). In Vilovo, evaluations were made before the treatment (21.07.2014.), two days after (23.07.2014.), seven days after (28.07.2014.) and 16 days after treatment (06.08.2014.). The efficiency (E%) was determined according to the Henderson-Tilton-in (Wentzel, 1963) and the significance in differences between the number of adults i treatments and the control was tested using ANOVA.

Results and discussion

Results on the control of *D. v.virgifera* adults in Parage and Vilovo are presented in Tables 1-5. Table 1 shows the number of adults on yellow sticky traps 3 days before the experiment, as well as after the treatment. Based on the presented results, it can be concluded that the number of adult insects decreased after the treatment with insecticides compared to the control.

Based on the observations before the experiment (Table 2) the average number of adults in Parage was 33.0 to 44.0 per replication. Strikingly, adults were present in a high number, but exceptional mobility does not give a true picture of the real numbers per plant. Three days after the application of Avaunt 15 EC (0.25 l / ha) and Fobos-EC, the number of adults was at a significantly lower level compared to the control (Table 1). The efficacy of the tested preparations three days after the application was 92.5 to 100%.

Control	**33.0**	3.74	**21.5 a**	7.05	
LSD 5%			7.85		

x-average number; Sd – standard deviation; E%-efficacy

Seven days after the application of insecticides, the number of adults was on significantly lower level in comparison to the control (Table 3). Efficacy of the tested preparations for the control of adult *D.v. virgifera* ranged from 85.4 to 97.3%. The number of the adults, 15 days after the application of Avaunt 15 EC and Fobos-EC, was on significantly lower level compared to control. Efficacy of insecticides ranged from 87.1 to 92.9%.

The average number of *D.v. virgifera* adults in Vilovo prior to treatment was 24.5 to 27.7 per replication (Table 4). In this locality in visual assessment, the number of insects was slightly lower but in neighboring plots (outside the experiment) was much higher. Two days after the treatment with insecticides, the number of adults was significantly lower compared to the control. The efficacy of Avaunt 15 EC was 90% and of Fobos-EC 84.6%.

In order to avoid the emergence of resistant strains of *D. v. virgifera* caused by frequent use of insecticides with the same mode of action, the use of tank mix combinations or alternative use of the preparation of different modes of action is recommended and is the main strategic principle in combating the resistance. For the control of *D. v. virgifera* no data on resistance to indoxacarb and bifenthrin exist. There is a certain level of resistance of *Helicoverpa armigera* Hübner towards indoxacarb (Pakistan) and in populations that are highly resistant to the insecticide belonging to the group of pyrethroids, organophosphates and carbamates (Ahmad et al., 2003).

Test results on the European corn borer indicate the nature of indoxacarb as pro-insecticides which requires hydrolytic activation (Analysis et al., 2008). By topically applying indoxacarb its toxicity was antagonized if the larvae were previously treated with DEF - an inhibitor of hydrolytic enzymes. DEF also inhibited the activity of hydrolytic enzymes and the formation of active metabolites, both *in vivo* and *in vitro*. Hydrolytic activation of indoxacarb is a unique among chemical insecticides and may be particularly important in the control of insects that have developed a resistance as a consequence of increased hydrolytic metabolism. If the same hydrolytic enzymes are responsible for the resistance to pyrethroids, carbamates and organophosphates in connection with activation of the indoxacarb, there is the possibility of negative cross-resistance to indoxacarb. Agricultural extension services pay a lot of attention

to detecting the presence of *D. v. virgifera* in Serbia, monitoring the conditions for the development, the occurrence and prognosis of this pest. However, one of the aggravating moments in the monitoring and prognosis is a long season of maize growing, with maize hybrids from early maturing to late once. The forecast and severity of larvae and adults depends on the soil type (normal or heavy soils), growing conditions (repeated sowing or monoculture), assortment (mercantile, seed, silage), as well as on the choice of the method for determining the critical number. But according to some authors also will depend on the abundance in the previous year, the sex ratio in the population and assembly plants (Edwards et al., 1994). Bearing in mind the above mentioned it is necessary to determine the economic thresholds and recommend adequate measures according to the conditions and good knowledge of pest biology.

Conclusions

Based on the tests and the results achieved in control western corn rootworm (*Diabrotica virgifera virgifear*) on commercial corn with insecticides Avaunt 15 EC (indoxacarb) and Fobos-EC (bifenthrin), the following conclusions can be made:

Three days after application of the products Avaunt 15 EC (0.25 l/ha) and Fobos-EC at Parage site, the insecticides showed efficacy of 92.5-100%, while in the locality Vilovo two days after the application of insecticide efficacy was 84, 6-90%.

Seven days after insecticides treatment, the number of western corn rootworm adults was significantly lower compared to the control at both locations. The efficiency of the tested products for control of adult corn rootworm ranged from 85.4-97.3%, depending on insecticide sand locality.

The number of *D. virgifera virgifera* adults 15, or 16 days after the application of insecticides was considerably lower level compared to the control in both locations. Efficacy of insecticides ranged from 87.1 to 100%.

The applied insecticides successfully controlled *Diabrotica virgifera virgifera* in corn.

Abstract

Colletotrichum destructivum O`Gara, inducer of alfalfa and red clover anthracnose, is widespread in many areas in Serbia. Considering that and, also, the damage it can cause, anthracnose is economically very important disease. During ten years period, especially in summer and autumn, plants with anthracnose symptoms were studied in alfalfa and red clover fields. Stem infection results in wilting and death of the upper portion of the steam, giving rise to the characteristic “shepherd’s crook“ symptom. Strain of *C. destructivum* were isolated from diseased alfalfa stems collected from different locations in Serbia.

To examine the level of sensitivity of different red clover genotypes in experimental conditions, one isolate Coll-8 (*C. destructivum* originating from Serbia) were used. Fourteen commercial red clover genotypes of different origin (K-27, K-39, K-32, K-38, Una and Kolubara originating from Serbia, Čiroku, Lea, Virgiana, Valentine, Wilo, Repio and Diana originating from USA) were examined in this study. Infected plants showed typical symptoms of anthracnose. Necrotic lesions appeared on the plant stems and gentle bending of the top of the upper third of stems occurred on tested plants. Necrotic lesions further spread onto the whole plant and in some plants led to withering. Assessment of damage by pathogen inoculation was based on the scale of 0-5. All studied isolate caused symptoms of red clover anthracnose in the plants. Investigated genotypes showed contrasting resistances to *C. destructivum* isolate. The aim of this study was to determine sensitivity of commercial red genotype.

Key words: anthracnose, *Colletotrichum destructivum*, genotypes, red clover, sensitivity

Introduction

Red clover (*Trifolium pratense* L. var. *sativum* Sherb.) is one of the most important forage crops in Serbia. The fungus *Colletotrichum destructivum* O` Gara, which is causing anthracnose disease in red clover, is an important limiting factor for red clover growth, plant vigor and persistence (Boland and Brochu, 1989). During the summer and autumn, diseased plants start appear in the field. *C. destructivum* was isolated from alfalafa stem lesions typical of *C. trifolii* (Graham et al., 1976). Conidia form in the acervuli on stem lesions. Rainsplash or wind carry the conidia to the growing petioles and stems. The fungus grows down infected stems into the crown and taproot, causing killing of tissue, predisposition to winter injury, wilting or plant death. Nevertheless, soil infections of alfalfa by *C. destructivum* have caused considerable yield losses in North America **(**Boland and Brochu, 1989), Europe (Robotic and Klokocar-Smit, 1983), North Africa and South Africa (Koch et al., 1989). The host range of *C. destructivum* is wide and includes legumes such as *Phaseolus lathyroides* L., *Glycine max* (L.) Merr., *Trifolium* spp., *Lotus* spp., *Leucaena leucocephala* (Lam.) DeWit., *Melilotus albus* Desr., *Vigna unguiculata* (L.) Walp., *Coronilla varia* L., as well as tobacco (*Nicotiana tabacum* L.) and dodder (*Cuscuta* spp.) (Latunde-Dada et al., 1996).

The aim of this study was to determine sensitivity of commercial red clover genotypes to *C. destructivum* in Serbia, and possibilities for breeding the resistant red clover genotype.

Material and methods

The sensitivity of commercial red clover genotypes was tested in order to find potential sources of resistance to *C. destructivum*. Fourteen commercial red clover genotypes of different origin (K-27, K-39, K-32, K-38, Una and Kolubara originating from Serbia, Čiroku, Lea, Virgiana, Valentine, Wilo, Repio and Diana originating from USA) were examined in this study.

Isolate included this study were selected in the spring of 2010, based on morphological and molecular traits. The study included one isolate from Serbia Coll-8 identified as *C. destructivum*. The experiment was conducted in the greenhouse of the Institute for forage crops, Kruševac (Serbia). Red clover seeds were sown in plastic containers at a depth of 2 cm in sterile substrate. Conidial suspension was prepared from cultures of tested isolate, grown for ten days on PDA medium at 25° C in the dark. The concentration of spores was determined by hemocytometer by Thom and it was 4-6 x 10^{-4} spores/ml. Inoculated red clover plants were old 7 week and scarred prior to inoculation by cutting and sprayed with spore suspension. The experiment was conducted in ten repetitions, 10 plants per genotype and red clover plants inoculated with sterile water used as a negative control.

Sensitivity of different red clover genotypes to isolates of *C. destructivum* was evaluated four weeks after inoculation using a modified method by Ostazeski et al. (1969), according to a scale of 1-5:

1 - no stem lesions or only few small water-soaked or black spots
2 - stems with elongated black lesions but without acervuli
3 - stems with long, wide, but non-gridling lesions, with acervuli present
4 - large, coalescing and sporulating lesions which gridle and kill upper part of seedling
5 - seedling dead

Based on the results, severity index was calculated according to the following formula:

$$I = \Sigma \frac{(n \times k)}{N \times K} \times 100$$

I = severity index	N = total number of seedling
n = number of seedlings in class	K = number of categories
k = number of individual categories	$\sum$ = sum of products

According Ostazeski et al. (1969), where 1 and 2 are assigned to resistant plants. Plants were scored individually, two weeks after inoculation. Disease intensity or severity of infected plants was calculated using the severity index.

Results and discussion

All studied isolate caused symptoms of red clover anthracnose in the plants. Four weeks after inoculation, necrotic spots in the lower parts of stem appeared in infected red clover plants of all genotypes (K-27, K-39, K-32, K-38, Una, Kolubara, Čiroku, Lea, Virgiana, Valentine, Wilo, Repio and Diana) (Table 1). As the disease progresses stem changed color to glossy yellow, the crown bended in the form of a hook and plants started to wilt.

According to Ostazeski et al. (1969), sensitive genotypes have 10% of healthy plants, while the genotypes with over 65% can be deemed resistant. Genotypes Arc, which is resistant to race 1 of *C. trifolii,* has the severity index 2.72 to 2.25 (Ostazeski et al., 1979). The isolate Coll-8 showed higher pathogenicity and number of resistant plant were very low in genotypes Kolubara and Wilo inoculated with this isolate (5%). By the severity index (3.3), it can be concluded that the genotypes Kolubara had the moderate resistance. Also genotypes Wilo showed a higher resistant to isolate Coll-8, with severity index 1.9.

The genotypes K-27 and Čiroku had the highest ratio of healthy plants (40%), but genotypes

K-27 had the severity index (3.2), this genotypes is moderate resistant to tested isolate. By the severity index (2.4), it can be concluded that the genotypes Čiroku is resistant to the studied isolate.

Table 1. Evaluation of sensitivity in commercial genotypes of red clover to isolate *C. destructivum* (Coll-8)

Genotypes	Percentage of plants in score classes					Severity index (%)	Resistant plants (1+2%)
	1	2	3	4	5		
K-27	0	40	10	0	0	3.2	40
K-39	0	10	25	10	5	3.2	10
K-32	0	10	20	10	10	3.4	10
K-38	0	35	5	20	0	2.5	35
Una	0	35	15	0	0	2.3	35
Kolubara	0	5	30	10	5	3.3	5
Čiroku	0	40	5	0	5	2.4	40
Lea	15	10	25	0	0	2.2	25
Virgiana	0	10	35	0	0	2.7	10
Wilo	0	5	15	10	0	1.9	5
Repio	5	30	10	5	0	2.3	35
Diana	0	15	20	5	10	3.3	15
Valentina	0	0	35	0	10	3.6	0
Kontrol	-	-	-	-	-	-	-

The genotypes K-38, Una and Repio showed similar results for sensitivity on the tested isolate, and they showed higher resistance to tested isolate *C. destructivum*.
Also genotypes K-39, K-32 and Virgiana had very low the number of resistant plant and they showed moderate resistance (Table 1). The genotype Valentina had the lowest resistance to tested isolate.
The results indicate high variability of genotypes responses to isolate. In addition, the response of individual plants within genotypes to inoculation with pathogenic isolate was also very variable. A small number of individual plants have managed, despite clear symptoms of disease, to produce seeds. Progeny of these plants is an excellent source of resistance to the tested isolates of the pathogen and will be included in the next cycle of selection for this trait. Considering the results of Devine et al. (1971) who showed that after several cycles of selection the level of resistance can be increased, we believe that it is justified to continue investigations in this direction. Boland and Brochu (1989), O'Neill et al. (1989) and Schubiger et al. (2003), in their studies of pathogenicity, showed that the species *C. trifolii* is more infectious for alfalfa than *C. destructivum*. Boland and Brochu (1989) and O'Neill et al. (1989) reported that *C. destructivum* in an enclosed space showed a higher level of infectivity and the same level of infection as *C. trifolii* in field conditions.
Three races of *C. trifolii* (races 1, 2 and 3) have been described based on differential responses of alfalfa cultivars (Ariss and Rhodes, 2007) conferred by two separate dominant genes, designated *An1* and *An2*, are attributed to anthracnose resistance. *An1* confers resistance to race 1 and likely, race 4, whereas *An2* confers resistance to races 1 and 2. It is noteworthy that the race 3 of *C. trifolii* was reported 1982 (Allen et al., 1982), but this fungus was subsequently reclassified as *C. destructivum* (Yang et al., 2008, Ameline-Torregrosa et al., 2008). Despite the large number of studies, which indicated that resistance to anthracnose is controlled by major dominant or recessive genes and other resistance mechanisms, resistance to *C. trifolii* is not clear enough (Melotto et al., 2000; Schubiger et al., 2004). In the

studies by Schubiger et al. (2003), only two Mattenklee cultivars (Pavo and Merula) exhibited 50% resistance or more to *C. trifolii*. The other Swiss cultivars of the persistent Mattenklee type showed an intermediate level of resistance. Vasić et al. (2010b) reported that investigated cultivars and breed populations showed various resistances to different *C. trifolii* isolates. The resistance degree depends on both the isolates of *Colletotrichum trifolii* and red clover cultivars. Vasić et al. (2010a) showed that alfalfa clones had different resistance to *C. trifolii*. Comparison of American and Serbian cultivars showed the American alfalfa cultivars had the higest level of resistance (64.5% plant survival). Among the varieties listed in Serbia, their cultivars showed the uneven resistance levels, the percentage of surviving plants was 0-56.4% on average. The most susceptible tested cultivar was with a plant survival rate of 56.4%.
Selected red clover genotypes that showed higher levels of tolerance to the tested isolate will be further used in field trials in order to accurately assess the level of resistance. This will enable the separate genotypes to be used in the further process of selection and breeding of red clover to improve the level of resistance.

Abstract

Citrus is one of the most important cultivated crops in Turkey. As for all agricultural crops, plant protection problems such as pests and diseases are the major factors decreasing crop yield. There are more than 150 pest species causing damage on citrus. Among them scale insects are main pests. There are lots of predators and parasitoids feeding on scale insects. *Rhyzobius lophanthae* Blaisdell, a polyphagus predator, is one of the most important predators of scale insects and widely distributed in citrus plantations in Turkey.

In this study, we investigated the maternal effect on the reproduction and development of *R. lophanthae* at the 1st, 10th, 20th and 30th days. One day age adults are used in the treatments. *Aspidiotus nerii* was used as the prey. Trials were performed in a climatic chamber with 26±1 °C temperature and 65±1 % RH.

The average numbers of offsprings produced by the eggs laid by 1, 10, 20 and 30 days old females were 179.0, 143.0, 264.0 and 314.5, respectively. Life table parameters were also calculated. Net reproductive rate ($\mathbf{R_0}$), intirinsic rate of increase ($\mathbf{r_m}$) and mean generation time ($\mathbf{T_0}$) were found to be 24.409, 19.067, 24.256 and 25.732 females/females/generation, 0.130, 0.107, 0.132 and 0.106 females/females/day, 24.658, 27.456, 24.227 and 30.671 days, respectively.

Keywords: Maternal effect, *Rhyzobius lophanthae*, intrinsic rate of increase, life table

Introduction

Citrus is the most important cultivated crop among fruits in the World. Turkey has an important place in terms of citrus production among the Mediterranean countries (Uzun, 2012). The Mediterranean Region of our country is the most important cultivation area for citrus production. In recent years, it was reported that there had been a significant increase both in the number of pests and the number of populations in this area (Uygun and Karaca, 1998). Among these pests, Diaspididae which are called scale insects are very important and one of the most important species is Red scale insect *Aonidiella aurantii* (Maskell) (Homoptera: Diaspididae) (Kansu and Uygun, 1980). Although measures are taken against these pests, they can destroy citrus trees in a short time (Anonymous, 1991; 2008).

Various control methods have been applied against these pests that cause major damage on citrus. The most common method is chemical control. However, populations of the pests increase in a short time after the applications of insecticides and they become harmful again (Uygun and Şekeroğlu, 1981). So, it seems that chemical control is a temporary solution. In addition, pesticides disturb the natural balance and have given rise to undesirable chemical drug residues on the products. Nowadays, studies have continued on the development of integrated pest management (IPM) which aims to keep pest populations below economically damaging level without adversely affecting beneficial insects in agriculture. ‘‘Biological Control’’ is the most important method in IPM (DeBach, 1969; Uygun et al., 1987).

The majority of the agents used in bological control are insects, and the majority of the insects are from Coccinellidae. *Rhyzobius lophanthae* Blaisdell (Coleoptera) which belongs to this

family is known as an important predator of scale insects (Hodek, 1973; Hodek ve Honek, 1996). In the studies carried out in our country, it was reported that this predator was common in citrus areas where scale insects were intensive (Tunçyürek, 1970; Öncüer, 1977; Kansu and Uygun, 1973; 1980; Uygun and Şekeroğlu, 1981; Uygun et al., 1987; Uygun vd., 1992 a, b; Uygun vd., 1995).

In this study, we investigated the maternal effect on the reproduction and development of *R. lophanthae* at the 1st, 10th, 20th and 30th days.

Materials and Methods

Aspidiotus nerii culture:

In this study, *A. nerii* population which was reared on potato tubers in the insectarium of Biological Control Laboratory of the Department of Plant Protection, Faculty of Agriculture, Süleyman Demirel University, was used. Clean potato tubers in plastic trays were deliberately infested with crawlers of *A. nerii* to build up the population. This procedure was continued for the duration of the study for two or three times a week. Rearing studies of *A. nerii* were carried out in rooms adjusted to 25±1°C, L:D 16:8 h photoperiod and 65±5% RH.

Rhyzobius lophanthae culture:

In this study, individuals of *Rhyzobius lophanthae* which were used as main material were collected from the citrus areas intensively infested with the pest, in Antalya (Steiner, 1962). In this way, both adult and immature stages of this predator insect were separately dropped into the jar with potatoes infested by scale insects (Nar et al., 2009). Potatoes were changed at least twice per week, in the culture jar throughout the study. Rearing studies of *A. nerii* were carried out in rooms adjusted to 25±1°C, L:D 16:8 h photoperiod and 65±5% RH.

Establishment of the experiments:

In this study, 9x9x8 cm plastic storage containers were used for individuals of *Rhyzobius lophanthae*. Pupae of this insect which were obtained from production source were taken into the container. After they became adults, 20 individuals (10♀, 10♂) were taken into separate containers. Eggs, left by the females completed the development, were separetely transferred into trial containers (an egg onto one potato tuber). Four different experimental groups were formed from females in this population. Eggs laid in the 1st, 10th, 20th and 30th day were taken onto separate potatoes infested with the scale insect. Individuals, belonged to each experimental group were observed from egg to death. During this time, each development stage and the number of offsprings were daily recorded. At least 20 repetitions were used for each experimental group. Rearing studies of *A. nerii* were carried out in rearing rooms adjusted to 27.5±1°C, L:D 16:8 h photoperiod and 65±5% RH.

Life table, Weibull distribution and analyses

The data that was obtained at the end of the trial were evaluated with age-related life table for each experimental group. All parameters were calculated by RmStat-3 according to Euler-Lotka equality (Birch, 1948).

Parameters were:

Survival rate (l_x) and fecundity (m_x), (Birch, 1948),

Net reproductive rate, $R_0 = \sum l_x.m_x$ (Birch, 1948),

Intirinsic rate of increase (r_m), $\sum e^{(-r_m.x)}.l_x.m_x = 1$ (Birch, 1948),

Mean generation time, $T_0 = \frac{\ln . R_0}{r_m}$ (Birch, 1948),

Gross reproduction rate, $GRR = \sum m_x$ (Birch, 1948),

Finite rate of increase, $\lambda = e^{r_m}$ (Birch, 1948),

Doubling time, $T_2 = \frac{\ln 2}{r_m}$ (Kairo & Murphy, 1995)

Reproductin value, $V_x = \frac{\sum_{y=x} (e^{r_m \cdot y} . l_y . m_y)}{l_x . e^{-r_m . x}}$ (Imura, 1987),

Life expectancy, $E_x = \frac{\sum_{y=x} \frac{l_y + l_{y+1}}{2}}{l_x}$ (Southwood, 1978; Carey, 1993),

Stable age distribution, $C_x = \frac{l_x . e^{-r_m . x}}{\sum_{x=0} (l_x . e^{-r_m . x})}$ (Birch, 1948).

Life table parameters were calculated for the populations at different parantal ages. The differences in r_m values were tested for significance by estimating the variance using the jack-knife method (Meyer et al., 1986; Özgökçe & Atlıhan, 2004). Then, these values were used in the Tukey multiple comparison test. In this study, age-dependent survival curves of the populations of different ages were obtained by Weibull distribution (Pinder et al., 1978).

$$S_p(t) = e^{\left[-\left(\frac{t}{b}\right)^c\right]} \qquad t, b, c > 0$$ (Deevey, 1947).

In the above formula; $S_p(t)$ is probability of survival, b is measure of slope, c; form of slope, t is time. The values of C parameter could be c > 1, c = 1, c < 1. Adhering to these values, c > 1 represents growing populations, c = 1 represents stable populations and c < 1 represents decreasing populations (Deevey, 1947; Pinder et al., 1978). The parameters that were obtained according to this curve is calculated using CurveExpert pro (ver. 1.6.7), SPSS (ver. 17), MS Excel (ver. 2003).

Results and discussion

In this study, survival rate (l_x), fecundity (m_x) and reproduction value (V_x) of the different age groups are shown in the graphic. As seen in the graphic, survival rates decreased and fecundity (m_x) and reproduction value (V_x) demonstrated differences depending on the age (Figure 1).

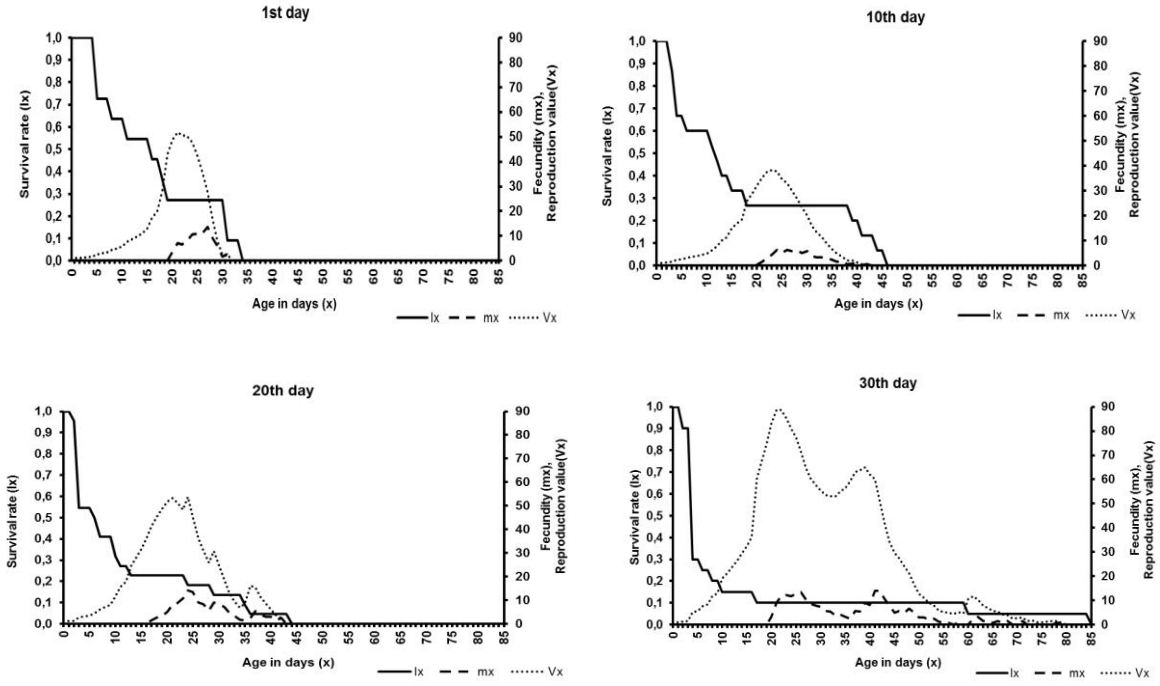

Figure 1. Survival rate (l_x), fecundity (m_x) and reproduction value (V_x) of *Rhyzobius lophanthae* in different age groups

Total development time and the other periods of *Rhyzobius lophanthae* in the different mother age groups were given in Table 1. Hatching times of the eggs were same for each age groups. Although there were differences between the development stages of larvae in different groups, pupae and adult stages were statistically same.
Preoviposition times were between 2.000 – 4.750 days, oviposition times were between 8,333 – 37,000 and postoviposition times were between 1,000 – 10,000 days in different groups (Table 1).

Total life time	16,636±3,350a	17,533±4,213a	11,864±2,747a	11,900±4,780a
Daily fecundity	13,401±0,781a	5,409±1,414a	10,303±3,736a	5,420±1,095a
Total fecundity	179,000±15,875a	143,000±38,074a	264,000±80,238a	314,500±128,500a

In this study, life table parameters of different groups were given in Table 2. As a result of the analyses, intrinsic rate of increase (r_m) was found between 0.106 - 0,132 female/female/day and there was not statistically significant difference between age groups. The values of net reproductive rate (R_o), mean generation time (T_0) and gross reproduction rate (**GRR**) showed differences among different groups (Table 2).

Table 2. Life table parameters of *Rhyzobius lophanthae* in different mother ages

	Mother age			
Life Table Parameters	**1st day**	**10th day**	**20th day**	**30th day**
Euler-Lotka (Birch, 1948)				
Intrinsic rate of increase, r_m	0,130a	0,107a	0,132a	0,106a
Net reprocution rate, R_o	24,409	19,067	24,256	25,732
Mean generation time, T_o	24,658	27,456	24,227	30,671
Gross reproduction rate, ***GRR***	91,167	72,333	149,283	266,318
Doubling time T_2	5,349	6,456	5,266	6,546
Finite rate of increase, λ	1,138	1,113	1,141	1,112
n	11	15	22	20

In the literature, it is reported that intrinsic rate of increase (r_m) of *R. lophanthae* was 0.122 female/female/day (Stathas et al., 2005) and between 0.038 – 0.155 female/female/day at different temperatures (Nar et al., 2009). Survival rates of adults of different groups were given in Table 2. According to the C parameter that determine the format of the slope of the Weibull distribution, all groups is similar to Type 3 ($c < 1$) of Holling. In addition, values of C parameters according to different groups were given in the Table 3 and graphics of Weibull distribution were given in Figure 2.

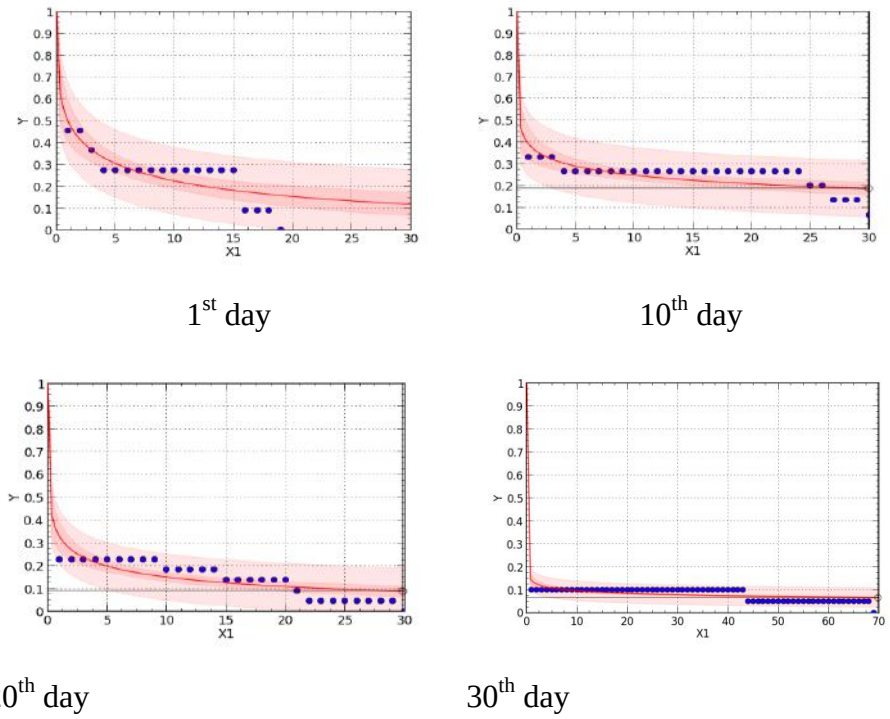

Figure 2. Survival rates of adults of different groups

Table 3. Values of C parameters according to different groups

Parameters	1st day	10th day	20th day	30th day
b	2.95±0.66	1.43±0.71	0.60±0.27	0.60±0.27
c	0.33±0.061	0.17±0.04	0.23±0.035	0.08±0.01
Type	3	3	3	3
R^2	0.65	0.41	0.61	0.61

In conclusion, *R. lophanthae* in the four different mother age groups show similar reproduction rate patterns. Thus, it can be concluded that parents developed from eggs laid by adults of different age could represent same reproductive performance. However, it is necessary to study reproduction behaviour of the natural enemy under field conditions.

Abstract

This research was conducted to determine the reaction of 25 (18 lines and 7 cultivars) bread wheat genotypes developed for dry lands against Stripe Rust (*Puccinia striiformis* f.sp. *tritici*) in 2012-2013 growing seasons in Konya ecological conditions. The inoculation of Stripe Rust was performed artificially. Observations and evaluations of Stripe Rust disease development were made according to Modified Cobb scale. 11 of 18 bread wheat lines showed immune level of resistance against Stripe Rust. No. 8 line was evaluated as the most susceptible genotype with 100S value. Among the standard cultivars, Bezostaja and Gerek were determined as very susceptible with 100S value. Regarding to results, candidate varieties namely, BDME 09/1K, BDME 11/1K, and BDME 11/2K, were evaluated as highly resistant to Stripe Rust.

Key words: *Bread Wheat, Dry areas, Stripe Rust, Genotype, Reaction*

Introduction

Wheat (*Triticum aestivum* L.) is the first important and strategic cereal crop for the majority of world's populations. Worldwide, wheat provides nearly 55% of the carbohydrates and 20% of the food calories consumed globally (Breiman and Graur, 1995). Despite of its economic importance, wheat is attacked by number of pathogens which cause diseases like fungi (rusts, smuts, bunts etc.), bacteria (bacterial leaf blight, bacterial mosaic, black chaff etc.) and virus (wheat dwarf, wheat spot mosaic, wheat streak mosaic etc.). Food protection of the world, rely on production of two important cereal crops i.e., rice and wheat. Wheat rusts problem has emerged due to attack of fungus all over the wheat growing areas of the world.

Leaf rust caused *Puccinia recondite* f. sp. *tritici* and Stripe Rust caused *Puccinia striiformis* f. sp. *tritici* and stem rust caused by *Puccinia graminis* f. sp. *triticiare* potential risk that cause decrease in the yield of wheat (Singh et al., 2005). It has been known that the crop yield loss has ranged between %12-15 since yellow rust and unexpected disease epidemics can cause enormous yield losses (Kınacı, 1982). The rust diseases can occur in all wheat production areas; in general yellow rust is epidemical in Middle and East Anatolia, while stem and leaf rust are common in Aegean and Marmara Regions and in Southeastern, only stem rust is widespread in Turkey (Aktaş, 2001).

Stripe Rust (*Puccinia striiformis* f.sp. *tritici*) is an important disease threatening wheat production and it can be seen in majority of wheat growing area and from time to time its epidemics can cause significant loss in crop yield and quality. When the spring is cool and rainy through the years, the pathogen can multiply very fast and spread out by wind to long distances. According to research reports, in the years of 1991 (in Central Anatolia) and 1995 (in Çukurova Region), it was experienced significant crop yield loss due to yellow rust epidemics in Turkey (Braun and Saari, 1992; Düşünceli et al., 1999). As an alternative to chemicals which have many side effects such as being non-economic, disruption of the natural balance, environmental pollution, researchers focused on developing of new resistant

varieties for plant disease control. Since the pathogen can often develop new race, the continuous studies on developing new varieties has become necessary.
Therefore in this study, it was aimed to determine the reactions of some wheat lines developed in Bahri Dağdaş International Research Institute for dry lands against to Stripe Rust in 2012-2013 years.

Material and method

The plant materials were consisted of wheat lines at the stages of regional yield trials that were developed for dry lands by breeders at Bahri Dağdaş International Research Institute and the experiments were conducted in the growing season of 2012-2013 years.
The reactions of genotypes were tested in disease nursery of Bahri Dağdaş International Research Institute. The plantings were done with 1 meter rows and 5-7 depth one replication for each line/variety. As control plants, one row of Stripe Rust susceptible variety “Little Club” was planted every 5 rows. Additionally, the experimental area was surrounded with “Little Club” as six rows to encourage the disease development.
As inoculum source, Stripe Rust uredospores, which were collected from field a year in advance and stored in liquid nitrogen, were used. Inoculation was prepared as mixture of water, Tween 20, glycerol, and Stripe Rust uredospores. Sunset, rain, and cloudy weather were preferred for plant inoculations. Besides, mini sprinkle system was used for irrigation and encouraging the disease progress on dry days.
The evaluation of reactions of genotypes was done according to Modified Cobb Scale (Peterson et al., 1948) and the severity of stipe rust and infection types were recorded. When the disease development on control plants “Little Club” reached 90-100S scale value, the reactions of genotypes were evaluated twice through the season. The final disease severity data for the Stripe Rust was converted into a coefficient of infection (CI) by multiplying severity with a constant value for field response (Yadav, 1985; Stubbs et al., 1986; and Roelf et al., 1992). In order to calculate CI, for infection type values were S (Susceptible): 1, MS (Moderately Susceptible): 0.8, M (Moderately: intermediate reaction): 0.6, MR (Moderately Resistant): 0.4, R (Resistant): 0.2 (Stubbs et al., 1986). In the growing season of the 2012-2013years, the numbers of tested plant materials are given in Table 1.

Results and discussion

The disease development of Strip Rust was accomplished by artificial inoculations for the growing seasons in 2012-2013 years and the performance of each line/variety was determined. Evaluation was made when the disease score reached 90-100S on control plants “Little Club”. According to results, among 25 genotypes including lines and varieties, the Stripe Rust severity was varied between 0-100 percent. As seen in Table 1, the varieties of Gerek, Bezostaya, no.10, and no.11 genotypes were highly susceptible with 80-100S score values while genotypes numbered as 7, 8, 14, 15, 17, 18, 19, 20, 21, 22, and 23 were determined as resistant at immune level. No. 12 and 16 genotypes gave moderately resistant (MR) reaction with 10% disease severity while No.13 line and the variety of Tosunbey were moderately susceptible (MS) with %20 disease severity.

* Percentage of Flag Leaf Area Covered by Stripe Rust pustules

**S (Susceptible), MS (Moderately Susceptible), MR (Moderately Resistant), R (Resistant)

Development of resistant varieties against the disease is always an important objective in wheat breeding programs for crop improvement. These resistance genes, however, became ineffective due to the acquisition of virulence to that particular resistance gene (Sajid et al., 2014). As an alternative control method for controlling Stripe Rust, utilization of genetically resistance resources is inevitable way and in this regard, the importance of these studies emphasized one more time in this study.

Conclusion

In brief, the breeding for screening of resistant variety would be considered as long-term studies since some pathogens like Stripe Rust could change form and generate new pathogenic race often. It is needed to take precautions including the registered varieties for screening studies of resistance to prevent the disease attack and losing the resistant varieties.

DETERMINATION OF OPTIMUM O_2 OR CO_2 FOR APPLE CV. STARKRIMSON DELICIOUS UNDER CONTROLLED ATMOSPHERE STORAGE

İsa EREN*, Özgür ÇALHAN, C. Ebru ONURSAL, Atakan GÜNEYLİ, Tuba SEÇMEN, Süleyman AKOL

Directorate of Fruit Research Institute, Eğirdir, Isparta,Turkey
*Corresponding author: isaeren37@hotmail.com

Abstract

In developed countries, instead of regular atmosphere (RA) storage, controlled atmosphere (CA) storage is used for storing apples. In Turkey, Isparta is the major apple production area. However, CA storage is not widespread. Some of the main reasons why CA storage is not widespread are as follows: the effects on fruit quality of CA storage are not sufficiently understood, there is still a lack of knowledge on storage composition and conditions, and technical staff. This study was conducted for the purpose of determining optimum gas compositions for Starkrimson Delicious variety, which is widely produced in the region, under CA storage. The apple fruits subject to the study were harvested at optimal harvest date and then stored at 0°C for 8 months under both RA and CA storage conditions (1% CO_2, 2% O_2; 2% CO_2, 2% O_2; 3% CO_2, 2% O_2), followed by a shelf life of 7 days at 20°C. During storage periods, fruit quality analyses (firmness, weight loss, TSS, TA, ethylene production, respiration rate, fruit color) and biochemical analyses (antioxidant activity and total phenols content) were performed. The analyses made demonstrated that, compared to RA storage, all CA storage conditions were in general more effective in preserving the quality of fruits. CA storage led to reduced weight loss, suppression of ethylene production and respiratory rate, and maintenance of firmness. Antioxidant activity and total phenols content increased under both CA and RA storage conditions during storage. The results obtained indicate that the most suitable CA storage composition in maintaining apple quality factors is 2% O_2 + 3% CO_2.

Keywords: *Apple, Starkrimson Delicious, fruit quality, controlled atmosphere*

Introduction

The world apple production is approximately 76 million tons. The group of Red Delicious corresponds to 19% of the said production (Özongun et al., 2014). According to the data of 2014, Turkey is ranked as the third in the world apple production, with a production amounting to 2.480.444 tons (TUİK, 2015). Isparta province meets 22% of Turkey's apple production with 615.000 tons. Nearly half of the apples produced in Turkey are Red Delicious (Erkut, 2009). Starkrimson Delicious is an apple variety included in the said group.

Isparta is a significant province of Turkey in terms of apple production and cool storage rooms. In the province, apple fruits are commonly stored at regular atmosphere storage rooms. In recent years, there has been an increase in controlled atmosphere storage capacity. In line with this increase, researches conducted on storage conditions for the apple varieties grown in the region have become crucial.

In recent years, CA storage rooms have been used in order to maintain quality for a longer time and reduce losses during the storage of apples (Bai et al., 2005). The CA technology makes it possible to store products at higher quality for a longer time (Beaudry, 2009). In CA storage, ambient air composition at cool storage rooms (21% O_2, 0.03% CO_2 and 79% N_2) is modified by reducing oxygen and increasing carbon dioxide. Thus, cold storage and shelf life is extended for many fruits and vegetables compared to regular storage (Karaçalı, 2009). The performance of fruits in CA storage systems varies by type or even variety (Brackmann and

Streif, 1993). The effects of O_2 and CO_2 levels in atmosphere composition on a product depend on product species and variety, maturity phase in harvest, and gas concentration at the storage room (Thompson, 1998). In addition, product's sensitivity to low O_2 and high CO_2 under the ecological conditions of the region where the product is grown is also effective (Lau, 1985; Ertan et al., 1992; Volz et al., 1998). For this reason, in controlled atmosphere storage, optimum gas composition needs to be determined for each product according to the ecological conditions under which it is grown. Depending on species and variety, CA storage below or above the optimum leads to specific low oxygen and high carbon dioxide harms. On the other hand, anaerobic respiration and fermentation cause deteriorations in aroma, changes in taste, and irregularities in ripening (Karaçalı, 2009).
This study was aimed at determining the gas composition suitable for CA storage in the apple variety "Starkrimson Delicious", which is widely produced in Isparta (Eğirdir) region.

Material and methods

In the research, a 25-year-old Starkrimson Delicious on seedling rootstock in the Directorate of Eğirdir Fruit Research Institute was used as the material. Having been harvested at optimal harvest time, fruits were pre-cooled at 4°C. Following pre-cooling, fruits were stored in CA and in 3 different atmosphere compositions and under RA conditions for 8 months (Table 1). In order to determine the effects of treatments on shelf life quality, some of the samples taken every 2 months were kept for 7 days under shelf life conditions. The fruit samples taken every other 2 months during storage were analyzed in terms of weight loss (%), skin color (b* and h°), fruit flesh firmness (N), total soluble solids (TSS) (%), pH, titratable acidity (TA)(%), respiration rate (mL.CO_2/kg.h), ethylene production (µl.C_2H_4/kg.h), total phenols content (GAE mg/100 ml) and antioxidant activity (µmol TE/ml).

Table 1. Storage type, atmosphere composition and storage conditions

Storage type	Atmosphere composition		Storage conditions	
	CO_2 (%)	O_2 (%)	Temperature (°C)	Relative humidity (%)
CA-1	1	2	0	90-95
CA-2	2	2	0	90-95
CA-3	3	2	0	90-95
RA	0.03	21	0	85-90
Shelf life	0.03	21	20	60-65

Completely randomized design was replicated 3 times; 20 fruits per replication. The data obtained from the trial were subjected to variance analysis, using the JMP 7 statistical package program. Every storage period, differences between storage conditions averages were grouped according to the LSD multiple comparison test ($P<0.05$).

Results and Discussion

During storage periods, different levels of weight loss occurred in fruits under different storage conditions (fig 1). In terms of weight loss, there was a statistical difference between storage type averages. The highest weight loss occurred in regular atmosphere (RA) storage, while the lowest weight loss took place in CA-2. As reported in previous studies, fruits lose more weight in RA storage than CA storage (Erkan et al., 2004; Çalhan et al., 2014). The reason is that the relative humidity rate is lower in RA storage. The amount of weight loss continued to increase during shelf life. Especially in the fruits taken from CA storage rooms, the weight loss was higher than the one observed during storage.

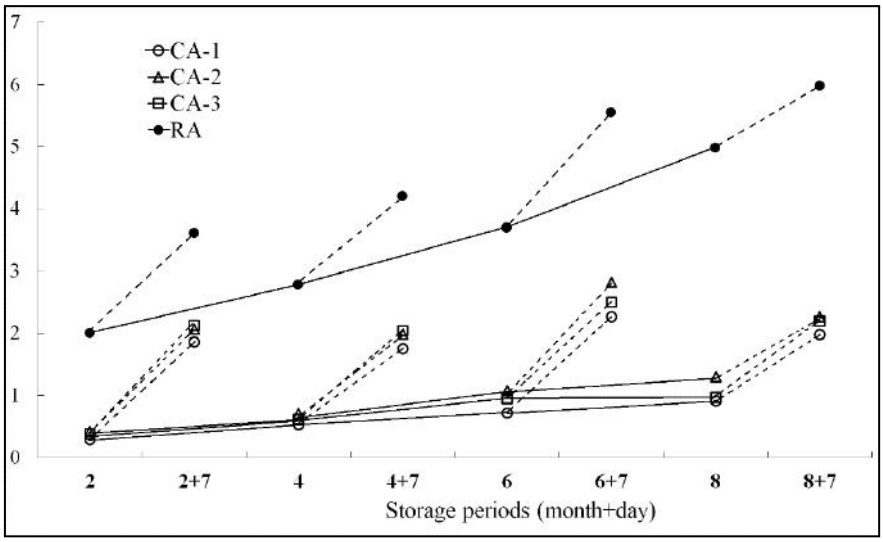

Fig. 1. Effects of different storage conditions and storage periods on weight loss of Starkrimson delicious apple fruits (dashed line: at the end of shelf life period)

Fruit flesh firmness is another quality criterion in apples significant for consumers. Important differences were found in terms of firmness both during storage period and between storage type (Table 2). Beginning from harvest, a decrease was encountered in firmness levels during storage period (Zanella, 2003; Çalhan et al., 2014). The decrease in question increased further during shelf life. Especially at CA storage, decrease in firmness considerably slowed down during cold storage (Erkan et al., 2004). Here, fruit flesh firmness was best preserved at CA-2 and CA-3 storage type. The level of CO_2 was higher in the said storage rooms compared to CA-1, affecting the decrease of firmness. At the end of cold storage, a difference of approximately 10 N occurred in firmness values between CA storage and RA storage. However, the difference decreased during shelf life.

Having been 11.2% during harvest, the amount of TSS in fruits first increased at all storage rooms and then slightly decreased towards the end of storage (Table 2). In RA storage, the decrease in the amount of TSS in fruits was slightly higher than other storages.

Taking part in the creation of taste and aroma in fruits, acidity is another quality criterion. If acidity is maintained specifically during storage, it means the fruit has been stored better. In our study, acidity in fruits continuously decreased compared to the acidity during harvest. The decrease in question was more rapid in RA storage than CA storage (Zanella, 2003; Fan et al., 1997). The best results in maintaining acidity in fruits were obtained under CA-2 conditions.

Starkrimson Delicious has a completely red skin. During storage, no considerable change was observed in fruit skin color. A difference was seen between storage types in the statistical analysis performed in terms of hº color value. The highest hº values were obtained from RA and RA + shelf life fruits. In general, CA storage conditions were more effective in preserving hº color values in fruits.

Table 2. Effects of different storage conditions and storage periods on firmness (N), SSC (%), acidity (g/100ml) skin color (h^o) of Starkrimson delicious apple fruits.

Storage conditions	Periods (month+day)	Firmness (N)	SSC (%)	Acidity (g/100ml)	Skin color (h^o)
	Harvest	75,2 a	11,2 c	0,26 a	32,3 c
CA-1	**8**	63,4 c	13,1 b	0,24 b	31,2 cd
	8+7	52,2 de	14,4 a	0,23 bc	25,6 e
CA-2	**8**	65,4 bc	14,4 a	0,26 a	31,4 cd
	8+7	51,6 e	14,2 a	0,26 a	28,5 de

* Level of significance: *P≤0.05; **P≤0.01; ***P≤0.001.

The ethylene production of fruits was 0,31 µl/kg.h during harvest. However, during storage and especially RA storage, it increased very rapidly and reached ~80 µl/kg.h. On the other hand, in CA storage, ethylene production was suppressed and increased up to 15-25 µl/kg.h during cold storage. Previous studies also reported that CA storage suppressed ethylene production in apples (Wünsche and Heyn, 2015; Fan et al., 1997). It was seen that ethylene production decreased as the level of CO_2 increased between CA storage types. The lowest levels of ethylene production were measured under CA-3 conditions. CO_2 was seen to suppress ethylene production in fruits. During shelf life, the level of ethylene production increased in the fruits taken from CA storage but remained the same in the fruits taken from RA storage. However, the level of ethylene production of the fruits at CA storage rooms was found to be lower. During shelf life, the fruits stored at CA storage rooms were statistically in the same group.

Respiration rate is one of the most important factors determining the life of fruits after harvest. Increased respiration rate means a shorter post-harvest life. For this reason, the more the respiration rate of a fruit is suppressed under different storage conditions, the longer the fruit is stored. In our study, fruit respiration rates continuously increased in RA storage but first decreased and then returned to the levels during harvest in CA storage. In CA storage, fruit respiration decelerates as O_2 decreases and CO_2 increases (Fan et al., 1997). In our study, no statistical difference was found between CA storage rooms. However, the lowest respiration rate was obtained from CA-3 conditions. During shelf life, fruit respiration rates slightly increased compared to cold storage. The said increase results from keeping fruits at 20ºC in shelf life.

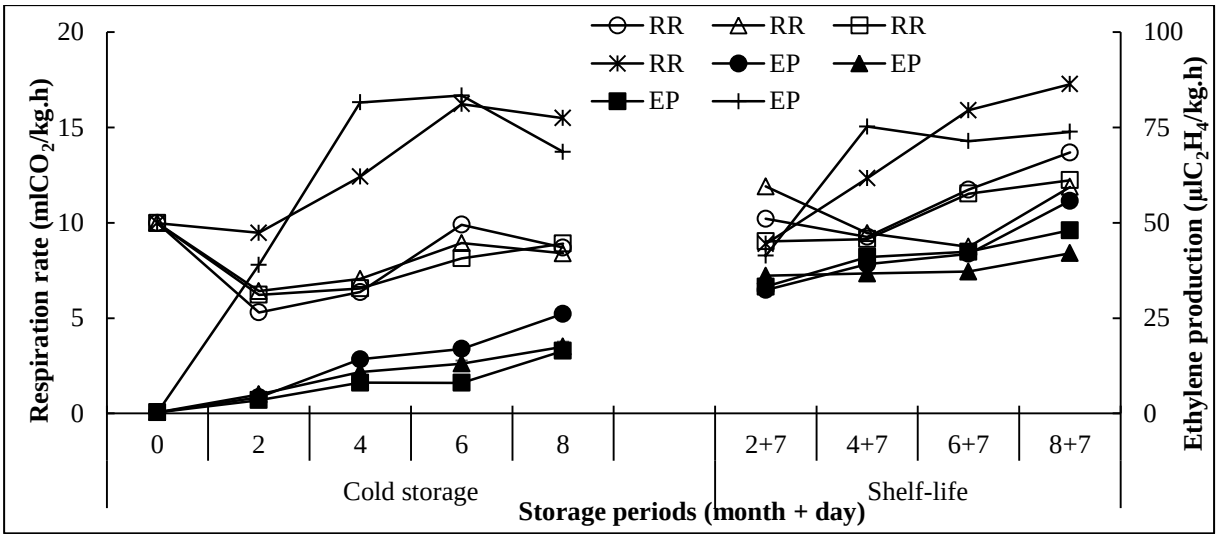

Fig. 2. Effects of different storage conditions and storage periods on respiration rate (RR) (ml CO_2/kg.h) and ethylene production (EP)(µlC_2H_4/kg.h) of Starkrimson delicious apple fruits.

During harvest, fruits' AA and TP contents were 6,17 µmol TE/g FW and 90,01 mg GAE/100 g FW, respectively. But, they increased during storage (Fawbush et al., 1997; Kuzucu and Aydın, 2014). At the end of storage, the highest increase was obtained in RA storage. An increase was also observed at CA storage rooms but it was lower than that at RA storage rooms.

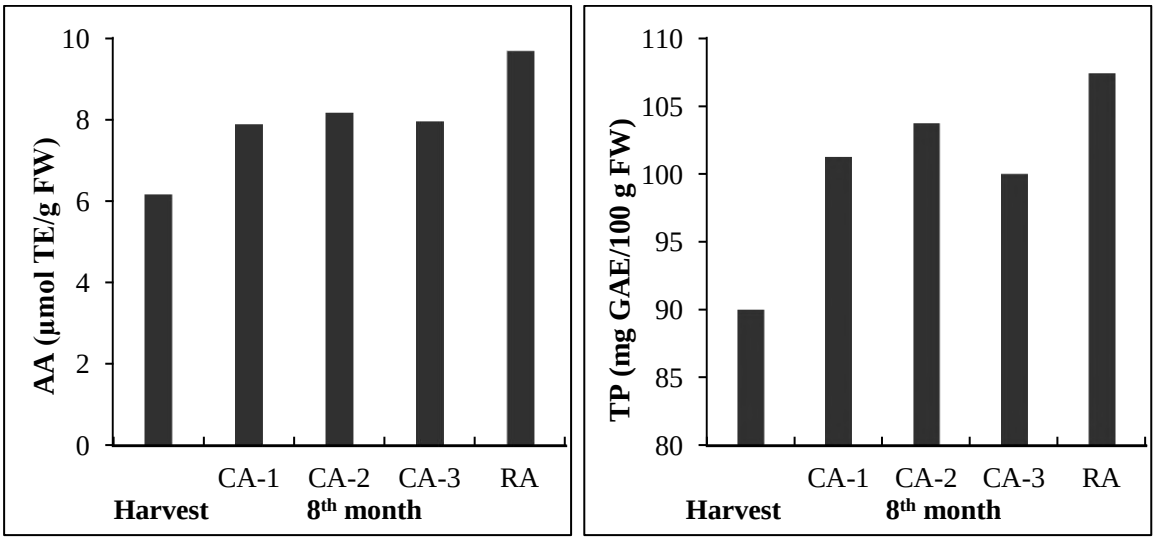

Fig. 3. Effects of different storage conditions on antioxidant activity (AA)(µmol TE/g FW) and total phenols (TP)(mg GAE/100 g FW) of Starkrimson delicious apple fruits at 8th month.

Conclusion

In Starkrimson Delicious, the level of weight loss did not exceed 5% for 8 months under both RA and CA storage conditions but the level of fruit flesh firmness highly decreased under RA conditions after the 6th month. For this reason, Starkrimson Delicious apple fruits cannot be stored for longer than 6 months under RA storage. For Starkrimson Delicious, during 8-month storage, CA-2 and CA-3 storage conditions were effective in preserving quality criteria (weight loss, ethylene production, respiration rate, fruit flesh firmness). However, the best storage condition was found to be CA-3 (2% O_2 + 3% CO_2).

Abstract

In current study, metal, non-metal and and heavy metal contents of different parts (buds, leaves, fruit and stems) of caper collected fromroadsideandinterior regionsof two different locations (Konya and Mersin) collected were determined by Inductively Coupled Plasma Atomic Emission Spectrometry (ICP-AES). K contents of samples changed between 10741 mg/Kg and 32529 mg/Kg. While the Ca contents of caper parts collected from roadside in Konya are found between 3344 mg/Kg (stem) and 17278 mg/Kg (leave), Ca contents of caper parts collected from interior regions was reported between 1762 mg/Kg (bud) and 10171 mg/Kg (leave). The same element was found between 4008 mg/Kg (stem) and 29104 mg/Kg (leave) on roadside in Silifke location. Cd contents of *C.ovata* and *C.spinosa* parts ranged from 0.06 mg/Kg (fruit) to 0.21 mg/Kg (stem) and 0.05 mg/Kg (fruit) to 0.54 mg/Kg (leave), respectively. Ni contents of *C.ovata* and *C.spinosa* parts changed between 0.37 mg/Kg (stem) to 1.53 mg/Kg (bud) and 0.19 mg/Kg (stem) to 4.91 mg/Kg (bud), respectively. In addition, while Zn contents of *C.ovata* change between 3.1 mg/Kg (stem) and 41.8 mg/Kg (leave), Zn contents of *C.spinosa* ranged from 11.5 mg/Kg (stem) to 44.6 mg/Kg (fruit).While the Cu contents of samples are found between 2.2 mg/Kg and 13.6 mg/Kg, Fe contents ranged from 32.9 mg/Kg to 117.7 mg/Kg.

Key words: caper, leave, fruit, heavy metal, road side, ICP-AES

Introduction

Caper is a plant with medicinal and aromatic properties. It is a long-lasting shruby plant that belongs to the Capparaceae family; capers occurs in various types (more than 350) and grows naturally in all the continents in many different regions of the world (Rodrigo et al., 1992; Özcan, 1996; Özcan, 2005). It is a tropical/subtropical plant (Rodrigo et al., 1992; Özcan and Akgül, 1998). The caper plant, which is called bubu, gebre, gabar, gevil, kapari, keper, kebere, turþuotu and Þebellah in different parts of Turkey, is an economically valuable plant. In various regions of the world different organs of caper species have been profitable for several purposes since ancient times. Young shoots, flower buds, and fruit are used for human nutrition. Capers have very important roles in the food industry; the flower buds are stored in brine and have become a costly product during recent years (Alvarruiz et al., 1990; Özcan, 1996). The composition of capers and especially *Capparis spinosa* have been widely evaluated showing that palmitic, linoleic acid, linolenic acid and sterols are the major components. In addition, rutin and kaemferol-3-rutinoside are the most abundant flavonol glucosides (Özcan, 1996; Inocencio et al., 2000; Giuffrida et al., 2002; Tlili et al., 2010). In the studies carried out about the nutritional value of caper. It was determined that the flower buds of caper (*C. sipinosa*) contained water, raw cellulose, vitamins, oil, fatty acids, protein, amino acids, and mineral substance (Costro Ramos and Nosti Vega, 1987). Caper organs such as buds, fruit and young shoots were found to be important sources of nutrients and essential elements. In addition, it is apparent that caper parts are good sources

of the macro and micro minerals, and consumed as a food ingredient to provide the human nutrition. The aim of current study is to determine heavy metal contents of caper parts contaminated exzost fumes in roadside and interior regionsof different areasfromtwo different locations.

Material and methods

Material

The parts (stem, leave, bud and fruit) of *Capparis ovata* Desf. Heywood and *Capparis spinosa* var. *spinosa* were harvested from roadside and interior regions of different areas in Konya (Selçuklu) and Mersin (Silifke) in Turkey, respectively. They were kept in cooled bags for transport to the laboratory. The samples were cleaned, and were dried under clear air conditions. Each sample was ground in a mill, and kept in colour vial till analyses.

Determination of mineral contents

Caper samples were dried at 70 °C in a drying cabinet with air-circulation until they reached constant weight. Later, about 0.5 g dried and ground sample was digested by using 5 ml of 65 % HNO_3 (Merck, Darmstadt, Germany) and 2 ml of 35 % H_2O_2 (Merck) in a closed microwave system (Cem-MARS Xpress, Matthews NC, USA) at 200 °C. The volumes of the digested samples were completed to 20 ml with ultra-deionized water, and mineral contents were determined by Inductively Coupled Plasma Atomic Emission Spectrometry (Varian-Vista, Australia). Measurements of mineral concentrations were checked using the certified values of related minerals in the reference samples received from the National Institute of Standards and Technology (NIST; Gaithersburg, MD, USA) (Skujins, 1998).

Working conditions of ICP-AES:

In this study, ICP-AES (Varian-Vista) was used. Its RF Power changes between 0.7 and 1.5 kw (1.2-1.3 kw for Axial). In addition, plasma gas flow rate (Ar) ranged from 10.5 to 15 L/min. (radial) 15 “ (Axial). Auxilary gas flow rate (Ar) is 1.5 “. Viewing height is between 5 and 12 mm. Copy and reading time change between 1 and 5 s (max.60 s).

Statistical analyses

Results of the research were analysed for statistical significance by analysis of variance (Püskülcü and Ýkiz, 1989).

Results and Discussion

Mineraland heavy metal contents of different parts (buds, leaves, fruit and stems) of caper collected from road side and interior regions of different areasfromtwo different locations collected is given inTable 1. In general, it was observed that differences in element contents depend on plant partsand thelocations. Element contents of leaves were found high when compared with other parts. B, Cd, Cr, Mn, Mo, and Ni contents of caper leaves collected from the roadsideat the Konya locationwere found higherthancollected from the interior (off the road) areas. Cr, Fe, Mn and Ni contents of caper buds collected from the roadsideat the Konya locationwere determined higher than collected from the interior(off the road) areas of the same location. InSilifkelocation, Cr, Fe, Mn and Ni contents of caper buds collected from the roadsidewere determined higherthan those collected from the interior(off the road) areas of the same location. In addition, B, Cd, Cu, Fe, Mo and Zn contents of caper fruits collected in the interior(off the road) areas of the same location were established higherthan those collected from the roadside areas of the same location. OnlyMn andNicontents of caper fruits growing inroadsidewere found higherthan others. It is intersting that B, Cd, Cr, Cu, Fe, Mo, Ni and Zn contents of fruit stems collected from both inside fields were found higher compared with fruit stems on the road side. As a major elements, Ca, K, Mg, P and S were established in all samples. Of elements, K was found of the highest levels, and between 10741

mg/Kg and 32529 mg/Kg. Generally, K contents of stems were determined higher than those of other caper parts. It was followed by S, P, Ca, and Mg. While the Ca contents of caper parts collected from roadside in onya are found between 3344 mg/Kg (stem) and 17278 mg/Kg (leave), it was found between 1762 mg/Kg (bud) and 10171 mg/Kg (leave) in inside fields. The same element was found between 4008 mg/Kg (stem) and 29104 mg/Kg (leave) on roadside in Silifke location. In addition, this element in inside field at the same location was determined between 4231 mg/Kg (fruit) and 13789 mg/Kg (leave). Generally, while K contents of all samples change between 10741 mg/Kg (stem in Konya roadside) and 32529 m/Kg (stem in Silifke roadside), P ranged from 153 mg/Kg (stem in Konya road side) and 5405 mg/Kg (fruit in Silifke inside field). Ni contents of *C.ovata* and *C.spinosa* parts changed between 0.37 mg/Kg (stem) to 1.53 mg/Kg (bud) and 0.19 mg/Kg (stem) to 4.91 mg/Kg (bud), respectively. In addition, while Zn contents of *C.ovata* change between 3.1 mg/Kg (stem) and 41.8 mg/Kg (leave), Zn contents of *C.spinosa* ranged from 11.5 mg/Kg (stem) to 44.6 mg/Kg (fruit).While the Cu contents of samples vary between 2.2 mg/Kg and 13.6 mg/Kg, Fe contents ranged from 32.9 mg/Kg to 117.7 mg/Kg. The Ca, Fe, K, Mg, P and Zn levels are adequate. In previous study (Hamurcu et al., 2010), mineral and heavy metal levels of some fruits grown at the roadsides were established , and the results showed that the average level of Cu changed between 0.27 mg/kg (Sample 11) and 0.05 mg/kg (Sample 15), Cr 0.32 mg/kg (Sample 14) and 0.18 mg/kg (Sample 13), Ni 0.68 mg/kg (Sample 12) and 0.26 mg/kg (Sample 15), Pb 2.86 mg/kg (Sample 12) and 1.54 mg/kg (Sample 4) and Se 12.96 mg/kg (Sample 14) and 5.42 mg/kg (Sample 7).The levels of Cu, Cd and Cr in samples do not appear to reach pollution levels. Delibacak et al. (2002) researched the amounts of trace elements (Fe, Mn, Zn, Cu and B) and heavy metals (Co, Ni, Cr, Pb and Cd) of plants irrigated with water of Gediz river polluted by industrial and domestic wastes. In the vegetables from areas exposed to this pollution, copper was found in amounts from 0.10 to 3.26 mg/kg and zinc from 0.88 to 27.90 mg/kg. Copper in vegetables, fruit and cereals from areas differing in the degree of industrial pollution and from greenhouses copper amounted to 0.14-1.20 mg/kg and zinc from 1.0 to 10.60 mg/kg (Szymczak et al., 1993). Calcium is the major component of bone and assists in teeth development (Brody, 1994). The essential role of selenium for human health has been well established in recent years (Foster et al., 1998). Selenium has an active role as a modulator in inflammatory and immune responses (Neve,1991). The differences in chemical properties, mineral contents of caper parts belong to both plants were probably due to environmental conditions in conjunction with the analytical methods used.

Conclusion

As a results, relatively highoccurrenceof heavy metalsin samples collectedfrom the roadside,it wasprobably caused byvehicle emissions. Relatively highoccurrenceof heavy metalsin samples collectedfrom the roadside in Silifke location could be due the exhaust fumes of vehicles, due to close to inland regions, thetrafficto be more density in this location. In addition,the prevailing windscould have causedcontamination by dragging onto theplantof theexhaust fumes. Higher occurence of these values in the leavesmay be duemoreto be contaminated compared totheother organs ofthecaper and larger surface of leaves. Theexcessof the other elementsmay have probably resulted from nutrients,varieties and genetic structure. The main sources of heavy metals in plants are their growth media, nutrients, agro inputs and soil. Other sources may include pesticides and fertilizers. It is concluded that heavy metal contents of soil and emissions from vehicles may be the major source of heavy metal contamination. The levels of Cu, Cd and Cr in most of the analysed samples do not appear to reach pollution levels.

Abstract

Jeromine is apple variety which is new breeding by mutation from Early Red One®. Isparta region is one of Turkey's most important apple-growing regions. Due to new varieties that are breeding introduce to this region, determining of storage performance of these varieties is necessary. With the aim of studying the influence of storage and shelf life quality of Jeromine apple variety, fruit stored at 0 °C and 85-90% relative humidity for 6 months. During cold storage, apple samples were removed at 4 and 6 months, and the half of them were analyzed, the other half were held at 20 °C and 60-65% relative humidity for 7 days to shelf life. In addition, immediately after harvest the half of fruit were treated with 625 ppb 1-methylcyclopropene (1-MCP) at 10 °C for 24 hours. Fruit weight loss, firmness, skin color, soluble solids content (SSC), titratable acidity (TA), ethylene production, respiration rate, α-farnesene and conjugated trienol (CT) concentrations and antioxidant activity and total phenols content were measured at intervals during storage and shelf life. Generally, firmness and TA decreased, and weight loss, ethylene production and respiration rates increased during storage of fruit, but 1-MCP markedly inhibited ethylene production and respiration rates. α-farnesene and CT concentrations of 1-MCP treated fruit were low. 1-MCP treated suppressed superficial scald in apple during both cold storage and shelf life. Especially, quality of untreated fruit was lower than 1-MCP treated. However, Jeromine apple variety stored quality manner for 6 months with both treatment.

Keywords: *Apple, Jeromine, fruit quality, storage, 1-MCP*

Introduction

Turkey, which ranks 3rd in the world, is one of the major apple producing countries, with 3.128 thousand tons apple production. Commercial apple production was continued traditional varieties such as Starking Delicious, Golden Delicious, Granny Smith, etc. in Turkey. However, in recent years, new breeding apple varieties started to introduce to Turkey. Commercial orchards were started to plant with this new apple varieties. Jeromine apple variety is one of them.

Origin of Jeromine is French mutation of Early Red One® Erovan. General characteristics: standard form of medium-low vigour extremely productive, fruit uniformly dark red, high quality. Ripens at the same time as Early Red One® Erovan*, about 5 days before Red Delicious spur types. Fruit is conic, symmetric, slightly ribbed; large size, higher quality than other Red Delicious clones (Anonymous, 2015).

1-methylcyclopropene (1-MCP), an inhibitor of ethylene biosynthesis, binds irreversibly to ethylene receptors in plants (Blankenship and Dole, 2003). Positive effect on postharvest fruit quality of 1-MCP was studied by a lot of researchers (Sisler et al.,1999; Fan et al., 1999; Watkins, 2006). 1-MCP-treated apples are exhibited more firm, more acidity, less ethylene production and respiration rate, less de-greening than untreated during both storage and shelf life (Çalhan et al., 2014).

Objective of this research was to investigate the responses to storage duration, 1-MCP treatment, and shelf life on fruit quality of Jeromine apples variety grown in Isparta.

Material and methods

Apples [*Malus sylvestris* var. *domestica* (Borkh.) cv. Jeromine] were harvested in a commercial orchard in Eğirdir, Isparta. Assessment of fruit maturity (starch index, firmness) was performed and then fruits were harvested on 22.9.2014. Fruit was exposed the day of harvest to 625 ppb 1-MCP at 10 ºC for 24 h in plastic bag. SmartFresh (AgroFresh, Inc.,) tablet was used to generate 1-MCP gas. After 24 h, the plastic bag was vented. Untreated and treated fruits were stored at 85-90 % relative humidity at 0 ºC for 6 months in regular atmosphere (RA). Stored fruits were taken from cold rooms at 0, 4 and 6 month, and then the fruits held for 7 days to simulate shelf-life (20 ºC, 60-65% RH) and analyzed.

Quality parameters

Weight loss was measured on 15 fruits during cold storage and shelf life. Results were expressed as % of weight loss relative to the initial weight.

Firmness was defined as the maximum load required to push the 11 mm probe into the fruit flesh (after skin removal) on two opposite sides of each fruit, to a depth of 10 mm (Güss FTA Type GS14, Strand, South Africa). The results were expressed in Newton (N).

Skin color was determined using a colorimeter CR-400 model (Minolta Co. Ltd., Japan) and expressed as L*, a*, b*, C* and hº.

The concentration of soluble solids (% SSC) and titratable acidity (TA) were performed with a refractometer (HI 96801 model Hanna, UK) and with a automated Titrator (T50, Mettler Toledo), respectively. NaOH 0.1 N was used to titrate 5 ml of juice + 45 ml pure water to pH 8.1. The results were calculated as malic acid equivalents in g/100 ml.

The ethylene production and respiration rate of fruit was measured with a gas chromatography (Agilent 6840) with equipment column FID and TCD. Ethylene production and respiration rate expressed as μLC_2H_4/kg.h and $mLCO_2$/kg.h, respectively.

Severity of superficial scald was assessed visually according to Jung and Watkins (2008).

α-farnesene and conjugated trionels (CTols) analysis method of Isidoro and Almeida, (2006) was used with modifications. Absorbances of appropriate dilutions of the hexane extracts were measured at 232 nm (α-farnesene) and at 258, 269, 281 and 290 nm (CTols) using a UV/Vis spectrophotometer (Cary® 50 model, Varian). Concentrations of α-farnesene were calculated using a molar extinction coefficient of ε232= 27700 (Huelin and Coggiola, 1968) and CTols were calculated molar extinction coefficient of 25 000 (Anet, 1972) in $\mu g/cm^2$.

Total phenols (TP) were determined according to the Folin–Ciocalteu method (Waterhouse, 2002). Absorbance was measured at 725 nm in a UV-Vis spectrophotometer (Cary® 50 model, Varian). TP were expressed as mg gallic acid equivalents (GAE)/100 g FW. Antioxidant activity (AA) of apple phenolic extracts was measured using method of Benzie and Strain (1996) with some modification. Absorbance was measured at 515 nm. AA was calculated as μmol Trolox equivalents (TE)/g FW. All samples were analysed in triplicates.

Data were subjected to analysis of variance (ANOVA, JMP7), means were separated by mean of LSD test ($P<0.05, 0.01, 0.001$).

Results and Discussion

During both cold storage and shelf life, weight losses were increased, as expected (Çalhan, et al, 2014). Weight loss of 1-MCP-treated fruit was slightly lower (Table 1). It has been reported that while in some studies 1-MCP affected on weight loss (Özkaya and Dündar, 2009), in some studies 1-MCP did not affect (Porat et al., 1999).

1-MCP-treated fruit were consistently firmer than untreated fruit during both cold storage and shelf life. Like other similar findings, this finding shows that 1-MCP effectively delayed apple firmness loss (Fan et al., 1999; Dell et al., 2002). Firmness of 1-MCP-treated apple higher than control fruit (~10 N) at the end of storage.
Firstly, SSC was increased from harvest to during storage periods. But, a tendency was observed to decrease in SSC towards at the end of storage. 1-MCP-treated apple had higher SSC than control fruit (Fan et al., 1999). TA declined throughout storage periods, but this was particularly noticeable in control treatment. A lot of studies were reported that loss of TA in 1-MCP-treated apple reduced (Fan et al., 1999; Wünsche and Heyn, 2015).

Table 1. Effects of treatments and storage periods on weight loss (%), firmness (N), SSC (%), acidity (g/100ml) of Jeromine apple fruits.

Respiration rate and ethylene production of control fruit increased during storage periods, while they were reduced substantially by 1-MCP treatment (Fig 1). Ethylene production was fifty fold at 6^{th} month and nine fold at $6+4^{th}$ month+day greater in control fruit than in 1-MCP-treated fruit. This is in agreement with the finding that 1-MCP reduces ethylene production in fruit at both cold storage and shelf life (Fan et al., 1999; Çalhan et al., 2014). During storage periods, respiration rate of 1-MCP-treated lower than control fruit and respiration rate was around half that of control fruit.

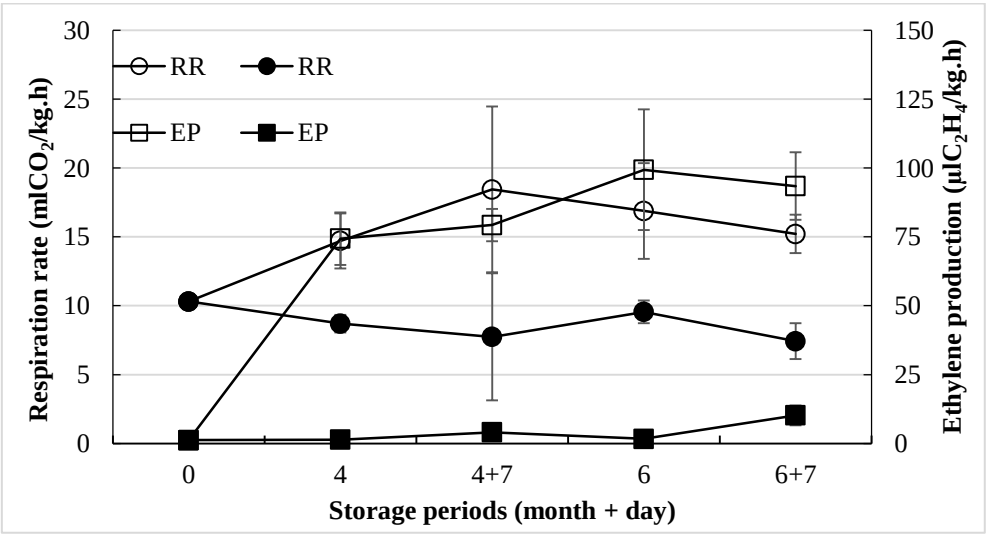

Fig. 1. Effects of treatments and storage periods on respiration rate (RR) ($mlCO_2/kg.h$) and ethylene production (EP) ($\mu lC_2H_4/kg.h$) of Jeromine apple fruits. Vertical bars represent standard deviation of the means.

Superficial scald severity was just significantly different (P<0.01) at 0.94 and 0 at the end of storage for control and 1-MCP-treated fruit, respectively (Fig 2). It was observed that 1-MCP inhibited superficial scald during storage periods (6 months + 7 days) (Zanella, 2003). The concentration of α-farnesene in peel tissue had continued to increase over storage in both treatments, but this increase was higher in control fruit than 1-MCP-treated (Fig. 2). α-farnesene of control apples increased dramatically during the initial of storage, and then declining (Jung and Watkins, 2008; Çalhan, et al, 2014). The level of CTols remained high in control fruit and was three fold greater than in 1-MCP-treated fruit (Watkins et al., 2000).

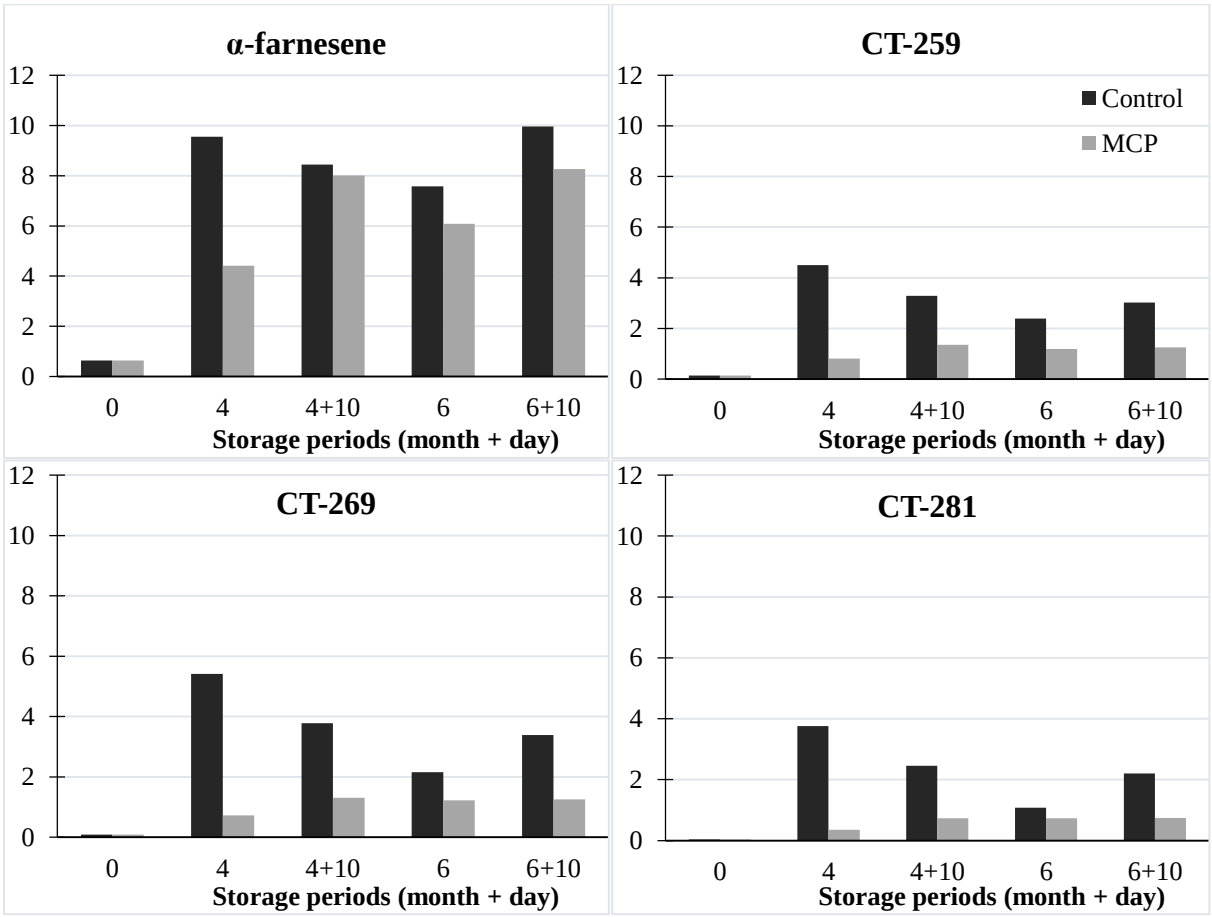

Fig. 2. Effects of treatments and storage periods on α-farnesene, CT-259, CT-269 and CT-281 (μg/cm^2) of Jeromine apple fruits.

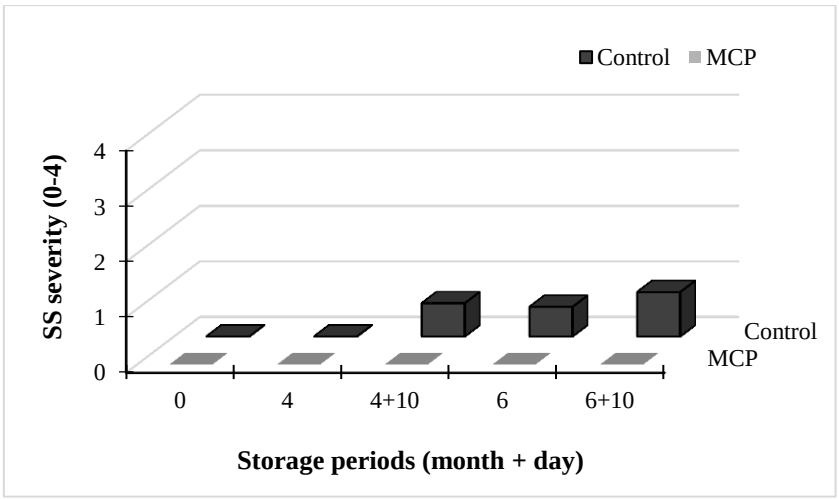

Fig. 3. Effects of treatments and storage periods on superficial scald severity of Jeromine apple fruits.

The AO and TP content of 1-MCP-treated fruits lower than control fruit during storage periods. The AO and TP content of both control and 1-MCP-treated fruit higher at cold storage than shelf life. AA and TP of Jeromine apple slightly decreased during storage periods (Fig. 4). Previous studies described different response of apple TP to cold storage and shelf life after removal from cold storage caused fluctuations in TP (Goulas et al., 2014).

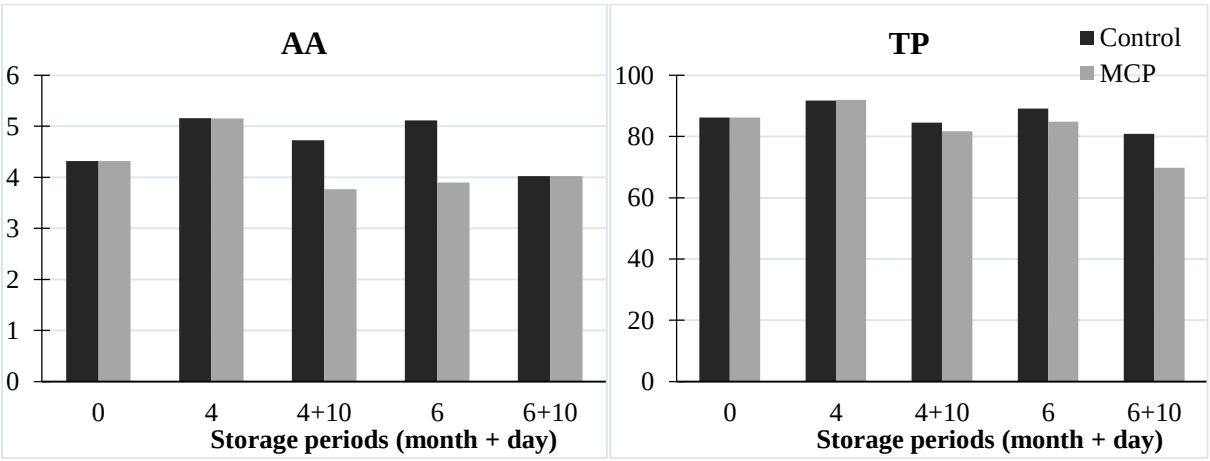

Fig. 4. Effects of treatments and storage periods on antioxidant activity (AA)(µmol TE/g FW) and total phenols (TP)(mg GAE/100 g FW) of Jeromine apple fruits.

Skin color of Jeromine apple did not clearly determine during RA storage and shelf life. With regard to all color values did not significantly difference between treatments (Data not shown). This was probably due to dark red skin color of Jeromine apple variety and skin color did not change throughout storage periods.

Conclusion

Jeromine apple stored in RA maintained a good firmness, skin color and weight loss. During RA storage, there was a clear difference in ethylene production and respiration rate between untreated and treated with 1-MCP. On the other hand, 1-MCP was more effective in preventing superficial scald. 1-MCP maintained firmness during both cold storage and shelf life. Our results show that Jeromine apple may be stored at 0 ºC for 6 month then at 20 ºC for 7 days shelf life. But, treated 1-MCP apple have higher fruit quality than untreated apple at the end of storage periods.

Abstract

Fruit and vegetables are attractive and eye-catching to a large degree because of the richness of pigments that they contain. Color is derived from the natural pigments in fruits and vegetables, many of which change as the plant proceeds through maturation and ripening. The primary pigments imparting color quality are the fat soluble chlorophylls (green) and carotenoids (yellow, orange, and red) and the water soluble anthocyanins (red, blue), flavonoids (yellow), and betalains (red). In addition, enzymatic and non-enzymatic browning reactions may result in the formation of water soluble brown, gray, and black colored pigments. Preservation of chlorophyll in vegetables, red to purple anthocyanins, yellow, orange and red carotenoids in both fruits and vegetables is of vital importance to maintain quality. The enzymes involved in browning reactions include polyphenol oxidase, which catalyzes the oxidation of polyphenolic compounds, and phenylalanine ammonia lyase, which catalyzes the synthesis of precursors to phenolic substrates. Color changes in fresh-cut fruits and vegetables may have different origins, for example decreased green pigmentation in fresh-cut lettuce may results from senescence, heat exposure or acidification; discoloration or browning of sliced mushrooms and sliced apples and pears is brought about through the action of polyphenol oxidases; white blush development in carrots is initially caused by desiccation, and then lignifications. In this study, color quality of fresh-cut fruit and vegetables, and the methods for preventing color changes was reviewed.

Keywords: *Fresh-cut, fruits, vegetables, color, browning, white blush, senescence.*

Introduction

Fresh-cut fruit and vegetable is defined that washed, trimmed, peeled, chopped or sliced, ready to use or cook, and packaged with suitable polymeric packaging material with covering tightly. These type foods are named such as fresh-cut, minimally processed, ready-to-use or ready-to-eat. (James and Ngarmsak, 2010; Barry-Ryan ve O'Beirne 1998).This group of food has emerged by variation of consumers demands in recent years.

In particular, because increase in labor intensity of working people, time limitations and increase in income level, the demand of ready-to-use food was increased. (Martin-Diana ve ark.2007). Also, high nutritional value of fresh fruit and vegetables has come to forefront each year. Especially, these products are rich in terms of beta-carotene, anthocyanins, lycopene, and antioxidants such as ascorbic acid. (Negi ve Roy 2000). The risk of developing chronic disease, also, decreased with consumption of these type food. (Li ve ark. 2000).

Fresh-cut method is used for widely in lettuce, cauliflower, carrots etc. since 1990's. But, the use of fresh-cut methods for fruits was began later because the difficulty of protecting quality. (Soliva-Fortuny ve Belloso, 2003). But, fresh cut technology is started to use also for fruits, recently. (Erbay, 2007 Oms-Oliu, 2010).

The sector of fresh-cut fruit and vegetables evolved over the last 20-30 years, and primarily in the United States it spread to the entire world. However, it was seen the fresh cut sector prominance both commercial and scientific in Canada, France and Italy. (Ergun 2006). Fresh-cut products markets has occured in USA, in the year of 2007, including 27 percent of

catering sector and 73 percent of consumer, and also $ 15.5 billion in total. (Cook 2008; James and Ngarmsak, 2010).

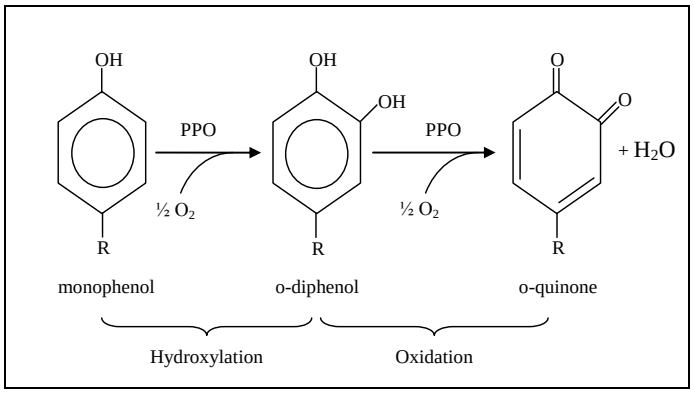
Appearance of fresh-cut fruit and vegetables is the most effective factor for the preference of consumer and purchase of produce. The visual quality of product is effected by many factors such as infections from microorganisms, wound tissue and discoloration. Even if these factors occurs different reasons or creates different results, eventually causes loss of product attractiveness. (Toivonen ve Brummell 2008). Visual quality changes in fresh-cut products are enzymatic browning, loss of chlorophyll, and microbial growth. In this study was compiled studies made to preserve the color.

The colors derived from natural pigments has much change during maturation process, in fruit and vegetables. Primary pigments that effecting color are fat soluble chlorophyll (green) and carotenoid (Yellow, orange and red), and water-soluble anthocyanins (red, blue), flavonoids (yellow) and betalaines (red). In addition, enzymatic and non-enzymatic browning reactions can cause grey or black color pigment formation. In the formation of enzymatic browning reactions, the enzymes of polyphenol oxidase and phanylalanine ammonia lyase that catalyse oxidation of phenolic substance are effective. Chlorophylls are sensitive against acidity and temperature, but are stable against alkaline conditions; whereas carotenoids susceptible to light and oxidation but relatively stabil against temperature. Carotenoids can be bleached by an enzyme called lipoxygenase which catalyzes the oxidation of lipid compounds. Flavonoids are sensitive to oxidation but relatively resistant to temperature; whereas anthocyanins are susceptible both pH and temperature, also betalains sensitive to temperature like anthocyanins. Moisture content of surface, wax formation and postharvest application has effected of brightness of fresh cut fruit and vegetables. (Barrett et al 2010)

Enzymatic Browning

The most important visual quality loss in all fresh-cut fruit and vegetables that especially have white flesh are browning occured in the cut surface. These browning reactions occured as result of reaction of polyphenol oxydase (PPO) and peroxydase (POD) enzymes with oxygene and phenols. (Toivonen and Brummell 2008).

PPO's are oxidoreductases containing copper. Currently, catechol oxidase, laccase and phloroglucinol were defined as three different PPO enzymes, and the most common PPO enzyme in plants kingdom is katechol oxydase. This enzyme has two activity including hydoxylation (krezolaz activity) and oxidation (catechol activity) (Fig. 1). Indeed; monophenols are transformed o-quinones through firstly hydroxylation and then oxidation. The o-quinones are formed trihydroxybenzenes (THB) through hydroxylation. Hydroquinones has formed by interacting of THB with o-quinones, and these compound turned firstly polimers red-brown colors and then melanins that brown color. (Cemeroğlu et al 2004).



Şekil 1. The mechanism of action of catechol oxidase (Toivonen and Brummell 2008).

Another group of enzymes that influence the browning are peroxidase (POD). Fruit and vegetables have peroxidase mostly containing iron. POD enzyme has different action. But activity of enzymes known as "hydroxylation effect" that diphenol formation from monophenols like PPO enzyme activity is not important. But the need of hydrogen donor for perform this operation, is the difference of POD's from PPO. POD caused discoloration, redution of taste and loss of nutritioral value according to subtrate used. (Cemeroğlu et al 2004). It was determined that POD caused oxidative breakdown of ascorbic acid (Zheng and Lu, 2011), bleaching of carotenoids (Song et al. 2010, Gandul-Rojas et. al. 2004) and betalains (Wasserman and Guilfoy, 1983), breakdown of chlorophyll (Martinez et al. 2001, Funamoto et al. 2003).

Control of Enzymatic Browning

Enzymatic browning could be controlled with both chemical or physical methods using alone or both of them. Physical methods are considered as reduction of temperature and/or oxygene, modified atmosphered packaging, edible coatings, gamma irradiation or high pressure. Some chemical compounds are used as chemical methods. The effects of these chemicals are to preventing of enzyme activity, to removing or inhibiting of activity of substrate (oxygene or phenolics). (Garcia and Barrett 2002).

Chemical Treatments

Initially, sulphites were used commonly. But they caused allergenic reactions and health risks, the using of them in fresh fruit and vegetables were banned by Food and Drug Administration (FDA) in USA at 1986 (Madinez and Whitaker, 1995; Taylor 1993). From this date it has been studied of many chemical compounds to preventing enzymatic browning.

Antibrowning Agents

Heat treatments are widely used to inhibition enzymatic browning in food processing industry. But, this method caused the losses of texture, taste and nutritional value of product. Therefore, some chemical compound was used to preventing of enzymatic browning which called as "antibrowning agents" (Garcia and Barrett, 2002). These agent are divided six group:

Acidulants:

For PPO enzyme activity, optimum pH range is considered 6.0-6.5; it is known that the enzyme activity was low below pH 4.5. Hence, product has lower pH or acidifier product is widely used for preventing enzymatic browning. (Garcia and Barrett 2002). Citric acid is the most widely used material for this purpose. Beside of citric acid; acetic acid, formic acid, fumaric acid, malonic acid, pruvic acid, oxaloacetic acid, succinic acid, tartaric acid, malic acid, oxalic acid, lactic acid, phosphoric acid, hydrochloric acid could be used (Son et al. 2001). As well as citric acid is used to preventing browning, it has slowing down effect on respiration. (Kato-Noguchi and Watada 1997).

Reducing Agents

This type of antibrowning agents were caused conversion of o-quinones to colorless diphenols through chemical reducing. During this reaction, reducing agent is oxidated irreversibly. This means that, they only provide a temporary protection due to they consume during reaction. If reducing agent is not added, the PPO activity begins again and browning occurs (Oms-Oliu et al. 2010). Thiol-containing compounds such as ascorbic acid and cysteine is included in this group. But, when these agent used together with calcium salts, the effectiveness is increased. (Arias et al. 2008, Gorny et al. 2002, Bieganska-marecik ve Czapski 2007, Rocha ve ark 1998)

Chelating Agents

Chelating agent prevents to PPO enzyme activity through forming a compounds with copper in PPO's active part. In this group, EDTA (ethylenediamine tetraacetic acid) (Arabacı 2015)

and a-phosphate-containing chelating agent is found. ((Garcia and Barrett 2002, Arabacı 2015).

Complexing agents

This group agent, have ability formation of complexing with reaction products and PPO substrates, or retention of them. Cyclodextrins (sugar molecules ring structure) and non-reducing cyclic oligosaccarides are used. (López-Nicolás et al. 2007).

Enzyme inhibitors

Sulphides are effective for activity of PPO enzyme, but using of them in fresh fruit and vegetables is forbidden. Na2So3, NaHSO3 and SO2 from them could be used. But, the residue level of SO2 should not exceed the permissible limits. It is also used as the PPO inhibitor of 4-Hexylresorcinol. (Piližota and Šubarić 1998).

Other antibrowning agents

Sodium chloride (NaCl), calcium treatments (Calcium chloride, calcium ascorbate, calcium lactate, calcium propionate) and substances such as honey are used for this purpose. (Son et al. 2001).

Physical Treatments

Low oxygene treatments

Living tissue is required oxygene. Fresh-cut products can not be held without oxygene environment because they maintain their viability. However, if oxygene is not present in reaction environment, enzymatic browning can be delayed. The cutting methods applied in fruit and vegetables are cutting of product under water, brine or syrup; so diffusion of oxygene to product was retarded. When contacting of the tissue with oxygen, the browning will be occured, in these methods (Garcia and Barrett, 2002). Modified atmosphere, controlled atmosphere conditions and edible coatings have been used for reducing oxygen. (Baldwin et al. 1995).

Heat Treatments

Low temperatures provides slowdown of metabolic activity in the product. It was effective including slowing of respiration rate, extending of shelf life and reducing activity of microorganism. However, low temperatures can delay activity of enzyme limited level (Siddiqui et al. 2011). Heat treatment is more effective for control of browning compared to low temperature storage. But, increases of temperatures, were caused sensory changes and tissue losses. Browning in pears cubes were prevented by heat treatments that applied in 95 C for 3 min, however, an acceptable reduction of texture has been occured. (Pittia et al 1999).

Gamma Irradiation Treatments

Gamma irradiation is a method for using quarantine purpose. It has effective reducing in microbial activity as well as inhibiting browning and losses of visual quality. It was found that gamma irradiation reduced browning of fresh-cut lettuce (Zhang et al. 2006) and the iceberg lettuce (Fan and Sokorai 2011).

High Pressure Treatments

High pressure applications are effective in inactivation of harmful enzymes. Variation of flavor quality and nutritional values of foods is very little changed or no changes obtained when this technology is used together with low temperature, (Garcia and Barrett 2002). Sometimes it can also be achieved that inactivation of enzyme when using antibrowning agent together with high pressure treatment (Guerrero-Beltrán et al. 2005). The activity of lipase, lypoxygenase, pectinmethylesterase, peroxidase and polyphenol oxidase enzymes were inactivated by high pressure processing (Siddiqi and Cash 2000), and losses of vitamins, pigments and flawor loss were remain minimum level(Weemaes ve ark., 1999).

UV Irradiation Treatments

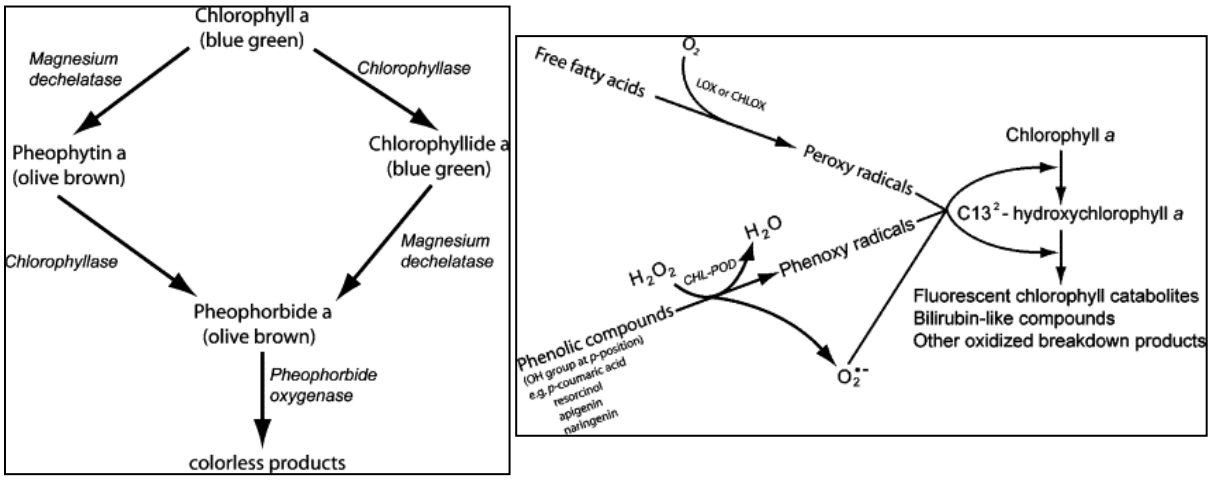
Different results were obtained by UV applications. Forexample, enzymatic browning of apple slices treated with UV-C for a few minutes was inhibited without quality loss (Manzocco et al 2009). But, Gomez et al. (2010) determined that browning of fresh-cut apple slices increased by UV-C treatments.

Whitening of Surface of Carrot (White Blush)

Whitening, is a special color variation that occured as result of drying of cut-surfaces during peeling and cutting, and also is named "White Blush". Although, drying is a physical process, "white blush" is occured in carrot surface in response to wounding of tissue. In fact, the process is associated with wound formation, this special process was starting by ethylene which was not part of lignification mechanism. Lignification is a serial process that was started by phenylalanine ammonia lyase, and involving numerous enzymatic transformations (Toivonen and Brummell 2008)."White blush" formation delayed by steam treatments, and also lignin formation retarded through producing soluble phenolic or isocoumarin (Howard et al. 1994). Also, it was determined that "white blush" formation was reduced by high relative humidiy of environment. (Cisneros-Zevallos et al 1995).

Loss of Chlorophyll or Yellowing

Yellowing is the emergence of colorless substances due to decreasing of the green pigment chlorophyll in fruit and vegetables during maturation and ripening. This type chlorophyll breakdown is named Type I fragmentation (Fig 2). While, colorless substance was formed on the one hand; the color pigment such as orange, purple or red on the other hand are synthesized during the maturation process. A major problem was encountered in many leafy vegetables including especially broccoli, brussel sprouts or spinach was yellowing. The methods widely used for the prevention yellowing during postharvest handling process are low temperature storage, heat treatments, exogenous cytokinin treatments, etyhlene inhibitors, modified atmosphere or controlled atmosphered storage (Zaicovski et al. 2008). Brown color substances was occured in the cut surfaces instead of colorless substances as results of chlorophyll breakdown. In this case, the degradation of chlorophyll is mediated by oxygene radicals. This type chloropyll breakdown is named as Type-II degradation (Fig. 2). In case of fresh-cut product, chlorophyll degradation appears as a form of Type II reactions (Toivonen and Brummell 2008).



Type I Type II

Fig. 2.Schematic representation of Type I and Type II chlorophyll breakdown pathways in green plant tissues (Toivonen and Brummell 2008).

Conclusion

In minimally processed fruit and vegetables; visual quality is the most important quality criteria for consumer. In this way color changes occured in fresh-cut fruit and vegetables are determined preference of consumer. There are three types of color changes are occuring in fresh-cut fruit and vegetables. Although, enzymatic browning has occured minimally processed fruit and vegetables, yellowing and whitening is the other color changes in mostly vegetables. For the preventing of color changes different methods were done, by researchers. In this study, color changes of minimally processed fruit and vegetables, and also preventing of these discoloration were investigated. For preventing of enzymatic browning or whitening of fresh-cut fruit and vegetables; either acidifiers or chelating agent were used varies fruit and vegetables. With the use of these chemicals for preventing color changes of fresh-cut fruit and vegetables; enzymatic browning, yellowing and whitening could be inhibited. But timely the effect of chemicals was decreased, and quality of fresh-cut fruit and vegetables were also decreased. Consequently studies about color changes of fresh-cut fruits and vegetables must be continued, for the consumer acceptance.

THE METHODS TO PREVENT THE NEGATIVE EFFECTS OF ETHYLENE ON THE ETHYLENE-SENSITIVE CUT FLOWERS

Rezzan KASIM[1]*, M.Ufuk KASIM[2]

[1]Kocaeli University, Vocational School of Arslanbey, 41285 Kartepe-Kocaeli, Turkey

Abstract

Postharvest performance is of crucial importance to the value of cut flowers. The life span of flowers is generally determined by the time to abscission of petals that are still turgid, or by the time to petal wilting or withering. In many species, these phenomena are regulated by ethylene. Exposure to ethylene can reduce flower longevity by causing undesirable physiological disorders to vegetative and flowering organs. Ethylene-mediated premature floral senescence has been noted in several species, and many species have been shown to wilt in response to ethylene, including rose (Rosa hybrida), carnation, anthirhinum majus, orchids (Phalaenopsis), gerberas, lily flower etc.Premature senescence and abscission resulting from exposure to exogenous or endogenous ethylene can be controlled, both pre-treating flowers with inhibitors of ethylene biosynthesis and action.There are several inhibitors of ethylene biosynthesis, including aminooxyacetic acid (AOA) and aminoethovinylglycine (AVG). However, these chemicals are only effective against the effects of ethylene produced by the flower itself, and have no effect when flowers are exposed to exogenous ethylene, as can occur during transit and marketing. Therefore, the common treatments are of inhibitors of the response of flowers to ethylene. The negative effect of exogenous ethylene on cut flower quality was reduced with 2,5-norbornadiene (2,5-NBD), silver thiosulfate (STS) and 1-methycyclopropene.In this review, the effect of ethylene on cut flower vase life, and the methods to inhibiting the negative effect on cut flower longevity, was investigated.

Keywords: Ethylene, cut flower, silver thiosulphate, 1-methycyclopropene, vase life.

Introduction

The commercial value of cut flowers is determined by postharvest quality and long vase life expressed as color, brightness, turgority of flowers after harvest. Vase life of cut flower is defined as the time of abscission of petals that are still turgid, and by the time of petal wilting or withering (van Doorn, 2001). The reduction of vase life in most types of cut flowers associated with early petal senescence or wilting of petals, is caused with the effect of ethylene. Also, exposure to ethylene shorten cut flower vase life leading to unwanted physiological disorders in vegetative and floral organs.Ethylene one of the plant hormone that has growth inhibitor activity is synthesized in the plant during ripening and senescence process. Also, ethylene is released into the atmosphere that living plants as a result of ripening of fruits burning hydrocarbons such as propane and gasoline or via operation of construction machines. Ethylene, in the atmospheres that producing, transporting or storing area of flowers has detrimental effect on the flowers even low concentrations like 1 ppb (Reid 2000). In this study, cut flowers, that has special importance in Turkey and in the World trade, were investigated in terms of sensitivity of ethylene and the methods inhibiting ethylene effect.

Ethylene Sensitive Flower Species

In the studies conducted in order to determine the ethylene-sensitive flowers species (Woltering and Van Doorn, 1988), it was found to be there are 93 species of several families are ethylene sensitive. Petal abscission of these species was controlled by endogenous ethylene production. Flowers that belongs to families of Labiate (Lamiaceae), Ranunculaceae, and Rosaceae were showed ethylene-dependent petal abscission. Some families such as Orchidaceae showed petal wilting dependent of ethylene.

Ethylene-sensitive flowers are grouped into three categories. Senescence of the flowers in the first group is occured as a result of increasing ethylene production after pollination or during flower growth. The examples of flowers showing this way senescence can be given as carnation and petunia (Serek et al. 1995a). In the flower species like cyclamen in the second group, ethylene only showed increase during pollination and flowers have became sensitive against ethylene (Halevy et al. 1984). Flowers (eg. rose) in the third group, showed ethylene sensitivity during opening of flower bud while the production of ethylene was not show increase during senescence (Kumar et al. 2008).

When cut flower species exposed to ethylene, different response occurs. Petal wilting is occured as response to ethylene in the orchid (Palaenopsis) hibiscus (Çelikel and Reid 2002a) and carnation (*Dianthus caryophyllus*, Serek et al., 1995b). In the *Anthirhinum majus*, *Rosa hybrida* (Serek et al. 1995 a) and waxflower (*Chamelaucium uncinatum*, Macnish et el. 2000), ethylene encouraged petal or flower abscission. Cut flowers are affected at different rates from ethylene. Ethylene-sensitivity classes of cut flowers according to van Doorn (2001); (a) non-sensitive, (b) low-sensitive, (c) moderately sensitive, (d) highly sensitiveand (e) very highly sensitive as have been found (Table 1).

Table 1. The effect of ethylene on some cut flower species, and ethylene-sensitivity.

Family	Species	Ethylene effect	Sensitivity class
Amaryllidaceae	*Alstroemeria pelegrina*	*Perianth wilting, abscission*	Moderate/high
	Narcissus pseudo-narcissus	*Wilting, withering*	Moderate
Asphodelaceae	*Kniphofia* (hybrid)		Low sensitive
Cannaceae	*Canna* hybrid (3 variety)		Non-sensitive
Caryophyllaceae	Carnation	*Sleepiness of buds, non-opening, petal inrolling*	High sensitive
Iridaceae (Gladioleae)	*Gladiolus* hybrid	*Wilting, abscission*	Low/non sensitive
Ixieae	*Freesia* hybrid		Non-sensitive
Liliaceae	*Liliummartagon*		High
	Lilium hybrids		
	Brunello (Oriental)	*Wilting, withering*	Low
	Montanegro (Oriental)		Non-sensitive

Prevention of Negative Effect of Ethylene on Cut Flowers

Whether cut flowers are sensitive to ethylene or not is affected by ethylene. Therefore it is necessary to protect of flowers against to negative effect of ethylene. In previously studies, two strategy was developed, towards preventing or reducing of ethylene effects. While the first strategy is to prevent to ethylene biosynthesis, the other one is to inhibition of ethylene action**.**

Prevention of Ethylene Biosynthesis

The various chemicals are used for inhibition of endogenous ethylene production, and also delaying senescence of cut flowers. The use of inhibitors of ethylene biosynthesis leads to a reduction of the endogenous ethylene production of plants. Some of these inhibitors are: cobalt ions (Lau and Yang. 1976), aminoxyacetic acid (AOA, Baker et al., 1982), aminoethoxyvinylglycine (AVG, Yang and Hoffman 1984), and methoxvinylglycine (MVG, Reid and Wu 1992). Preparation of AVG and MVG of these chemical is to difficult, and it has been found expensive for practical use. The compounds like AOA and AVG even reduced endogenous ethylene production of flowers, they did not effect on exogenous ethylene that exposed of flowers during postharvest transportation, storage and marketing process.

Prevention of Ethylene Action

Because of the prevention of endogenous ethylene production of cut flower species can not be successful for extending of postharvest life of flowers; the studies has been directed preventing of negative effect of exogenous ethylene. Ethylene action inhibitors are interact with ethylene receptors, and reduced by response to ethylene (Scariot et al. 2014). These compounds are; silver thiosulphate (STS, Veen 1979), 2.5 norbornadiene (2.5 NBD, Wang and Woodson 1989), diazocyclopentadiene (DACP, Serek et al. 1994), and 1-methylcyclopropene (1-MCP, Serek et al., 2006).Silver thiosulphate (STS) has been used commercially in many species of cut flower's as an inhibitor of ethylene action (Veen 1983). Because silver contained in STS has environmentally pollutant effect, it is considered harmfull compound and leads to reducing of application value (Serek and Reid 1993).Silver thiosulphate (STS) has been used commercially in many species of cut flower's as an inhibitor of ethylene action (Veen 1983). Because silver contained in STS has environmentally pollutant effect, it is considered harmfull compound and leads to reducing of application value (Serek and Reid 1993). Results a series of studies examining structure of the binding site during the ethylene biosynthesis, a compound that ethylene action inhibitor is found named 2.5 norbornadiene (NBD) (Sisler and Blankenship 1993).2.5 NBD, however, has not been commercially implemented, because of the lack of permanent effect, toxic effects, and bad smell. Similarly, DACP has not been used due to explosive effect and not stable.1-MCP used as an inhibitor of ethylene action is a gaseous, non-toxic chemical that inhibited ethylene action due to binding to its receptor. Because of the 1-MCP is a gaseous form, difficulties in practical application has encountered (Serek et al. 2006).Thus, in latest studies, a formulation of as a non-volatile form 1-MCP in the structure of nanosponge-based β-cyclodexrin (β-CD-NS, 1:8) has been developed (Seglie et al. 2011).

Ethylene Sensitive Flowers Species and Anti-Ethylene Treatments

Roses:The first negative effect of ethylene on cut rose flowers were determined by early flower-opening or early petal abscission due to excess ethylene given by lamps used for lighthing (Zimmerman 1931). Similarly, petal abscission of Sonia cut flower cultivar was accelerated with ethephone treatments (de Stigler 1981). The negative effects of exogenous ethylene (0.5 ppm) on cut rose flowers were defined as such as do not opening of flower bud or early flower opening, acceleration of petal abscission and the distortion of opened flower.

In all rose cultivars, however, sensitivity of ethylene was not found, and the effect of exogenous ethylene on opening of flowers and senescence changed by dependent on species (Oraee et al. 2011). When examined 38 different hybrid tea rose genotype, it was determined that the vase life of roses changed 4.5-18.8 day at 21oC, and also rate of opening of flowers were showed significant differences among the genotypes. When these genotypes treated with ethylene at the dose of 1µL/L (21^{o}C temperature 24 hours), 27 of these showed petal wiltering and abscision, and the vase life of these genotypes were decreased 0.8-84 day (%18-47) response to ethylene. In ethylene sensitive 17 genotypes, the rate of opening flower were decreased but the vase life of flower irresponsive to ethylene, and also 5 genotypes were not response to against ethylene (Macnish 2010). The various applications were performed to the ethylene-sensitive rose varieties for maintain of the negative effect of ethylene and improved of vase life.The oldest method of these applications is silverthiosulphate (GTS) addition into vase solution (Reid 2004). These treatments had been used in large quantities in initially, but it has lost its importance due to harmful effects of silver on the environment. In contrast, in the recent years in the limited rate of STS is used with 1-MCP, sucrose application, HQS, nitric oxid, thidiazuon, sodium benzoat for the increase of resistance and vase life of flowers (Table 2).

Table 2. The applications preventing ethylene effect on cut rose flower varieties.

Variety	Treatments	Dose/time	Effect	References
First red	STS	0.5 mM	Increasing of vase life	Chamani et al..,
Rosa hybrida L. cv. Diana	STS, Sucrose+HQS	0.2 mM , 2h STS +120g/L sucrose+10h HQS	Increasing of vase life to 9-10 days	Liao et al. 2000.

STS: Silverthiosulphate; 1-MCP: 1-methylcyclopropene, HQS: Hydroxyquinolinesulphate

Carnations;Ethylene production of carnations is increased during senescence and there is climacteric ethylene rise in petals (Woodson et al. 1992). Carnations species, however, showed sensitivity against exogenous ethylene, and exposure to ethylene causes premature petal wilting, referred as "Sleepiness". Some of the newer cultivars are less sensitive to ethylene than the standard ‘Sim’ types, and carnations have now been genetically modified by

the addition of a mutation of the ethylene binding site that makes them insensitive to ethylene (Reid 1997).Postharvest studies for the protection of the negative effects of ethylene to ethylene sensitive carnation varieties was began in 1980's, however, innovative studies is still ongoing with emerging technologies (Table 3).

Table 3. The applications preventing ethylene effect on cut carnation flower varieties.

Lisianthus: Lisianthus is one of the flower species that sensitive to ethylene. Flowers of this species ethylene causes premature senescence. Therefore, the presence of ethylene into flower environment is the most important factor that limiting vase life. Lisianthus flower is produced ethylene especially pistil during flower development, while ethylene sensitivity can not observe during anthezis, sensitivity increased with senescence (Ichimura et al. 1998). Thus, for the reducing of ethylene-sensitivity of flowers; STS (Cho et al. 2001), 1-MCP (500 nL/L)+holding solution (6% sucrose+glucose, Cho et al. 2001), ethanol treatment (25-50 kg/L; Farokhzad et al. 2005), benzyladenine (BA; Hassanpour-Asil and Karimi, 2010) or asetaldehyde (1, 2, and 4%; Seighalani et al. 2013) is used.

Anthirhinum: Although snapdragon flower is preferred because of spike-type flower structure and colors, vase life of flowers is relatively short due to ethylene sensitivity (Serek et al., 1995). The effect of ethylene show itself especially on florets on the spike. But, ethylene sensitivity varies according to variety, and in some snapdragon variety there is natural resistance to ethylene. Whereas, especially susceptible varieties should treated with ethylene action inhibitor 1-MCP or STS.Thus, it was determined that in Rocket and Potamac Pink snapdragon varieties since 1 µL/L ethylene caused 100% floret abscission, it was determined that using of STS or 1-MCP to preventing negative effect of ethylene is necessary (Çelik et al. 2010).

Freesia: Ethylene sensitivity of freesia varies as depends on opening or non-opening of florets. While opened florets on the spike were not affect from ethylene, ethylene is prevented of development of unopened florets, thereby vase life of freesia flower is shorten. Therefore the use of ethylene action inhibitor compound is required to increase the postharvest vase life of freesia. It is found that one of this compounds, STS was effective to prevent floret abortion on the spike (Reid, 2000). Also, vase life of spike was increased using of 1-MCP (4nL/L; 4h) (Zencirkıran 2005).

Lilies: Flower life of lilium is an important quality criteria as in other type flowers. In general, vase life of lily varied from 5 days to 14 days depends on variety and postharvest handling process, and vase life is ended with wilting or withering of petals. It is determined that, lilies were much less sensitive to ethylene; susceptibility is varies according to variety (Woltering and van Doorn 1998); also vase life of flower is decreased by ethylene (Jones and Moody1993).Lily plants are divided into three main groups regarding ethylene susceptibility.(1) Unaffected by ethylene exposure.; The varieties of oriental lily and Lilium longiflorum are not affected by ethylene.(2) Minor responses to ethylene; some Asian varieties (Apeldoorn, Goldena, Elite, Mona) is effected from ethylene a little rate.(3) The effect of ethylene depends on concentration; ethylene at the high concentration decreased open-flower rate and opened-bud rate in the Asian lily varieties like Cordeila and Preta.Even ethylene reduced opened-bud or opened-flower, it did not effect on flower quality. Therefore, STS and 1-MCP treatments did not provide succeed against protect from ethylene, but vase life of 1- MCP treated Elite and Cordelia varieties was increased about 1.5 day (Elgar et al. 1999).

Gypsophila: Gypsophila is an important cut flower species is used as filling floral arrangements. However, postharvest vase life of flower is short due to unsuitable handling conditions and especially ethylene. Vase life of flower is reduced by early senescence caused by increasing of exogenous ethylene (van Doorn and Reid, 1992). While ethylene caused by wilting to opened flower, it is caused sleep or sleepiness or do not open, in buds. STS (4mmol/L, 30 min.; van Doorn and Reid, 1992) and AVG were tested for eliminate the negative effect of ethylene on gypsophila flowers, but both chemical compounds did not provide much more protective effect against exogenous ethylene. Therefore, 1-MCP that developed as alternative to STS was protect opened-flowers to ethylene effect but then it lost its effectiveness on newly opened flowers (Newman et al. 1998).

Orchids: Orchid flowers are extremely sensitive to ethylene at a very low level (Goh et al., 1985). Ethylene production rate of flower increased by pollination and emasculation, and result fast wilting. In the orchids species like Cymbidium, dortitaenopsis, dendrobium and plahaenopsis flower wilting is accelerated as a result of ethylene production following pollination; water loss occurs from cells on the outside of petals; the petals are folded down, and it becomes water soaked appearance (Porat 1994). AOA application to orchids as an ethylene biosynthesis inhibitor are not reduce ethylene sensitivity (Wang and Wang 2000). But, vase life of Oncidium Goldiana is increased by STS treatment at 30 min (Ong and Lim 1983); and similarly STS treatments at the doses of 4mM for 10 min is increased vase life of flower (Hew et al. 1983). The harmful effect of ethylene on Dendrobium and phalaenopsis flowers was inhibited completely with STS treatment (0.5 mM, 24 h) following 1-MCP treatment (0.1µL/L, 12h) (Wang and Wang 2000). Although 1-MCP treatment (0.1-0.4 µL/L) has protective effect to high concentration of ethylene (10 µL/L); its effect did not continue more than 7 days, at room temperature. In phalaenopsis cut flower trade, flowers is treated with 0.5 mM STS after cut, immediately.

Other flowers:Phlox (*Phlox paniculata* cv. Rambrant) flowers are one of the most sensitive species to ethylene. Exposure to ethylene enhanced flower abscission in a concentration-dependent (1 µL/L ethylene, 12 h; 50% abscission). It also accelerates the opening of ethylene flowers. The use of 1-methylcyclopropene (l-MCP), completely inhibited the ethylene-induced flower abscission and hence the reduction in the number of open flowers on the stems.l-MCP was maximally effective in inhibiting the ethylene response at a low concentration (25 nl/L) (Porat et al. 1995). Ethylene also accelerates petal abscission of Dahlia flowers. Ethylene production of pistil and petals during harvest is relatively high. 1-MCP and 5-benzylaminopurine (BA) applications are extended the vase life of flowers (Shimizu Yumoto and Ichimura 2013).In campanula varieties using as cut flowers like *C.*

barbata L., *C. latifolia* L., *and C. apunculoides* or *C. thacheliu*, 1-MCP application (1.14 pL / L) reduces senescence. C. barbata from these varieties gave the best results in terms of both increasing flower life and maintaining the petal color (Scariot et al., 2008).

Conclusion

Maintaining of quality of the cut flowers is the most important issues for both florist and dealing with flowers on the world trade. therefore, researchers are studied in terms of application for delaying senescence also increasing vase life. Flower senescence and vase life of flower are determined by so many factors. One of these factors, and perhaps most important one is ethylene that both produced by flower, and by ethylene supply into flowers environment. Ethylene, a plant hormone that is naturally produced during the growth of the cut flower, also limits postharvest life of plants. Ethylene caused: yellowing of leaf, abscission of petals, irregular flower opening, early flower death. Therefore, studies that determined the effect of ethylene on flower and prevention of ethylene effect were important. In this study, sensitiviy of different cut flower to ethylene and the methods to prevent ethylene effects were investigated. The negative effect of ethylene varies according to species, ethylene amount that exposure flower, and maturity stages of flower. Hence, it must be determined that the response of cut flower to ethylene, and the applicaiton must be done based on species and development stages of flowers.

Abstract

Crown rot is one of the most common plant pathogen, especially temperate climatic zones, and can infect more than 200 species, including the apple tree (*Malus domestica* Borkh.). It is often observed as the crown, collar and root rot in the apple trees. Although some control strategies are commonly recommended to control the pathogen, such as using resistant varieties or using fungicides, new and innovative approaches have promising results that can use in the near future, such as biological active formulations (BAF) and strains.

Efficacy of 10 BAF and strains (Companion, Symbion Vam, Green Miracle, Cropset, Isr-2000, Actinovate, Subtilex, Tricho plus, Combat Plus, Endo Roots Souble) against the crown rot on the Red Chief variety grafted onto MM106 rootstock were examined in the screen house for 4 months. The soil mixture artificially infected with the pathogen isolated from naturally infected apple trees was used at the experiments. Treatments were applied to the plantlets with 3 replications and each replicate consisted of the 6 plantlets that were transplanted the soil and BAFs and strains were treated in the soil, and the biological parameters of the plantlets, trunk diameter, tree height, branch lengths and branch number, were observed during the experiments. Among the BAFs and strains, Actinovate was the most effective products.

Keywords: *Crown rot, Apple, Biological active formulations*

Introduction

Apple is a widely cultivated plant species in different ecological conditions of Turkey and the World. Turkey is the third leading producer, accounting for 3128450 tonnes of world production (Anonymous, 2015). The crown rot caused by *Phytophthora cactorum* (Lebert & John) Schröeter is an important disease of the apple trees. Phytophthora root and crown rots (sometimes called collar rot) are common and destructive diseases of fruit trees throughout the World (Jeffers and Wilcox 1990; Brewster et al. 1997). Maden et al. (1995) and Kurbetli and Değirmenci (2011) have reported that crown rot is the most common plant pathogen in apple orchard fields and plantlet production fields where it resulted in severe yield reduction and decline of growth.

The trees infected by crown rot are commonly found in poorly drained areas of the orchard or yard. Heavy and wet soils that remain saturated for extended periods of time are required for disease development. Above-ground symptoms vary between tree species, but generally include reduced vigour and growth of the plant, yellowing or chlorosis of leaves, and eventual collapse or death of the tree. Rapid death of trees usually occurs following excessively wet periods. On trees that decline gradually, a reddish or purple discoloration of the leaves often occurs in autumn, while leaves on healthy trees remain green. Below-ground symptoms include reddish-brown discolouration of the inner bark and wood. A sharp line shows the contrast between the infected and the healthy portions of the crown (Watkins et al., 1992;

Ellis, 2008; Nakova, 2010). Literature reviews show that the members of Phytophthora are widely spread on fruit trees (apples, cherries, apricots, peaches and almonds), citrus trees, forest trees, ornamental trees and other species. (Erwin and Riberio, 2005).

Controlling Phytophthora crown and root rot can be successfully done using an integrated program of cultural practices, like choosing the most resistant tree species or rootstock, and using fungicides if it is necessary. Technical, economic and environmental factors are forcing to adopt new sustainable methods, such as the use of microbial antagonists, to control soil borne pathogens. Researches, have mainly focused on antagonistic fungi and bacteria, demonstrated that using these type of biologic Plant Protection Products (PPP) don't give promising results. Therefore, another new approach has investigated against to plant pathogens, combination of the biocontrol agents and some factors (agro-chemicals, agronomical treatments, solarisation or steam sterilization, enhancement of suppressive soils, amendment of the soil. Various biocontrol strategies were developed for different pathogens (Spadaro and Gullino, 2005).

Soil consist of many type of microorganism, and one of them is called as Plant Growth Promoting Rhizobacteria (PGPR) related to growth of plant root. Some of PGPR might act as bio-control agent or plant growth regulator in plants and improve plant growth. (Altın and Bora, 2005; Ganeshan and Kumar, 2005). PGPRs can impoverish harmful organism via antibiotics secreted root zone or improve systemic acquired resistance (Turan et al., 2014). Biological agents involved in eleven products were evaluated with a plant growth assay in pot using plantlets of MM106 rootstock to evaluate their effectiveness in controlling *Phythophtora cactorum*. The trial was performed with soil artificially inoculated with the pathogen.

Materials and Methods

Crownt rot isolates used in this study were isolated from naturally infected apple trees from Isparta. *P. cactorum* was placed and sub-cultured on carrot agar and the petri dishes were incubated at 23°C for 7 days. A few agar plug of *P. cactorum* were transferred in jars that a mixture containing volumes of inoculum (400 ml carrot juice + 560 ml vermiculite + 40 ml the seed of the oat cultures) and incubated for 14 days at 23°C until colony growth covered entire inoculum mixture. The inoculum mixture was added to soil mixture (1:1 mixture of garden soil: sand). The same soil mixture amended so that 3% of the final volume was a 14 day-old inoculum mixture (40:56:4, vol/vol, carrot broth: vermiculite: oat medium at 23°C) (Latorre et al., 2001).

In experiment, Red Chief variety grafted onto MM106 rootstock was used and treated ten active ingredient/microorganism for *P. cactorum.* Recommended ratio of all products are used in the trial. Alexin 95 PS formulates was used to compare other bio-formulates (Table 1). Plantlets were transplanted to a 7 litre pot containing to an infested soil mixture. Treatments were applied to plants with 3 replications and every replicate was 6 plants. Plants were placed in screen house for 4 months, and were kept constantly wet. Pots were subjected them in dripping at 6 h. three times during week. At the end of the growing season, trunk diameter (10 cm above the graft union), tree height, branch number (> 20 cm/tree), and individual branch lengths were recorded for all trees in all experiments. The results were subjected to analysis of variance in SAS-JUMP 7.0.

Table 1. The List of Product of Bio-Formulates.

Name and Action	Active Ingredient/Microorganism	Company or Origin
Companion	*Bacillus subtilis* GB03	Growth products
Symbion Vam	*Glomus Fasciculatum*	Stanes
Green Miracle	*Vegetable oil acid*	Stanes
Cropset	*Lactobacillus acidophilus, plant extract, MnSO4, FeSO4, CuSO4*	Ant tarım (Improcrop EU)
Isr-2000	*Lactobacillus acidophilus, plant extract, yeast extract, benzoic acid*	Ant tarım (Improcrop EU)
Actinovate	*Streptomyces lydicus*	Mts agro
Subtilex	*Bacillus subtilis* MBI 600	Bioglobal
Tricho plus	*Trichoderma harzihanum*	Bioglobal
Alexin 95 PS	*Fosfor pentaoksin (P2O5) 52%, Potasyum Oksit (K2O) 42%*	Sumitoma
Combat Plus	*Plant activators*	Bioglobal
Endo Roots Souble	*Glomus intraradices.....21* *Glomus aggregatum.....20* *Glomus mosseage.....20* *Glomus clarum.....1* *Glomus monosporus.....1* *Glomus deserticola.....1* *Glomus brasilianum.....1* *Glomus etunicatum.....1* *Gigaspora margarita.....1*	Bioglobal

Results and Discussion

At the end of the growing season, trunk diameter (10 cm above the graft union) were recorded for all trees in all experiments. Trunk diameters of the plants were near each other and the differences between them were not found significant statistically (Table 2). Individual branch lengths (>20 cm) were recorded for all trees in all experiments and found unimportant statistically. The differences between branch numbers were found important statistically. The most effective formulates against crown rot disease were ISR-2000 (2.4), Alexin 95 PS (2.3), K0 (2.2) and the least effective formulates were determined as Tricho Plus (1.1), Symbion Vam (1.4), and K1 (1.5), respectively. There were severe differences between trees heights, and these disparities were statistically important. The most effective formulates were found as Cropset (107.2), Green Miracle (105.2), Actinovate (102.3), Alexin 95PS (102.3) while the least effective treatments were Tricho Plus (83.1) and K1 (88.7), respectively.

The effect of fungicides on mycelial growth of crown rot has been reported in many studies (Weiland et al. 2009; Boughalleb et al. 2006; Thomidis and Tsipouridis 2001; Utkhede and Smith 1991; Tewoldemedhin et al.2011; Kurbetli et al. 2015). Biocontrol of *Pythium* and *Phytophthora* species with *Enterobacter cloacae* and *Erwinia herbicola* (Nelson 1988), *Enterobacter aerogenes* and *Bacillus subtilis* (Gupta and Utkhede 1986), *Trichoderma* (Roiger and Jeffer 1991), and *Muscodor albus* (Mercier and Manker 2005) have also been reported. It is well known that many *Trichoderma* and *Bacillus* species are suppressive to

plant pathogens in soil (Papavizas, 1985; Weller, 1988). For this reason, the effect of bio-fumigation on beneficial microorganisms should be the topic of further studies.

Table 2. Efficacy of the BAFs and strains on the biological parameters of the plant infected by crown rot

Product	Trunk Diameter	Tree high	Branch length	Branch number

^{NS} ; Not significant. There was no significant differences between the averages in the same column ($P>0.05$). *: Different letters indicate significant differences among means within a column ($P\leq0.05$) according to LSD Test.

Correa et al. (2010) has found that the target actinomycete strains are able to improve plant growth and nutrition, and benefit root colonization by AM fungi. Co-inoculation with both types of microorganisms showed synergic effects at enhancing plant growth and nutrient acquisition. Mohandas et al. (2013) has shown that it is clearly indicated the possibilities of using mycorrhizae associated actinomycetes as bioinoculant for growth promotion, nutrient mobilization and biocontrol agent in guava seedling production. Some biocontrol agents (*S. griseus, S. lydicus, B. subtilis* and *T. harzianum*) could be a possible alternative control measures of tea root disease, which in turn reduces the residual risk in made tea and it totally improves the tea ecosystem (Elango et al. 2015). Our finding are in agreement with the previous studies that they have shown that rhizosphere bacterial communities may suppress root infection caused by soil-borne pathogens. For example, inoculation with an antagonistic Bacillus subtilis strain reportedly protected young apple trees from *Phytophthora cactorum* crown and root rot (Utkhede et al., 2001).

Conclusion

As a result, the studies that we have done on crown rot have shown that some BAFs and strains, such as Cropset, ISR-2000, Green Miracle, Actinovate, Alexin can be successfully used against the crown rot. Further studies are required to investigate whether plant activators and biocontrol agents are compatible and can give enhanced control *of Phytophthora* in the field when applied alone or in combination.

FIRST REPORT OF WHITE MOLD OF THE GLOBE ARTICHOKE CAUSED BY SCLEROTINIA SCLEROTIORUM IN TURKEY

Tijen TASKIN*, Gulcan YIKILMAZSOY

Directorate of Plant Protection Research Institute, Bornova-Izmir, Turkey
*Corresponding author: tijen.taskin@gthb.gov.tr

Abstract

During the growing season 2013-2014, symptoms of severe leaf wilting and necrosis, brown to black buds and dark brown xylem discoloration were observed on globe artichoke [*Cynara cardunculus* var. *scolymus* (L.). Fiori] plants from a field in Cesme, Izmir province, Turkey. The plants were stunted and had water-soaked rotting of stems, smaller edible buds which were discolored with dried outer bracts, the roots exhibited vascular discoloration as previously described in Italy and Peru. Infected stem and root tissues collected from the field were surface disinfested in a 0,5 % NaOCl solution for 90 s, rinsed with sterile distilled water, and air dried before plating on potato dextrose agar (PDA). White mycelium and black sclerotia (2 to 3 mm in diameter and 4 to 7 mm long), characteristic of *Sclerotinia sclerotiorum* (Lib.) de Bary, were produced in all dishes. Identity of the pathogen was confirmed based on colony morphology and formation of sclerotia. Koch's postulates were fulfilled using a 2-day-old *S. sclerotiorum* colony growing on PDA, root dip inoculation technique. Three days after inoculation, all seedlings, inoculated with *S. sclerotiorum*, wilted and expressed symptoms similar to those observed in the field. None of the control plants showed symptoms of infection. Two weeks after inoculation, the pathogen was successfully reisolated onto PDA. To our knowledge, this is the first report of white mold caused by *Sclerotinia sclerotiorum* on globe artichoke in Turkey. Since Izmir is the largest cultivator of globe artichoke in Turkey, it is an important step to manage white mold in this crop.

Key words: Globe artichoke, fungal diseases, white mold, *Sclerotinia sclerotiorum*

Introduction

Globe artichoke is an ingredient of the Mediterranean food, which is also used for the production of medicines and dietary supplements. This plant is known for its therapeutic potential as diuretic, antidiabetic and antimicrobial agent. More than 130 000 ha of globe artichokes are cultivated in more than 30 countries worldwide. In terms of total production area (2 680,2 ha) and total production amount (34 576 tonnes) Turkey is one of the world's important producers of globe artichoke (Anonymous, 2015). Diseases cause significant economic losses to globe artichoke production. *Sclerotinia sclerotiorum* (Lib.) de Bary is a fungal pathogen causing white mold disease in a wide range of plants. It is capable of colonizing over 400 plant species found worldwide. *S. sclerotiorum* is an ascomycetous necrotroph fungus dispersed as airborne ascospores or soilborne sclerotia. The fungus can grow well even in an unfavorable environment and survive for up to 8 years in soil in the sclerotia form (Adams and Ayers, 1979). It causes water-soaked lesions on the leaves or stem rot in stems of some infected plants. The most obvious symptoms of plants infected by *S. sclerotiorum* are necrotic tissues covered with patches of fluffy white mycelia. Sclerotia are produced after mycelial growth when the nutrition is not sufficient or other conditions are favourable for sclerotial development (Christias and Lockwood, 1973). They play an important role in disease cycles as they are the primary structures for their long-term survival and produce inocula for further infection. Sizes of sclerotia are dramatically different

depending on their host (Wang et al., 2008). This study confirms the presence of the white mould, caused by *S. sclerotiorum*, on globe artichoke in Turkey.

Materials and Methods

During the growing season 2013-2014, *Sclerotinia sclerotiorum* isolates collected from globe artichoke production areas, in Cesme, Izmir province, western Turkey were used in this study. Infected plants were stunted and had water-soaked rotting of stems, smaller edible buds which were discolored with dried outer bracts, the roots exhibited vascular discoloration (Figure 1 and Figure 2).

(A) (B)

Fig.1. Dark brown xylem discoloration in transverse (A), and longitudinal (B) sections of roots of white mold–affected globe artichokes.

(A) (B) (C)

Fig. 2. Foliar symptoms of white mold in globe artichoke; Severe leaf wilting and necrosis (A), brown to black bud (B) and dark brown xylem (C).

The causal agent was isolated from symptomatic stems and roots. Small pieces of diseased stem and root tissues collected from the field were on the surface sterilized in a 0,5 % NaOCl solution for 90 s, rinsed with sterile distilled water, and air dried before plating on PDA. Inoculated plates were incubated at 22 ± 2°C. Identity of the pathogen was confirmed based on colony morphology and formation of sclerotia. Fungus was purified and microscopic characterization was done according to Bolton et al. (2006). The cultures were stored on PDA slopes at 4 °C and subcultured every 6 months. Koch's postulates were fulfilled using a 2-day-old *S. sclerotiorum* colony growing on PDA, root dip inoculation technique (Del Río et al., 2005; Bhat et al., 1999).

Results and Discussion

All tested isolates caused typical symptoms on globe artichoke of white mold. Inoculated plants developed symptoms of wilting 3 days after inoculation and were completely wilted within 15 to 20 days. Symptoms of wilting were soon followed by the appearance of white mycelium and black sclerotia. The control plants didn't exhibit symptoms and *Sclerotinia sclerotiorum* was reisolated from inoculated plants in two weeks (Figure 3). A fungus was consistently isolated from symptomatic stems of globe artichokes. The isolates showed specificity being pathogenic to the host they were obtained from.

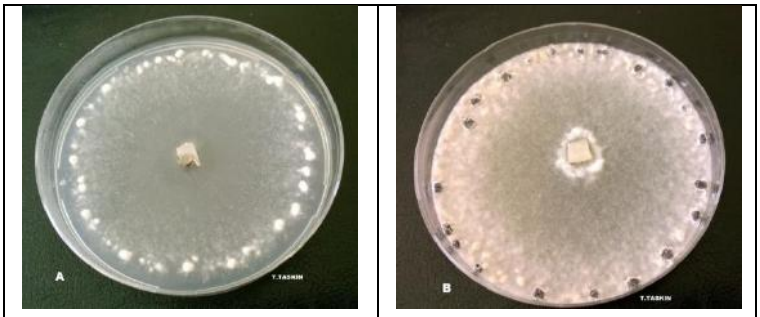

Fig.3. White mycelium (A) and black sclerotia (B) of a culture of *Sclerotinia sclerotiorum* isolated from infected globe artichoke growing on PDA.

To our knowledge, this is the first report of white mold, caused by *Sclerotinia sclerotiorum* on globe artichoke in Turkey. The identification of globe artichoke as a host for *S. sclerotiorum* is consistent with earlier researches. *Sclerotinia sclerotiorum* may occur with wide distribution in fields where very little or none had occurred in the previous year; the occurrence of *S. sclerotiorum* is associated with prolonged wet weather that is favorable for production of apothecia (Abawi and Grogan, 1979). When environmental conditions are suitable, copious amounts of white cottony mycelium and the subsequent production of black sclerotia of variable size and shape which are signs of the fungus occur. This pathogen is geographically cosmopolitan and has a broad ecological distribution, although it is most common in temperate regions. This disease was also reported on globe artichoke in Italy and also in Peru (Marcucci et al., 2010; Tarazona Matos, 2009).

Conclusion

Sclerotinia sclerotiorum is one of the important plant pathogen. White mold is a very serious problem in crops, especially when they are cultivated in contaminated wet soils in cool and wet weather. Extensive crop damage, lack of high levels of host resistance, and the general difficulty of managing diseases caused by *Sclerotinia* have been the impetus for sustainable research on this pathogen. This study is an important step to perform practical and cost-efficient strategies for managing white mold, which is an important effect limiting globe artichoke production. Further studies are needed to determine the distribution of white mold on globe artichoke in Turkey. Management of *Sclerotinia sclerotiorum* occurs at several stages of crop development. Techniques include: making the crop microclimate less conducive for infection, utilization of effective fungicides to protect susceptible plants, elimination of sources of inoculum, and selection of resistant plants. Successful disease control commonly requires implementation and integration of multiple techniques.

Abstract

Given the important economic losses caused by the seed-borne fungi to yield barley crop, with the absence of previous studies in Yemen by this study aimed to isolate and diagnosis the fungi. A laboratory study was carried out to investigate the seed-borne fungi and their effect on seed germination and seedlings growth of 64 sources gene of barley from the germplasm center of the Agricultural Research and Extension Authority (AREA),Yemen. Tested methods: incubation on blotting paper and on the Potato Dextrose Agar media (PDA) was proven that all the seeds in the study were carriers of a number of fungi, was recorded 7th genus of the fungus transmitted on the seed sources of barley according to the following: *Fusarium* spp, *Drechslera* spp, *Alternaria* sp, *Cladosporium* sp, *Ustilago* spp, *Aspergillus* sp and *Rhizopus* sp, and the results showed that there were differences between the genetic resources of barley on the percentage of the presence of fungus on various sources, they ranged between 3.3% -50%, and the *Fusarium* spp more genus fungal isolates in frequency and to cause a rot of the seeds and the death of seedlings, the source of genetic YG: 20217 More devoid of seed borne fungi, while the source of genetic YG: 20016 more sources borne fungi.

Key words: *seed-borne, fungi, barley genetic, Yemen*

Introduction

Barley is one of the important cereal crops on a number of the world's countries , and using seeds as a highly nutritional crops for human and animal feed, or as materials fodder green and may enter the barley with forage material mixture of leguminous crops like *Medicago* spp. and cowpea fodder to improve the nutritional value of the material feed while barley is used in Yemen as food for humans where it enters in many local meals and work Loaf (Almiloj) and local bread (Mujahid,1986).Barley occupies the fourth place among the world's cereal crops in terms of cultivated area and average production and is grown in most temperate regions and tropical under which distributed in the cultivation of wheat and barley, in Yemen is considered the most important field crops that are spread grown in cold areas of the central highlands and occupy an important position both in rain-fed or irrigated agricultural systems(Mujahid,1986).

Barley cultivation in Yemen suffer a severe decline in the productivity per unit area, where agricultural statistics show since 2000 and until 2008, the average productivity of grain ranged between 0.622 - 1.297 t / h , compared with the global average for the production of barley Ranged between 2.086 - 3.009 t / h for the same period (FAO, 2010).

The low crop yields per unit area return to several reasons, including the infecting of pests, from which the pathogenic fungus that is transmitted by seeds which cause economic losses starting with 4% and the passage of the seasons and frequency of cultivation the infected seeds that cause increased of economic loss all season even up to 80% of the yield, some fungi infect the crop in the field, such as fungus *Fusarium* , there is also other fungi movement with grain from the field to the store and causing discoloration of the seed ,

damage and the deterioration of their quality when the availability of conditions during storage period, such as *Penicillium*, *Aspergillus*, *Alternaria* and *Rhizopus* (Yahyaoui et al, 2004).

Given the important economic losses caused by these seed-borne fungi to yield barley crop, with the absence of previous studies in Yemen by this study aimed to isolate and diagnosis seed-borne fungi from some genetic barley sources collected from different regions of the Republic of Yemen and studied its effect on germination and infecting of seedling rates.

Materials and methods

The study was conducted on 64 seeds genetically source of barley, which have been obtained from the Genetic Resources Center for Agricultural Research and Extension Authority (AREA) of the Republic of Yemen.

Germination percentage test & Isolation of fungi

The following methods used to germination percentage test and isolation fungi from the barley seeds:

Planting in wet blotting paper

Wrapped blotting scale 24.5 cm rolls opposite paper so that the paper contains grooves where seeds are placed, put the leaves in a rectangular plastic dishes sterilized previously by alcohol ethanol concentration of 70%.To sterilize the seeds: 30^{th} seed from each genetic source immerse in Sodium hypo chlorite solution concentration of 1% for a period of 5 -3 minutes and then the seeds was tacked out and submerged in sterile and distilled water for 3-2 minutes to remove the sterile solution and after dried and placed in the grooves blotting paper at a rate of 10 seeds in each groove at a rate of three replicates each genetic source, put plastic dishes in a room temperature 25 c under the lighting 12 hours a day for a week, taking into account the daily moisturizing seeds sterile and distilled water, and after the completion of the germination process are recorded number of seeds , germinating seeds, rotting seeds and calculate the percentage of each genetic source , after that the isolation from rotting seeds was done .

Cultured way

The culture medium potato dextrose agar (PDA) was prepared and added the antibiotic Chloramphenicol at a rate of 0.05 g /L to prevent the growth of bacteria. It cleared 20 seed each genetic source superficial immerses for 3 minutes with a solution of sodium hypochlorite concentration of 1%. Seeds are sown on cultured PDA at 5 seeds in each Petri dish diameter of 15 cm and incubated dishes at a temperature of 2 ± 25 c under the lighting 12 hours a day reciprocal with the dark for a week and then examined colonies fungal formed on the seed and quoted all fungi to the culture medium new developing seeds Each genetic source separately in Petri dishes 9 cm in diameter were incubated in the previous incubation conditions for its development in the pure culture, was diagnosed depending on the form of the fungal colonies and the conidia and conidiophore of fungal spores and using some of classification keys of fungi (HASHMI & GHAFFAR. 2006 , GOEL & AULAKH. 1980.).

Results and discussion

The impact of fungus transmitted by seed of barley genetic resources Table 1 shows the results of impact seed- born fungi on the seed germination rates and found that the germination ranged between 20% -90% rates of the injury seeds fungi accompaniment ratios between 3.3% -50% and this is due to moisture high availability method of culture conditions in the paper in which the grew wet especially fungi because it helps speed the germination of spores and growth of fungal mycelium on seeds and this in turn led to affect seed germination percentage (SIMARD and LUDWIG, 1948). A negative correlation have found ($r = -0.541$) between the percentage of germination and the percentage of rot seeds , so when the rot seeds

increased the germination will decreased and this causes losses to the farmer consumes of seeds not only had a low germination rates, but requires to replanting the fail lines of farm and the cost of agriculture must be increased, these findings are consistent with a grandfather researchers. (IT and Somerx'ille, 1997, MAMLUK & VAN LEUR. 1986, SIMARD and LUDWIG, 1948.) , and found that the genetic source YG: 20217 more sources sensitivity where the percentage of germination and rot seeds 20 and 80%, respectively, in While the genetic source YG: 20016 more bearable sources where the percentage of germination and seed rot amounted to 90% & 10% respectively

The isolate and diagnose fungi associated with the seeds of barley genetic resources results indicated in Table 2 that the isolated result showed seven genus of fungi associated with the seeds of barley genetic resources are: *Fusarium* spp, *Drechslera* spp, *Alternaria* sp, *Cladosporium* sp, *Ustilago* spp, *Aspergillus* sp, *Rhizopus* sp. The genus *Fusarium* sp. (Image 1) was the most fungi infected the seed sources genetic barley may be is causing the rot of most seeds studied, and causing delay of germination, while the genus *Rhizopus* sp. Which the less fungi reluctant to most seed sources barley Genetic , these findings are consistent with the findings of researchers (ABUGHNIA and FARAJ, 1978, IT and Somerx'ille, 1997, Yahyaoui et al., 2004).

Indicated precedent Research (Malone and Lorimer, 1975) that the cover of the seed is the houses of the fungus cell, where it is the fungi *Rhizopus* sp, *Aspergillus* sp. present on the surface in the casing not affect vital seeds which fungi store, and this explains the high germination genetic source 6 YG: 2001 with the infected by the genus *Rhizopus* sp.(IT and Somerx'ille, 1997, Yahyaoui et al., 2004) while the cover and inside the seed houses of the following fungi *Fusarium* spp, *Drechslera* spp, *Alternaria* sp, *Cladosporium* sp, *Ustilago* spp

This fungi transmitted from the field and remain static in the seed until the next season and do more harm to their impact on the vitality of seeds germination or kill the seeds in addition to other fungi of rot seed when the availability of appropriate conditions because of enzymes degrading and toxins produced by fungi that affect the seeds and this explains the low germination of the genetic source YG: 20217 because of this injury of the fungi *Fusarium* spp, *Drechslera* spp, *Alternaria* sp respectively These findings are consistent with what the researchers. (Rao et al., 1999, LEE. 1980, IT and Somerx'ille, 1997, Hashmi and Ghaffar , 2006, Mamluk and van Leur, 1986, BEARDALL & MILLER. 1994.)

It also found fungi nurse moves from the last season by seeds such as *Fusarium* fungus that causes the disease blight seedling and symptoms in the field seedling dwarf yellow and then die, *Drechslera* fungus which causes rot disease seedling and symptoms in the field, brown spots. The fungus *Alternaria*, which causes blight grain and symptoms in the field, the presence of black dots on grain. The fungus *Ustilago* which causes covered -smut and symptoms disease in mass field of fungus spores replace and covered grains. This is the first study refers to isolate and diagnose fungi associated with barley seeds in Yemen and our results are compatible with what the researchers (Rao et al., 1999, IT and Somerx'ille, 1997, Lee, 1980) indicated previous studies (Lee, 1980, Goel and Aulakh, 1980) that the losses caused by the previous diseases mentioned on the barley crop, which is the loss accumulated increase from last season planting infected grain and so any attempt to improve barley in these affected areas will be failed unless the farmars must be use a health and sterilized by fungicides seeds.

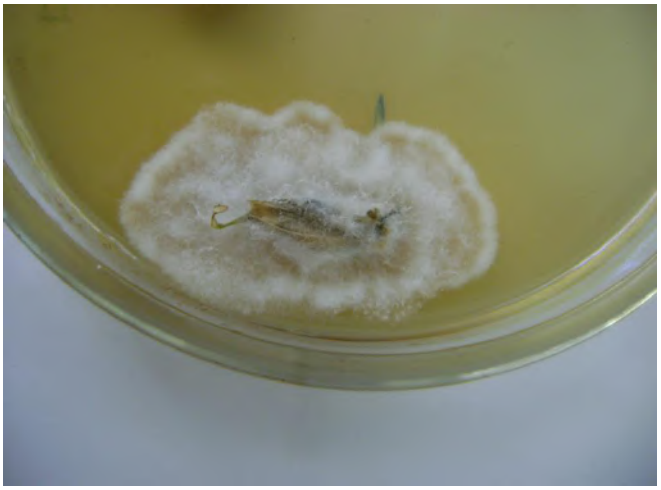
Alternaria sp



Fusarium spp

Image (1) some seed born fungi on the seeds of barley genetic sources of Yemen

Conclusions

The study was recorded 7th genus of the fungus transmitted by the seed sources of barley: *Fusarium* spp, *Drechslera* spp, *Alternaria* sp, *Cladosporium* sp, *Ustilago* spp, *Aspergillus* sp and *Rhizopus* sp. The seed-borne fungi caused an economic losses to yield of barley crop, so the main recommendations of this study are: The seeds must be testing for the seed-born fungi before entering in the gene bank , keeping under cooling and fungicide treatment. Also the re-planting seeds annually to maintain the vitality is very important to conservation of the genetic sources of the Yemeni's barley.

Abstract

This study was a survey of estrogenic mycotoxin zearalenone contamination in corn for human consumption and feed. Samples were taken by the representatives of the Agricultural Extension Service of Republic of Srpska from field or different storage facilities in regions of Banja Luka, Prijedor, Doboj, Bijeljina and Gradiška, where corn is commonly grown. Samples are analyzed by competitive enzyme immunoassay (ELISA) with microplate based kit produced by EuroProxima, the Netherlands that also contains standards with different zearalenon concentration. In total, 77 samples are analyzed and the results showed that 58 samples (75,3%) were contaminated in a range from 100 to 986 μg/kg (ppb). Avarage content in all analyzed samples was 280,9 μg/kg.

Key words: *zearalenone, corn, Republic of Srpska.*

Introduction

Mycotoxins are secondary metabolites of fungi and that can develop on plants in the field and during storage. They are potentially toxic to humans and animals. Mycotoxins and mycotoxicosis were and still are a problem, although a scientific interest in mycotoxins began in the early 1960s. Increased interest in food safety in the whole world has influenced in increased interest of fungi contamination and mycotoxin production in foods. Mycotoxins commonly enter the food chain directly through contaminated food and indirectly through food of animal origin. Mycotoxins in foodstuffs appear in small doses, but its continuous intake in organism, even in a microdose, can result in their accumulation in human organism. In this sense , attention is continuously focused on *corn* (*Zea mays* L.) because it is one of the most important food and feed in different regions of the world (*Anon, 2004*). Corn is the third most important crop in the world after rice and wheat In the Republic of Srpska corn is mostly grown for grain and it takes almost a quarter of the total arable landin the country.

In recent years there are significant climatic disturbances at the global level accompanied by extremely high or low temperatures, emergence of large and heavy rains with floods or droughts occurrences. These stressful conditions have largely contributed the contamination of different cultivars of cereals with fungi and their metabolites, mycotoxins. In the Republic of Srpska the previous, 2014, was almost ideal (especially due to favorable weather conditions) for development of the *Fusarium* species which attack maize at the time of maturity.

Zearalenone (ZON) is a natural contaminant of harvested and stored grain. They are a metabolites of 18 species of the genus *Fusarium* (*F. graminearum, F. sporotrichioides, F. semitectum, F. equiseti, F. crookwellense, F. culmorum,* etc.) and include 15 derivatives of zearalenone with estrogenic effects. These mycotoxins are known for oestrogenic and anabolic effects on humans and animals. Consumption of large doses of ZON in food may cause the effect of food refusal, sexual apathy, miscarriages and cancer effects (carcinoma of the prostate for men and cervical cancerin for women). This is because ZON is quickly absorbed through intestinal tract. In children population it causes a syndrome of premature

puberty. ZON concentration of 60 μM for 72 h inhibits over 80% cell growth, DNA and protein synthesis (Abid-Esefi *et al.*, 2004). The aim of this study was to monitor the presence and distribution, as well the concentration of zearalenone in corn produced in the Republic of Srpska intended for human and animal nutrition.

Materials and Methods

In total 77 samples of corn intended for human consumption and for animal feed is analyzed. Samples were taken by the representatives of the Agricultural Extension Service of Republic of Srpska from field or different storage facilities in regions of Banja Luka, Prijedor, Doboj, Bijeljina and Gradiška, where corn is mostly grown. Samples were analyzed in Laboratory for Plant Protection of Agricultural Institute of Republic of Srpska, Banja Luka.

The quantity of 250 g of each sample was dried at 60°C for 72 h and in this way samples were prepared for further analysis on mycotoxins presence. Approximately 50-100 g of each sample was grinded and homogenized to a fine powder and 5ml of PBS/methanol was added to the samples in the proportions 40:60. Prepared samples were stirred for 30 min and centrifuged for 10 min at 2000 xg. The quantity of 25 μl of the supernatant obtained after centrifugation was diluted with 150 μl of dilution buffer. For further testing is used 50 μl of the dilutions, and each sample was tested in two replicates.

Samples were analyzed by competitive enzyme immunoassay (ELISA) with microplate based kit produced by „Euro Proxima“ (the Netherlands) that also contains standards with different zearalenon concentration. The ELISA test is highly sensitive and specific immunological reaction which enables the detection and quantification of very low concentrations of zearalenone. Test is based on the antibody for zearalenone. The microtiter plate is coated with sheep antibodies for rabbit IgG. Antibodies (rebbit anti-zearalenone), enzyme-labeled zearalenone (enzyme conjugate) and zearalenone standards or samples are added simultaneously to the pre-coated wells of a microtiter plate, and then incubated for 1 hour at 37°C. After incubation the enzyme labeled reagents are removed by washing. The amount of bound enzyme conjugate is visualized by adding of substrate chromogen (tetramethylbenzidine, TMB). The bound enzyme is transformed into stained chromogen product (Fig. 1). The substrate reaction was stopped by the adding of sulfuric acid. The mean optical density (OD) is measured photometrically at 450 nm and is inversely proportional to the concentration of zearalenone in the sample.

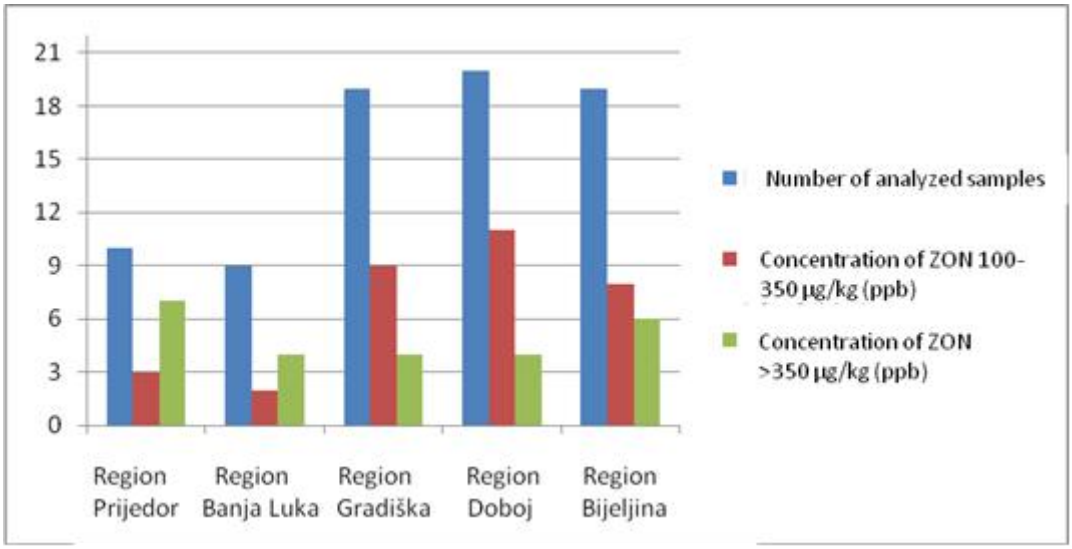
Photometric measurements were carried out on the Thermo Scientific™ Multiskan™ FC microplate photometer. The mean optical density (OD) of blank wells is subtracted from individual OD values of wells containing standards and samples. The OD value of six standards and the samples (value of the duplicates) are devided by the mean OD value of zero standard (wells A1 and A2) and multiplied by 100. Values (% maximum absorbance) calculated for the standards are plotted on the Y axis versus the zearalenone equivalents concentration (ng/ml) on a logaritimic X-axis. The amount of zearalenone in the samples is expressed as zearalenone equivalents. The zearalenone equivalents in the extracts (ng/ml) corresponding to the % maximal absorbance of each extract can be read from the calibration curve. Calculated equivalents are multiplied by a factor 120. All these calculations were done using the Thermo Scientific™ SkanIt™ software.

Results and Discussion

Results of analyzed samples of corn from different regions of the Republic of Srpska showed contamination levels of 75.3% or 75.3% while in samples was determined zearalenone content in the range from 100-986 ppb. Contamination of zearalenone in the amount of 100-350 μg/kg (ppb) were found in 42.8% of the analyzed samples, while in 32.5% of the analyzed samples zearalenone content was over 350 μg/kg (Table 1, graph.1).

Table 1. Presence of zearalenone in analyzed samples in examined regions

Region	Number of analzyed samples	Concentracion of ZON 100-350 µg/kg (ppb)	Concentracion of ZON >350 µg/kg (ppb)
Region Prijedor	**10**	**3**	**7**
Region Banja Luka	**9**	**2**	**4**
Region Gradiška	**19**	**9**	**4**
Region Doboj	**20**	**11**	**4**
Region Bijeljina	**19**	**8**	**6**
IN TOTAL:	**77**	**33**	**25**
%		**42,8**	**32,5**



Graph 1. Graphic presentation of results by regions.

The most contaminated samples were detected in region of Prijedor where the content of zearalenone was over 100 ppb in all 10 analyzed samples. In other regions, the percentage of contaminated samples ranged from 66% (Banja Luka Region) to 75% (Doboj Region). According to Regulations on maximum levels for certain contaminants in foods (Official Gazette Bosnia and Herzegovina 68/14) corn containing zearalenone between 100-350 µg/kg can not be used for direct human consumption, corn snacks and breakfast cereals. The average content of zearalenone in all analyzed samples was 280,9 µg/kg. In Bosnia and Herzegovina content of zearalenone in animal feed is not regulated. However, the introduction of zearalenone in the food chain through animal products has a huge importance, or when the animals eat contaminated food. If zearalenone is present in very high concentrations in animal feed, the risk of human exposure to this mycotoxin is high.

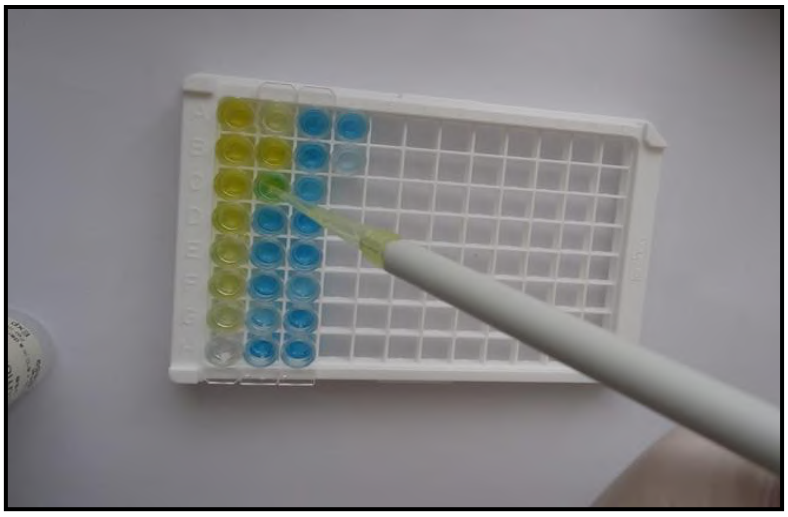


Fig. 1. Adding a chromogen substrate and transformation in the stained product

Mycotoxin zearalenone was named by the phytopathogenic fungus *Giberella* from which was isolated in 1962 (Delaš, 2010). The presence of zearalenone has been detected in various grains and corn, barley, wheat, rye, soybeans and their products (Ožegović and Pepeljnjak, 1995; Mitak, 1998; Duraković and Duraković, 2000). It is also found in milk, muscles, organs, tissues and eggs of animals that have been fed contaminated food (Prelusky *et al*., 1990). The available data in Europe show that corn is usually contaminated with zearalenone, but also a high content of zearalenone may have wheat, rye, oat and soy products (EC, 2004). Zearalenone is only partially decomposed under the influence of heat. Almost 60% of zearalenone in average remains unchanged in bread, while about 50% "survive" the production of macaroni. Concentration of zearalenone in fractions of flour and semolina is reduced by 80-90% during the dry milling of corn, while in the bran and germ found increased concentrations.

It is necessary to implement measures to minimize contamination of corn and other products during and after harvest, during processing and storage. Also, it is necessary to continue and expand the monitoring, as well to determine e relationship between this mycotoxin and health problems in humans.

Climatic conditions have a key role for production of mycotoxins. The ability of fungi to produce mycotoxins largely depends on temperature, relative humidity and stressful conditions to which plants are exposed (Miraglia *et al*., 2009). For all these reasons, further research of presence of mycotoxins and toxigenic fungi and their epidemiological importance in corn crops have a great importance.

Conclusions

Based on presented results it can be concluded that the climatic conditions in the Republic of Srpska during 2014 were extremly favorable for the appearance of mycotoxin zearalenone or fungi of *Fusarium* species which synthesize this toxin. Results also indicated a high level of contamination of unprocessed maize with mycotoxin zearalenone. Considering that the *Fusarium* species produce several types of toxins is would be reccomended to include other toxins such as fumonisin and deoxynivalenol, as well for other cereals (wheat, barley, and others.). In addition, it would be necessary to implement constant monitoring of imported food and feed for the presence of mycotoxins.

EFFICIANCY AND SELECTIVITY OF SOME HERBICIDES AT SWEETCORN

Atanas SEVOV*, Maya DIMITROVA, Dimitar STOICHEV, Plamen ZOROVSKI

Agricultural University, 4000 Plovdiv, Bulgaria
*Corresponding author: asevov@yahoo.com

Abstract

During the period 2011 - 2014 years in the experimental field of Agricultural University – Plovdiv a study for researching the effect of various herbicides on the productivity of six hybrids sweet corn - Challenger (F1), Erica (F1), Vega (F1), Honey Bentam (F1), GSS (F1) and Denitza (F1) was conducted. The effect of various herbicides and their combinations on the yield of cobs was treced. From all the used herbicides and their combinations most favorable effect on the development and productivity was found when combination of herbicides Merlin Flex 480 SC + Laudis OD doses of 42g / da after sowing and before emergence for Merlin Flex and 200ml / da foliar application for Laudis was used, and this is statistically proven. When combination of Merlin Flex 480 SC + Laudis OD was used, suitable to realize the highest total yield of cobs is GSS hybrid, and highest percentage of the total standard cob yield was found at Chellenger and Denitza.

Key words: Sweet corn (Zea mays ssp. sacharata Sturt.), herbicides, hybrids, yield.

Introduction

(Zea mays var. Saccharata) is a subspecies of ordinary corn, and in recent years in Bulgaria couses considerable interest. A major problem in the cultivation of this culture is weeding. It leads to strong reduction in yield, especially in the high density of the weeds in the early stages - between 2nd and 4th leaf. Then the plants rely yield, and weeding in this period can even completely compromise the yield. When control the weeds by chemicals, a large number of hybrids exibit phytotoxicity, and the sweetcorn plants die (Sevov et al, 2014).

According Waligóra et al. (2012) herbicide combination foramsulfuron + iodosulfuron methylosodium, shows very good control of annual dicotyledonous weeds, disregarding phytotoxic effect on any of the tested hybrids. Pataky et al. (2008) have studied the sensitivity of the 149 hybrid sweet corn to the herbicide nicosulfuron, foramsulfuron and mesotrione. In comparative research with 95 hybrids, phytotoxicity which leads to a complete death of the culture was recorded. Odero et al. (2013), has found that the efficacy of herbicides pyroxasulfone, S-metolachlor and mesotrione on soils with a high organic content (over 85%) is excellent - from 91% to 99%, without adverse effect on the culture.

Kopsell et al. (2011); report for changes in of sunscreens carotenoids, β-carotene, chlorophyll A and B content as a result of foliar treatment with mesotrione + atrazine at Rugosa hybrid. Changsaluk et all, (2009) and Rajablarijani et al. (2014) have similar results for physiological changes due to different herbicides applying.

There are many data not only on the efficacy of different herbicides in the ordinary corn, but for their economic feasibility also (Koprivlenski, 1997; 2011), Modern research has shown that the new sweet corn hybrids are highly sensitive to some herbicides, but here the problem is poorly understood. Contemporary researches show that new sweet corn hybrids are highly sensitive to certain herbicides, but in our country this problem is poorly studied.

Material and methods

The research was conducted during the 2011 – 2013 period, in the experimental field of the Agricultural University – Plovdiv on alluvial soils. Randomized complete block design was

displayed with five variants in three replications and size of the experimental plot 20 m^2, (table 1). The efficacy and selectivity of 4 herbicides and herbicide combinations to 6 maize hybrids: Challanger F1, Erica F1, Vega F1, Honey Bentam F1, GSS F1 and Denitza F1 has been researched. Soil and foliar herbicides are imported with a knapsack sprayer and working solution 300-400 l / ha. During the vegetation drop irrigation of the crop has been done.

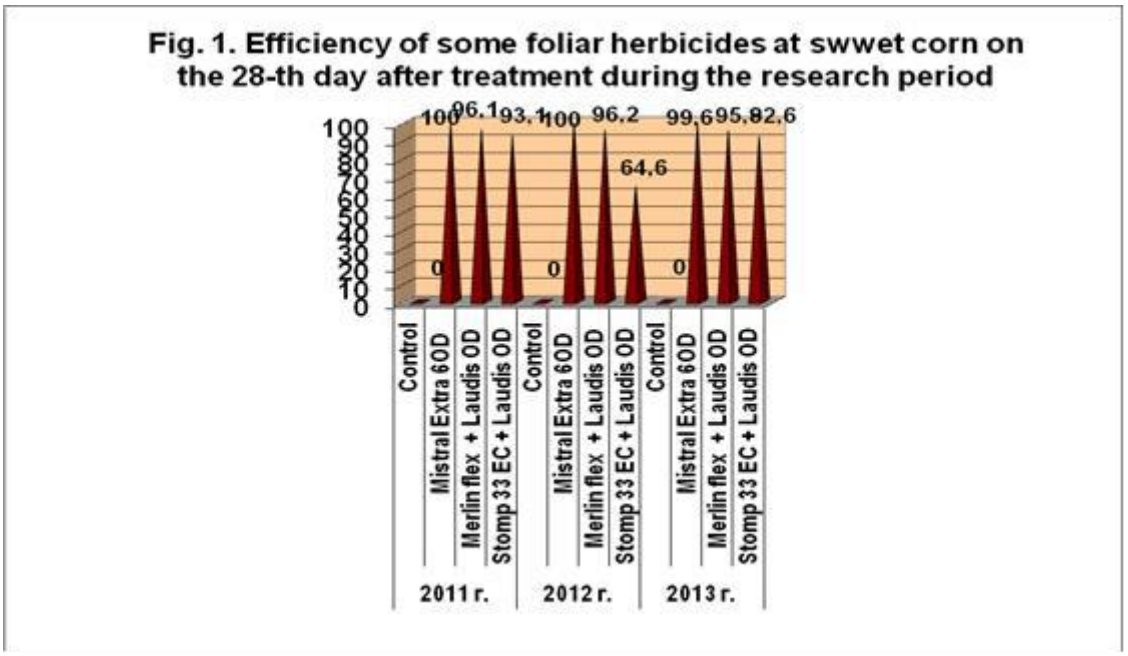
Table 1. Variants of experiment

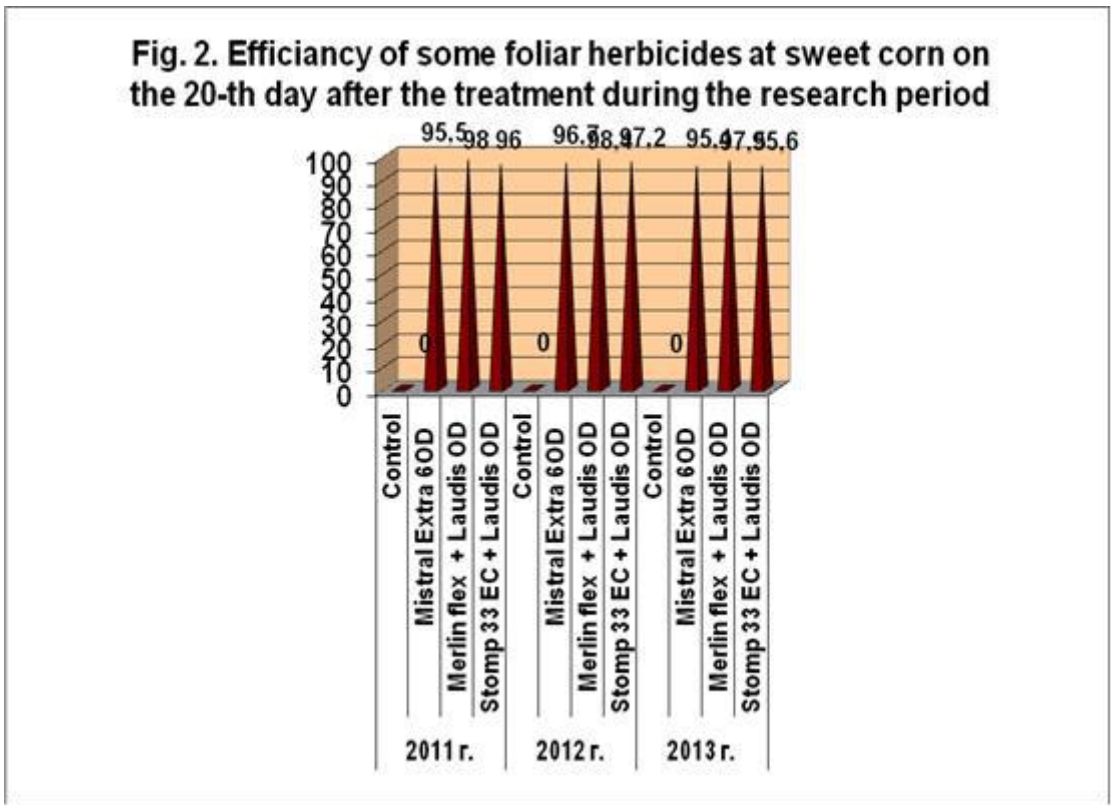
Variants	Herbicide	Active substance	Dose /ha
1	**Zero control (untreated)**	-	-
2	**Gardoprim Plus Gold 500 SC**	**312.5 g / l S-metolachlor + 187.5 g / l terbutilzin**	**4 l /ha** - *soil application*
3	**Mistral Extra 6OD**	**60g / l nicosulfuron**	**650 ml /ha** - *foliar application*
4	**Merlin flex + Laudis OD**	**240 g / l isoxaflutol + 44 g / l tembotrione**	**420 g /ha**- *soil application+* **2 l /ha**- *foliar application*
5	**Stomp 33 EC + Laudis OD**	**330 g / l pendimethalin + 44 g / l tembotrione**	**3,50 l /ha** - *soil application+* **2 l /ha**- *foliar application*

Years of the conducting experience are characterized with varying temperature and precipitation. The highest amount of precipitation in the period of sowing up to the 45^{th} day after treatment with soil herbicides (April and May) have fallen in 2013 - 183,0 mm, and at least in 2011 - 59,6 mm. In relation to temperature, warmest was 2013 - with temperature sum for April-May 34.0 C^0, and coolest is 2011 - 28,9S0.

Results and discussion

Sweet corn areas are weeding mainly with annual late spring weeds as: *Amaranthus retroflexus L., Solanum nigrum L., Chenopodium album L., Portulaca oleraceae L., Dathura stramonium L., Setaria viridis L., Setaria glauca L., Xanthium strumarium L., Echinochloa grus-galli L.*, rather than multi - *Sorghum halepense* L. In the untreated control the weed infestation level of is very high and ranges from 503 pcs. / m2 (2012) to 584 pcs / m2 (2013).
The efficacy of soil applied herbicides Gardoprim Plus Gold 500 SC, Merlin flex and Stomp new 330EK on the 28th day after treatment, average for the three year period is an excellent. In regard to the weeds highest efficiancy show Gardoprim Plus Gold 500 SC - 4 l / ha - 99,9%, followed by Merlin Flex - 4.2 l / ha - 96,1% and Stomp new 330EK - 3,5 l / ha (93,4%) (Figure 1).





Yearly, there was no substantial difference of the effect of the applied soil herbicides to the 45th day after treatment. Highest efficiency show again Gardoprim plus Gold 500 SC - 98.9%, followed by Merlin Flex - 4.2 l / ha - 93,7%. Less control on weeding - 89.7% was recorded in Stomp new 330EK - 3,5 l / ha.

For none of the used soil herbicides was established pytotoxity on the studied hybrids sweetcorn on the third, 7th and 21st day after the treatment (ball 1 on the scale of EWRS).

In foliar appended herbicides, both itself (var.3) and in combination with soil herbicides (var.4 and 5) efficacy on the 20th day after the treatment was very good.
In the variants where the combination Merlin Flex - 420 g / ha (soil application) + Laudis OD 2 l / ha- (foliar application) is applied the efficiency is 97.9%, and in variant 5 - Stomp new 33 EC - 3 5 l / ha (soil application) + Laudis OD - 2 l / ha (foliar application) - 96,3% (Figure 2). Lower weed control is obtained when treated with Mistral extra OD 6 - 650 ml / ha - 95,8%, and it is mainly due to weeds sprouted as a result of precipitation in April and May, and performed irrigations in the later period of vegetation of culture.
The herbicide controls the perenial species Sorghum halepense L. up to 99% and Laudis OD - 2 l / ha to 95% - 96%. In the untreated control the level of weed infestation is very high and ranges from 571 pcs. / M2 (2012) to 613 pcs. /m2 (2013).
Despite the high density of annual weeds in the research areas, the efficiency of the appended foliar herbicides, both alone and in combination is maintained until the 40th day after spraying.
In regard to the selectivity of the leaf herbicides negative impact on the studied hybrids sweetcorn is not reported, except Erica (F1). Mistral extra OD 6 at a dose 650 ml / ha and Laudis OD - 2 l / ha caused complete death of plants of this hybrid (ball 9 on the scale of EWRS). From 7 to 14 days after treatment, Laudis OD - 2 l / ha caused lightening of maize plants, which turn white from the top of the leaves to the base (ball 6-7 by EWRS) and on the 21th day wither and die (ball 9 on the scale of EWRS). When treated with Mistral Extra 6 OD on the 7th day, plants acquire anthocyanin colouring (ball 4 EWRS), on the day 14th necrosis (Ball 6 EWRS), and on the day 21st wither and die (9 ball EWRS).

Conclusions

Soil applied herbicides on the 28th day after treatment showed excellent effect against the weeds, which lasts until the 45th day after treatment. Efficacy varies from 93.4% at Stomp new 330EK - 3,5 l / ha, to 99.9% at Gardoprim plus Gold 500 SC - 4 l / ha.
Phytotoxicity of studied soil herbicides Gardoprim Plus Gold 500 SC at a dose of 4 l / ha, Merlin flex - 4,2 l / ha and Stomp new 330EK - 3,5 l / ha on the crop has not been established.

High efficacy against the weeds of leaf herbicides Extra Mistral OD 6 - 650 ml / ha - 95,8%, and the combination of Merlin Flex - 420 g / ha (soil +) Laudis OD 2 l / ha (leaf) - 97.9% has been reported.

Mistral Extra OD 6 - 650 ml / ha controls the perennial species Sorghum halepense L. up to 99% and Laudis OD - 2 l / ha up to 95% - 96%.
Prolonged control on weed infestation average of three years of investigations was reported when using combination of soil and foliar herbicide.
When treated with foliar herbicides Mistral 6 Extra OD at a dose of 650 ml / ha and Laudis OD - 2 l / ha phytotoxic effect on the hybrid Erica (F1) was reported and the herbicides cause complete death of plants - Ball 9 EWRS.

Abstract

Apple (Malus domestica Borkh.) is one of the most widely cultivated fruit in Europe. The apple tree is a deciduous tree, in the rose family, it is cultivated in many geographical areas and is the most widely grown species in the genus malus. About 80 million tons of apples were grown world wide and are often eaten raw, bur also be used in agricultural industries in order to produce different products with important properties for human nutrition. Apple distillate or cider brandy, obtained by the distillation of cider, made from cider-apple cultivars, is a common drink in many areas of Europe. Apple distillates are made from apple pomace – the solid residues generated after juice extraction and is composed of peel, pulp and seeds. The aim of this study was to evaluate the chemical composition of cider brandies from different varieties cultured in Naoussa- Pilio of Continental Greece. Analysis of major volatie compounds were performed by Head Space GC-MS. In general 43 components were identified. Terpenes(geraniol, nerol, linalool, a-terpenol etc.,alcohols(hexanol, 2-phenyl-ethanol,1-propanol etc.,, aldehydes(acetaldehyde, acetal etc.), esters(isoamyl acetate, ethyl acetate,isoamyl cetate, ethyl lactate, ethyl isovalerate etc. and fatty acids (hexanoic acid, octanoic acid etc.) were the determined major components in our samples. The results indicated that cider brandies from native apple varieties from different cultured areas of continental Greece has low concentration of toxic methanol, and is considered a high quality product and a factor of important economic repercussion.

Key words: *Cider, Spirits, apples, volatiles, distillates*.

Introduction

The alcoholic beverage produced by distillation of fermented apple pomace it is the popular cider brandy. It is characterized by a special aromatic flavor. Some compounds of this beverage originate from the fruit variety, but most of them are developed during apple pomace fermentation. Various factors influence the aromatic profile such as cultivation environment, soil and climate, the apple variety, the degree of fruit ripeness, the distillation apparatus which used for the spirits production, the pomace fermentation conditions, the distillation process and the aging of the spirits, if is used .

Cider Brandy volatiles can be classified in different chemical groups such as alcohols, esters, aldehydes, ketones, acids, terpenes etc. (Guichard, H.et al.,2003)**.** These compounds can be characterized by different volatility. Some compounds highly volatile, whi1e others exhibit lower volatility. These aroma compounds exist in a wide concentration range. Some of them are present at high concentrations (hundreds of mg/L), but most of them are found very low concentration range, from traces to 10mg/L. The concentration of toxic methanol which is well-known that its levels of in alcoholic beverages are related with the pectic substances present in fruit, as well as to the presence of pectinmethylesterases with the capacity to degrade it. Methanol (CH_3OH, methyl alcohol,carbinol,wood spirit,wood alcohol) is a

colourless liquid at ambient temperatures, with a slight alcoholic pungent odour when pure. It is well known that methanol is a toxic and harmful substance to human health (when taken orally at 340 mg/kg of body weight) of whose ingestion or inhalation can cause blindness or death. Following ingestion, it is oxidised to formic acid, both toxic to the central nervous system. Formic aldehydes deteriorates the optical nerve, causing blindness and reported that oxidised methanol produces lactic acidosis which is a metabolic disease caused by an increase in blood levels of lactic acid. Its symptoms lead to weakness, vomiting and finally coma and death. The level of 200 mg/L is considered the maximum safe concentration to be inhaled for a continuous eight-hour working dayGerogiannaki- Christopoulou M. et al. 2007.
Furthermore, the higher alcohols formed from amino acids during fermentation are also affected by the yeast strains employed and the fermentation temperature of ciders. Acrolein,off-flavors in cider brandies could be formed during cider maturation by microorganisms (Mangas, J. J et al, 1996).
The aromatic profile of fermented beverages will especially mark the characteristics of commercial spirits; however, the chosen distillation system also plays an important role in the final composition of the distillate (Gerogiannaki- Christopoulou M., et al. 2007). For instance, the extended length of heating in distillation systems, produces cider brandies with higher contents in furfural due to degradation of residual sugars, thus imparting a caramel aroma. The composition of distillates likewise varies depending on the material employed in the construction of the distillation system. On the other hand, traditional practices in the production process increase consumer approval of products. Apple distillates produced in copper traditional distillation apparatus , which consist of a pear-shaped pot at the top coupled to a recipient filled with cool water for condensing the alcoholic vapor.
In this paper, we study the volatile compounds of apple distillates from different apple varieties after fermentation of apple pomace. To do so, we carried out a preliminary analysis of the chemical composition during the distillation process and subsequently performed a chemical evaluation of the cider spirits thus obtained. Analyses were carried out according to European Union regulation parameters (Council Regulation 110/2008.Volatile compounds were analyzed by Head –space GC-MS.

Materials and methods

Raw Material. Apple distillates from two apple varieties **(**Brina and Norfolk Royal) was studied**.** The spirits produced in local distilleries of North Greece by means of traditional technology and were prepared from the fermented apple pomace of monovarietal apples. The pomace of apples fermented by wild microflora.
Distillation. The distillation of apple fermented pomace were realized with the a traditional copper alambic of 130L. The copper alambic, is hermetically closed in order to prevent any vapor leakage. When the temperature reached at 85^0 C, the liquid spirit starts to run and collected.
The apple distillate sample, collected and analyzed by head space GC-MS.

Chemical Analysis.

Chemical Analysis of Volatile Compounds by Head Space GC-MS

The volatile components present in headspace fraction of distillates were isolated and identified by using a balance pressure headspace system Perkin-Elmer HS40 (Perkin-Elmer Analytical Instruments, Uberlingen, Germany) coupled to a GC/MS-Q 5050 system (Shimadzu Co, Kyoto, Japan). A 2 mL sample from each sample was taken and introduced into a 22 mL round-bottomed vial with 1 mL aliquot of standard solution (2 mg pentanol-3 in ethanol-water solution (50:50 v/v)); then, the vials were sealed with aluminium-rubber septa.

The vials with samples were held at 50 °C for 25 min, purged and pressurised with helium at a flow rate of 40 mL·min^{-1}. The volatile compounds were driven through the transfer line which was held at 80 °C to the injector of the gas chromatograph. The volatile compounds were separated on an HP Innowax capillary column (60 m length × 0.25 mm internal diameter, 0.25 μm film thickness) at the following conditions: injector temperature 200 °C; carrier gas helium 0.6 mL·min^{-1}; temperature program: 45-100 °C at a rate of 4 °C·min^{-1}, held for 5 min and go to 200 °C at a rate of 8 °C·min^{-1} and held for 12 min. The GC column was directly connected without splitting to the ion source of QP 5050 quadrupole mass spectrometric detector which was operating in the scan mode within a mass range of m/z 30-350 at 2 scans·s^{-1}. The interface line to MS was set at 250 °C. The MS was operating in an electron impact mode at electron energy of 70 eV and was calibrated by auto-tuning.
Identification of the compounds was carried out by computer-matching of their mass spectral data with those of known compounds in the Shimadzu NIST62 Mass spectral Database and by comparing their retention times and mass spectra to 3-pentanol as internal standards solution.

Quantification was performed by integrating the peak areas of TIC (total ion chromatograms) by the Shimadzu Class 500 software.

Oven temperature programme, 50-260 °C at a rate of 4 °C·min^{-1}; transfer line temperature, 270 °C; carrier gas, helium at a linear velocity of 31.5 cm·s^{-1}; inlet split ratio, 1:60; MS source ionization energy, 70 eV; scan time was 1 s, covering a mass range of 40-300 amu.
The constituents were identified by comparison of their mass spectra with those in a computer library (LIBR-TR and Wiley 5 Library) or with authentic compounds. The identifications were confirmed by comparison of their retention indices of volatiles either with those of authentic compounds or with data in the literature.
Quantitative results were obtained by calculating the average value of three samples.

Results and discussion

The distillation fractions were analyzed by Head space GC-MS using the method described above. Table 1 contains the identified components of apple distillate from the native apple varieties.A-pinene has the higher concentration (211μg/l) and methanol. (125mg/L), are the major compounds.
Methanol, a toxic alcohol is clearly below the maximum permissible limits (EC-110/2008).

Abstract

In the present study the effect of various forms of fertilizers on the yield and mineral composition of cauliflower was examined. The experiment was conducted at the experimental field of University of Thessaly during 2013-2014 growing season. Four fertilizer treatments were applied: 1) Control (C), 2) farm yard manure (M), 3) standard fertilizer (F), 4) zeolite + standard fertilizer (F+Z). Seeds from cauliflower hybrid Centrum F1 were sown in seed trays containing peat and young seedlings were transplanted directly in the field. At the day of harvest plant features regarding plant development, such as the total plant fresh weight, the number of leaves, the fresh and dry weight of leaves, heads and shoots were recorded. In addition, mineral composition of heads and leaves were assessed. From the results it is suggested that the fertilizer type affects significantly the various plant features. More specifically, the treatments (F) and (F+Z) resulted in the highest total plant weight and head fresh weight, number of leaves and shoot weight and differed significantly from both control (C) and manure treatment (M). Regarding mineral composition, differences were observed in the Fe content of leaves, total nitrogen and Zn content of heads and leaves. In conclusion, the fertilizer type could affect both yield and mineral composition of cauliflower, whereas standard fertilizer application (alone or combined with zeolite) is essential for higher yield and final product quality.

Keywords: *cauliflower, fertlization, manure, nitrogen, zeolite*

Introduction

The use of chemical fertilizers is essential in order to achieve the maximum potential of the genetic material and, as well as to succeed the highest possible yield and quality of the final product. However, usually farmers are dependent on empirical methods for fertilizer application, without using the means that allow for better fertilizer use efficiency such as plant tissue and soil analysis. The common result is the irrational use of fertilizers that consequently leads to environmental pollution, and soil and ground water degradation, whereas sometimes such practices involve threats for human health due to low quality of the final product. The use of fertilizers other than chemical fertilizers (e.g. composts, manure, organic fertilizers) gradually gain interest as an environmentally friendly and compatible to sustainable agriculture practice (Knight and Newman, 2013). However, the main disadvantages of various organic fertilizers are the high cost per fertilizer unit due to limited nutrient availability, and the unstable composition, especially for products such as the manure.

Nitrogen is the one of the essential macronutrients that is important for plant growth and development and is widely added in crops in order to increase yield. Cekey et al. (2011) reported that increasing nitrogen rate in cauliflower crops up to 250 kg ha^{-1}, resulted in an increase of 31.4% in yield compared to control (no added fertilizers). Similarly, Bozkurt et al. (2011) reported that a nitrogen rate of 225 kg ha^{-1} combined with full irrigation treatment resulted in the highest yield for cauliflower crops. Quiros et al. (2014) examined the effect of three fertilizers (industrial and homemade compost and mineral fertilizer) on cauliflower crops. From the results it is concluded that although total yield was higher for mineral

fertilizer by 26 and 91% comparing to homemade and industrial compost respectively, the application of homemade compost had a significant effect on the quality of the final product, since the produced flower heads were bigger and heavier than the other treatments.
Zeolite has been widely used in agriculture for amelioration since it is suggested to improve soil properties, decrease nitrogen leaching and increase nitrogen recovery (Huang and Petrovic, 1994; Sepaskhah and Barzegar, 2010). Bybordi et al. (2013) evaluated the effect of zeolite and nitrogen application on plant growth, nitrate reductase activity and plant nutrient content of canola plants. From the results it was concluded that zeolite application can increase plant growth and seed production mostly due to better nitrogen use efficiency and soil amelioration. Similarly, the application of zeolite and urea resulted in an increase of dry matter content and mineral composition of silage corn (Bernardi et al., 2011).
The aim of the present study was to examine the effect of various fertilizers on plant growth and yield of cauliflower plants, as well as to evaluate the use of zeolite as a means for soil amendment and better use efficiency of nitrogen fertilizers.

Materials and Methods

The plant material used in the experiments was the cauliflower hybrid Centrum F1 [*Brassica oleracea* convar. *botrytis* (L.) Alef. var. *botrytis* L. (Rex F1)]. Seeds of the three species were sown in seed trays filled with peat on September 5th and transplanted in soil 35 days after sowing (October 10th). Cultivation was carried out in open field conditions at the experimental farm of the University of Thessaly. Four fertilizer treatments were applied: 1) Control (C), 2) farm yard manure (M), 3) standard fertilizer (F; NPK: 20-20-20), and 4) zeolite + standard fertilizer (F+Z; NPK: 20-20-20+Zeolite). For all the fertilizer treatments (M, F and F+Z) the total nitrogen rate was 250 kg ha^{-1}, whereas for F and F+Z treatment nitrogen was applied with three doses (the first dose before transplantation as base dressing and the second and third dose 30 and 60 days after transplantation respectively). In treatments F and F+Z, apart from nitorgen equal amounts of phosphorus and potassium were added (250 kg ha^{-1}), where for M treatment the total amount of added farm yard manure was calculated according to target nitrogen rate (250 kg ha^{-1}). The soil texture was SCL (48% sand, 29% silt and 23% clay). The pH of soil was between 7.7- 8.1 and the organic matter was 1.44%, EC=2.47 dS m^{-1}, CaCO3=2.80% (total) and P Olsen=122 mg Kg^{-1}.
Harvest took place when heads reached marketable size starting 120 days after transplantation. After harvest plant features regarding plant development, such as the total plant fresh weight, the number of leaves, the fresh and dry weight of leaves, heads and shoots were recorded. Fresh samples of leaves were oven-dried at 72 °C to constant weight. Subsequently, the dry samples were powdered using a ball mill, passed through a 40 mesh sieve, subjected to dry ashing in a muffle furnace at 550 °C for 5 h, and used to extract K, Na, Ca, Fe, Mn, Zn and Mg by means of 1 N HCl. The concentrations Fe and Zn in the aqueous extracts were determined by atomic absorption spectrophotometry (Perkin Elmer 1100B) and K by flame photometry (Sherwood Model 410). Phosphorus was extracted with Olsen method according to Sims (2000).
The statistical design was a randomized complete block with four replications per treatment (n=4; 16 plots in total). Each plot was 9 m^2 (3 x 3 m) and plant distances were 50 cm between rows and 40 cm within each row (50.000 plants ha^{-1}). Statistical analysis was carried out with statistical package Statgraphics Centurion (Statpoint Technologies Inc., USA).

Results and Discussion

From the results of the present study it is apparent that fertilizer application, either alone or combined with zeolite (F and F+Z), resulted in significantly higher total plant weight, leaf number and leaf fresh weight, whereas dry matter was higher when no fertilizers were applied

(Table 1). Similar effects were observed for total yield as expressed by head weight, with both fertilizer treatments being higher than farm yard manure (M) and control treatment (C), without however having significant differences with each other (Table 2). Moreover, shoot fresh weight was also higher for fertilizer treatments, whereas dry matter content of head and shoots was higher when farm yard manure was applied (Table 2). Similar results were reported from Bybordi et al. (2013) who concluded that zeolite application can increase plant growth and seed production due to better nitrogen use efficiency and soil amelioration. However, in our study no significant differences were observed between the zeolite+fertilizer and the fertilizer application. These results may be attributed to the fact that plant requirements for nitrogen were fully covered in both cases, therefore the potential of beneficial effects of zeolite were not profound.

Table 1. The effect of fertlizer treatment on plant growth (total plant weight and leaves).

Treatment	Total plant weight (g)	Number of leaves	Fresh weight of leaves (g)	Dry matter content of leaves (%)
C	745.9^{c}	17.6^{b}	290.1^{c}	9.0^{a}
Fertlizer+ Zeolite (F+Z)	1859.7^{a}	20.8^{a}	822.5^{a}	8.0^{c}
Fertilizer (F)	1715.8^{a}	21.1^{a}	773.2^{a}	8.0^{c}
Manure (M)	975.0^{b}	17.8^{b}	396.7^{b}	8.4^{b}
LSD	171.9	0.56	93.5	0.33

*Different latin letters represent significant differences between means of the same column according to Least Significant Differences test (LSD) at p=0.05.

Table 2. The effect of fertlizer treatment on plant growth (heads and shoots)

Treatment	Head fresh weight (g)	Dry matter content of heads (5)	Fresh weight of shoots (g)	Dry matter content of shoots (%)
C	395.4^{c}	7.0^{b}	52.2^{b}	8.2^{b}
Fertlizer+ Zeolite (F+Z)	925.9^{a}	6.0^{b}	103.6^{a}	6.8c
Fertilizer (F)	858.6^{a}	6.2^{b}	97.7^{a}	7.2^{c}
Manure (M)	541.8^{b}	10.3^{a}	56.5^{b}	9.4^{a}
LSD	99.8	1.33	9.9	0.44

*Different latin letters represent significant differences between means of the same column according to Least Significant Differences test (LSD) at p=0.05.

Regarding mineral composition, potassium content in heads and leaves, as well as Fe content in heads, phosphorus content in plant tissues and K and KCl content in soil were not affected by the fertilizer treatments (Tables 3-5). Fe content in leaves was higher for fertilizer treatment when combined with zeolite (F+Z), without however being significantly different from the fertilizer treatment (F; Table 3). Nitrogen content in plant tissues and Zn content in leaves was higher for both fertilizer treatments (F and F+Z), whereas Zn content in heads was higher for F+Z treatment, without significant differences between control (C) and fertilizer (F) (Table 4). Manure application resulted in the highest content of Zn and Fe in soil, without significant differences between C and F in the case of Zn, and F+Z and F in the case of Fe (Table 5). Bernardi et al. (2011) have also reported that zeolite and urea application not only resulted in an increase of dry matter content but also affected mineral composition of silage corn, especially regarding nitrogen content.

Table 3. Mineral composition of heads (K, Fe and Zn) and plant tissues (N) in relation to fertilizer treatment.

Treatment	K (%)	Fe (%)	Zn (%)	Total N
C	3.53	0.009	0.0039^{ab}	0.013^{b}
Fertlizer+ Zeolite (F+Z)	3.84	0.010	0.0042^{a}	0.022^{a}
Fertilizer (F)	3.27	0.009	0.0039^{ab}	0.021^{a}

Table 5. Mineral content in soil expressed in ppm.

Treatmnet	Zn (ppm)	Fe (ppm)	KCl (ppm)	K (ppm)
C	0.52^{ab}	4.28^{b}	698.5	366.7
Fertlizer+ Zeolite (F+Z)	0.47^{b}	5.63^{a}	824.5	349.5
Fertilizer (F)	0.50^{ab}	5.20^{ab}	796.3	417.6
Manure (M)	0.58^{a}	5.65^{a}	754.9	402.7
LSD	0.086	1.30	209.8	79.2

*Different latin letters represent significant differences between means of the same column according to Least Significant Differences test (LSD) at p=0.05.

Conclusion

In conclusion, fertilizer application was very important in order to obtain high yields, since plants had a better growth and finally formed larger heads comparing to the other treatments. Moreover, the application of zeolite had no additional beneficial effect comparing to fertilizer application, however we have to consider its beneficial effects as soil amendment.

Abstract

The design optimization of the tractor operated boom sprayer by Computational Fluid Dynamics (CFD)-Analysis has been successfully done for solving a problem of uniform nozzle pressure, spraying fluid losses and energy losses. The new conceptual model of boom sprayer with necessary modifications in old design has been software tested and fabricated for the field performance testing. The performance obtained by modified boom sprayer was stable in all directions after simulation and design optimization in software environment. The uniform length of boom-hosing, nozzle spacing and their orientation was uniform along the boom when measured stationery on a level surface, the distance between the lower edges of the nozzles and the surface was not varying more than 10 cm. The fluid distribution under a developed spray boom was found to be significantly improved when evaluated under the spray scanner. The discharge of **50** lit/min for rated rpm 950 and was able to maintain sufficient pressure in the nozzles. The fabrication of new conceptual design after CFD analysis has been proved successfully for the uniform pressure as well as the 150ml sprayer fluid which is lost during sprayer operations was saved up to 130-140ml.

Keyword: Boom Sprayer, CFD analysis, design optimization, nozzle pressure, simulation

Introduction

Sprayer is an equipment used for application of herbicide, pesticide, and fertilizer to agricultural crops. Tractor operated hydraulic boom sprayer is the most common method of applying pesticides to the field crops in the more developed and relatively wealthy agricultural regions of the world. These type of sprayers have high uniformity of spray, high working efficiency, and full utilization of tractor during idle time. In India, very few research studies have been done on boom sprayers for annual field crops. The existing research studies have showed that variation in nozzle pressure of boom sprayer affect the uniformity of the spray.

The design optimization of tractor operated boom sprayer in computational virtual environment by CFD method is the most useful tool for studying and designing much effective flow control system for spraying equipment to reduce problems arising due to pressure variation in the spray nozzles, which is quite difficult and time consuming with traditional design methods.

Objectives of this research are.

1. Study of existing design and its operational problems of tractor operated boom sprayer.
2. To prepare Computer Aided Engineering Analysis (CAE) report in CAD/CAE-Software.
3. The final confirmation of the boom sprayer specification and fabrication.
4. Field Performance evaluation of modified Boom Sprayer.

Materials and methods

The study of the operational functionality of the existing boom sprayer, modification made in the flow control system, CFD modeling of the flow control assembly of both existing and modified tractor mounted boom sprayer. Experimental set up used for laboratory testing of existing and modified boom sprayer, method adapted for evaluation of sprayer performance.

Existing (old) Boom Sprayer

The pump is driven by the PTO shaft of the tractor and the sprayer unit sucks the chemical and discharges it through the discharge line consisting of a delivery hose to the individual nozzles along the boom. The boom has a swivel arm to direct the spray correctly. The main frame allows the spray boom to be adjusted according to the height of the crops being sprayed. On the frame over which chemical tank and control panel were assembled. The specification of selected sprayer is discussed below.

The design characteristics of various components of the selected boom sprayer are described by constraining the following elements:

Chemical tank b) Main frame c) Boom stand d) Bottom frame e) Boom f) Boom folding arrangement g) Power transmission h) Pump i) Flow Control Assembly j) Spray Nozzles k) Hose pipes

Existing Boom Sprayer (Old):

The control panel consisted of four on-off valves, pressure regulator (PRV) and suck-back valve. It facilitate in spraying from any section of the boom, operating the hydraulic agitator and for suck back valve. Three on/off valves are provided for delivery and one was provided for operating agitator. Pressure regulator was provided for regulating the pressure. Pressure vessel was also provided to reduce the fluctuation of spray liquid is shown in Fig2.1 (a). The control assembly was mounted on the main frame from front side of the sprayer.

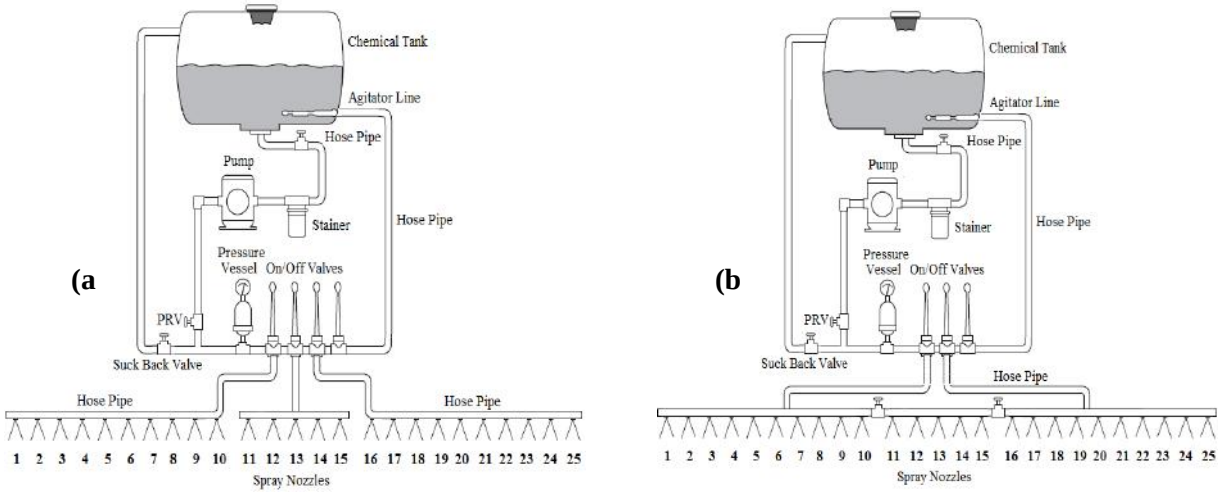

Fig. 2.1 Flow Control System of a) Old Boom Sprayer and b) New Boom Sprayer

Modifications Made in the Boom Sprayer(New):

The modifications in the existing boom sprayer were made only in the flow control system to reduce the variation in nozzle pressure to improve the sprayer performance. The control panel consists of three on-off valves, pressure regulator (CVA) and suck-back valve. Out of These three on-off valves two on-off are connected to the delivery line in such way that the distribution of the nozzles on both sides will be same. The remaining valve operates the hydraulic agitator. Pressure regulator valve is provided for regulating the pressure. Pressure vessel was also provided to reduce the fluctuation of spray liquid is shown in Fig. 2.1(b).

Initial Loading and Boundary conditions for Simulation cycle:
In order to obtain a well-posed system of equations, reasonable boundary conditions for the computational domain have to be implemented. Inlet boundary condition is a uniform liquid pressure at the inlet and outlet boundary condition is the pressure boundary condition, which is set as 101.325 kPa. Wall boundary conditions are no-slip boundary conditions for the liquid phase and free slip boundary conditions for the solid phase and the gas phase. The restitution coefficient for solid – solid has been taken default value of 0.9. The higher viscous effect and higher velocity gradient near the wall have been dealt with the standard wall function method. Table 2.1 shows the boundary and initial conditions for flow control system simulation cycle.

Conclusions

The pressure and discharge variation of the each individual nozzle was significantly decreased and was able to maintain uniform pressure and discharge in each section of boom.

The new flow control system was able to maintain recommended nozzle pressure of 280 – 300 Kpa at the standard operating pressure of 689.5 Kpa for boom sprayer.

The results predicted by the CFD software simulation environment were slightly higher than results observed during physical laboratory test. But the trend of variation in nozzle discharge rate and pressure was found to be same in both tests.

Abstract

Pathogens that survive in/on the soil and cause diseases in vegetable crops are defined as soil-borne plant pathogens. Soil-borne plant pathogens have always had impact on productivity and they can significantly reduce yield and quality of production. These pathogens are difficult to control because they can survive for long time in the absence of the host crops and often have a wide range of hosts. Detection and accurate identification of soil-borne plant pathogens is one of the most important strategies for controlling soil-borne vegetable diseases. The failure of conventional and culture based morphological techniques for identification and detection of these pathogens has led to the development of serological and molecular detection approaches. The aim of this study is to compare different detection techniques which are being used to detect and identify these pathogens. This paper highlights the brief outlines of traditional detection methods and discusses recent PCR-based techniques being used in detection of these pathogens. The results will show the comparison of methods that have been studied, in order to recommend rapid, sensitive and accurate methods for detection and identification of several soil-borne pathogens affecting vegetables. Therefore, this study is increasingly important for managing and control of soil-borne vegetable diseases.

Key words: *soil-borne pathogens, comparison, detection techniques, PCR, vegetable crops*

Introduction

Vegetable crops represent an important economic segment of the agricultural production worldwide. In 2011, world vegetable production was more than 1 billion tones (FAO, 2013). The production of vegetables, their availability and supply continue to play a major role for the global population. They are important food and highly beneficial for the maintenance of health and prevention from human diseases (Hanif *et al.*, 2006)**.** Although vegetables are susceptible to multiple plant pathogens, soil-borne pathogens present a serious threat in vegetable production. These pathogens are difficult to control because they can survive for long time in the absence of the host crops. The most familiar soil-borne diseases caused by fungal pathogens include *Phytophthora*, *Pythium*, *Sclerotinia*, *Fusarium*, *Rhizoctonia*, *Verticillium.* Among soil-borne pathogens, few diseases are caused by bacterial pathogens, including *Erwinia*, *Rhizomonas*, *Streptomyces*, *Pseudomonas* and *Xanthomonas*. There are very few soil-borne viruses that affect vegetable crops. Viruses generally survive only in the living tissues of the host plants. Indeed, many diseases caused by plant pathogens are difficult to predict, detect and diagnose. In this context, soil creates numerous of barriers to the isolation, detection and identification of soil-borne plant pathogens (Koike *et al.*, 2003). Control of diseases caused by such pathogens usually requires accurate detection, followed by proper identification of the causal organisms. Therefore, preventive measures to avoid planting in contaminated soil are of the highest importance in the context of an integrated approach to control such diseases (Martin *et al.*, 2000; López *et al.*, 2003). As many soil-borne pathogens remain for a long time in the soil, advanced methods of high sensitivity, specificity and reliability are required.

Conventional methods

In the past, conventional methods often rely on identification of disease symptoms, direct isolation in artificial media and laboratory identification by morphology or biochemical tests. In order to perform such techniques was required an experienced and skilled laboratory staff, although, these techniques could lead to problems in identification, incorrect results interpretation, incorrect disease diagnosis and ultimately disease treatments (Atkins and Clark, 2004; Martinelli *et al.*, 2014). In addition, these techniques were time consuming, non-quantitative, prone to contamination or errors and often delay in disease treatments. While conventional techniques are still widely used and are the mainstay of plant pathologists, although molecular approaches are becoming widely available. Therefore, in this review we will focus on the discussion of new molecular techniques which are becoming widely used for the detection and identification of soil-borne pathogens.

Advanced methods

Over the last 30 years, newer techniques have been developed which are being applied in plant pathogen diagnosis. These techniques include: immunological methods, DNA/RNA probe technology and polymerase chain reaction (PCR) (McCartney *et al.*, 2003). Immunological techniques rely on recognition by antibodies of specific antigens either present on the surface of or secreted by the pathogen (Dewey *et al.*, 1997). Immunological methods are available for more rapid presumptive identification, including enzyme-linked immunosorbent assays (ELISA), immunofluorescence colony staining and immuno-strip tests (Hampton *et al.*, 1990; Postnikova *et al.*, 2008). In the recent years, much effort has been devoted to the development of methods for detecting and identifying plant pathogens based on DNA/RNA probe technology and PCR amplification of nucleic acid sequences (Duncan and Torrance, 1992; Martin *et al.*, 2000). The introduction of serological and molecular techniques had a profound impact on plant disease detection and identification.

Results and Discussions

This paper highlights the brief outlines of conventional detection methods and discusses recent molecular techniques which are being used in detection of soil-borne plant pathogens. Table 1 compares detection methods for soil-borne plant pathogens based on their limit of detection, advantages and limitations.

PCR was initially used for highly specific detection of diseases caused by bacteria and viruses (Cai *et al.*, 2014). Moreover, it has been widely used for the detection of soil-borne plant pathogens as well. It is known that PCR depends on the efficacy of DNA extraction and the performance is affected by inhibitors present in the sample assay (Van der Wolf *et al.*, 2001).

Table 1. Comparison of methods for the detection and identification of soil-borne plant pathogens

Techniques	Limit of Detection (CFU/mL)	Advantages	Limitations
PCR	10^3–10^4	High sensitivity, common technology, portable and easy to operate.	Effectiveness is subjected to DNA extraction, inhibitors, polymerase activity and concentration of PCR buffer.
ELISA	10^5–10^6	Low cost, provide quantification and distinguish pathogens taxonomically.	Cross reactions, sometimes lack of specificity and sensitivity.
Conventional techniques	10^7–10^8	Low cost of analysis but sensitivity is not high.	Skilled laboratory staff, low sensitivity, incorrect results, and time consuming.

In addition to the basic PCR technology, advanced PCR methods such as reverse-transcription PCR (RT-PCR) has also been used for plant pathogen identification due to its high sensitivity (López *et al.*, 2003). The greatest advantage of these techniques comparing with conventional diagnostic techniques is the potential to be highly specific. They can distinguish between different plant pathogen species and within a single species (Ward and Adams, 1998). In comparison with conventional methods, molecular methods are relatively fast; results are often possible within one or two days of sampling. They are potentially more reliable than identification of visual symptoms, as they do not rely on the skills needed to distinguish subtle differences in disease symptoms. These techniques have several potential advantages over conventional diagnostic methods in that they are more accurate, they are faster and can be used by personnel with little experience in plant pathology.

Enzyme-linked immunosorbent assay (ELISA) is a popular screening method for identification of diseases based on antibodies and color change in the assay (Fox, 1990). In this method, the target antigens from the plant pathogens are made to specifically bind with antibodies conjugated to an enzyme. The detection can be visualized based on color changes resulting from the interaction between the substrate and the immobilized enzyme (López *et al.*, 2003). ELISA not only gives proof of the presence of a pathogen but is also capable of providing quantification (Cahill, 1999). An advantage of ELISA is that pathogens or a mixture of potential pathogens that may be difficult to distinguish taxonomically can be easily identified using these techniques. The performance of ELISA can be improved greatly with the application of specific monoclonal and recombinant antibodies which are commercially available (López *et al.*, 2001).

Conclusions

In this article we reviewed the conventional techniques and currently existing methods for detection and identification of soil-borne diseases caused by pathogens such as bacteria, viruses and fungi. Based in our study, conventional methods require an experienced and skilled laboratory staff, although these techniques could lead to problems in pathogen identification and incorrect results interpretation. Moreover, these techniques are time consuming, non-quantitative, prone to contamination or errors and often delay in disease treatments. In this review our aim was to compare conventional techniques with advanced methods of pathogen detection. The greatest advantage of molecular techniques comparing with conventional diagnostic methods is the potential to be highly specific. They can

distinguish between different plant pathogen species and within a single species. Molecular techniques are relatively fast, can be performed by personnel with little experience in plant pathology and results are often possible within one or two days of sampling. Although molecular techniques have been used in developed counties, up to date in developing countries such as Kosovo, their application in diagnostic labs has been limited. We do believe that this is about to change in the upcoming years.

POTENTIAL PREDATORS AND PARASITOIDS REGULATING INSECT PESTS OF MAJOR VEGETABLE AND FIELD CROPS IN SUDAN

Abdalla Abdelrahim SATTI

Environment, Natural Resources and Desertification Research Institute, National Centre for Research, P.O. Box 6096, Khartoum, Sudan

Abstract

Natural enemies are one of the main biotic factors restrained unlimited population buildup of agricultural pests under field conditions. They include predators, parasites and entomopathogens, which normally contribute to natural control that keeps equilibrium of pests below the economic injury level. Hence, exploitation of these enemies in biocontrol through various ways constitutes one of the major components of integrated pest management worldwide. This is important in alleviating the burden imposed by irrational applications of synthetic pesticides on the environment. The Sudan which encompasses various ecological situations is considered rich in its natural flora and fauna. Large numbers of bio-agents were reported to play important roles in natural control of agricultural pests, particularly in areas where slight or no pesticides are used. This paper highlights the potential predators and parasitoids regulating important insect pests of vegetable and field (legumes, cereals, forage) crops in the country. More than fifty predator and forty parasitoid species were listed. The key promising species were suggested to be stressed in future studies for better exploitation in biological control programs, which support the recent trends towards organic farming.
Keywords: *Biological control, natural control, natural enemies, Sudan.*

Introduction

Natural enemies (predators, parasites & entomopathogens) are one of the main biotic factors restrained unlimited population buildup of agricultural pests (viz. natural pest control). Importation, augmentation or conservation of these enemies (biocontrol) comprises an important component of many Integrated Pest Management (IPM) programs globally. But, with the advent of synthetic insecticides during the last century, the trend of pest control in the world has dramatically changed from natural approaches to adopt chemical approach as the sole measure of control. The application of chemicals was started earlier in Sudan where the DDT was used since 1940s. Thenceforth, different organochlorine, organophosphate, organocarbamate and pyrethroid insecticides were used at different periods for combating various pests. Regrettably, the extensive usage of synthetic pesticides has affected the natural enemies negatively (James, 2003; Williams and Price, 2004; Herrera, 1986a). As a result, scientists resorted again to pesticidal alternatives, among which natural enemies were stressed as potential tools in ecologically sound IPM programs.

The Sudan is chiefly an agricultural country which grows several crops for local consumption and export. Sorghum, millet, maize and wheat are the main cereals grown besides leguminous crops, while alfalfa (Lucerne) and Sorghum (Abu-Sabeen) are the important forage grown. Ordinary vegetable crops (e.g. okra, tomato, potato, eggplant, cucurbits, onion, etc) are cultivated in everywhere. However, before the era of pesticide application natural enemies were the major suppressing factors for most agricultural pests. In the Gezira scheme, central Sudan, for instance, more than 200 species of insect and spider predators were said to be found on cotton alone before 1940s (the time when chemical control was started), but less than quarter of that number was hardly detected at the end of the 20th century.

However, the adoption of an IPM program on cotton during the last century proved that the natural enemies prevailing in the Gezira area are capable of controlling *Aphis gossypii* and *Bemisia tabaci* to reasonable levels, provided that broad spectrum chemicals are applied judiciously (Abdelrahman and Munir, 1989). Therefore, great interest was arising to study these enemies and to evaluate their real contribution in pests' control. The surveys and studies conducted yet revealed valuable results (Bashir, 1968; Abu Zinid, 1982; El Abjar, 1985; Satti *et al*., 1998; Satti and Nasr, 2004 and Satti and Bilal, 2012).
This paper aimed to review the previous research findings regarding the major predators and parasitoids associated with the prevailing insect pests of vegetable and field crops in Sudan.

General situation overview

Among polyphagous common insect pests attacking most vegetable and field crops in Sudan are; cotton whitefly (*Bemisia tabaci*), cotton aphid (*Aphis gossypii*), cotton jassid (*Jacobiasca lybica*), cotton thrips (*Thrips tabaci*) and the agromyzid serpentine leaf miners (*Liriomyza* spp.). Various aphids such as cowpea aphid (*Aphis craccivora*) and other thrips, *Caliothrips* spp., generally attack leguminous (e.g. alfalfa) and other crops. Lepidopterous borers like *Earias* spp. mainly attack okra crop, and *Helicoverpa armigera* is a pest of tomato and different legumes. The mentioned pest species and some bollworms are important pests of cotton. Moreover, species of fruit flies (e.g., *Dacus* spp.) are major pests of cucurbits, and tingid bugs for eggplant. Among cereal pests, some aphid species and two lepidopterous stem borers, *Chilo partellus* (spotted stem borer) and S*esamia cretia* (pink stem borer), are the major pests of sorghum and maize. Although, *Helicoverpa armigera* (African bollworm) was reported as minor pest, Kranz *et al*. (1977) emphasized its potentiality as important pest.
The above mentioned pests have natural enemies in common, but specific bio-agents for some closely related pests are also found. Although, research studies on natural enemies in Sudan are sporadically performed, the results reported yet are really fascinating. Most studies were performed on cotton as the important economic crop for the country during the last century. Large number of predator and parasitoid (> 200) species were reported to be found in the Gezira cotton before the era of insecticides usage, but such enemies were drastically reduced thereafter as a result of wide scale spraying of broad spectrum chemicals (after the mid of the 20^{th} century). Earlier studies showed 140 species of natural enemies in 26 families, whereas subsequent research confirmed only 30 species in 17 families (Herrera, 1986b). Fortunately, the IPM program adopted during last decades of the past century has proved that the prevalent natural enemies in the Gezira area are capable of suppressing a number of cotton pests, particularly *Bemisia tabaci* and *Aphis gossypii*, at desirable levels if spraying of insecticides is delayed during the first phase of the cotton growing season (Abdelrahman and Munir, 1989). This encourages research interests on natural enemies, where several crops other than cotton were investigated, though more efforts are still needed. However, studies conducted at different parts of the country proved the richness of local habitats with diversified natural enemies, some of which seemed to be of potential importance.

Predatory species

The important predators reported to be associated with insect pests of most vegetable and field crops in the country are shown in Table (1). Such predators were arranged in the table according to their order and family, scientific names and key prey pests in addition to selected references. Most of these predators were reported from central States including Gezira, Sennar, White Nile, Gedarif and Khartoum (Dabrowski, 1997; Satti *et al*., 1998, and Satti and Nasr, 2004). For example, Satti and Nasr (2004) reviewed more than 40 species of predators belonging to 18 families of insects and spiders to be found in Khartoum State. Moreover, recent studies also manifested the occurrence of large number of predators even in the

northern dryer parts, but largely around the Nile River. Since insecticides are very rarely practiced in that region, numerous species of natural enemies were found flourishing on Table (1). The common predators attacking insect pests of vegetable and field crops in Sudan.

different crops. For instance, at El-Gorair scheme in Merowe Locality, Northern State, a total of 14 predatory species in 7 families were merely recorded from okra fields (Bilal and Satti, 2012). In such area, some crops like lucerne and date palms which found all the year round were detected as unique habitats in sustaining various predators, particularly during hot summer months when other crops are scarcely found. However, the importance of the recorded generalized predators in ecological pests' control was emphasized in various fields (Herrera, 1986a; Abdalla and Beije, 1997; Satti *et al*., 1998, and Satti and Bilal, 2012).

The important predators found associated with cereal pests may include; spiders (different species), *Chrysoperla carnea*, coccinellids (mainly *Hippodamia variegata*, *Coccinella undecimpunctata*, *Cydonia vicina* and *Scymnus* spp.) and *Campylomma* spp., the latter bug was detected as potential predator of aphids and eggs of *Helicoverpa armigera* showing its peak between September and December. All the previous predators were also found on cotton, vegetables, weeds (e.g., *Abutilon* spp.) and forage crops like alfalfa (Satti *et al*., 1998; Mahla, 2002, and Satti and Bilal, 2012). However, as explained in table 1, the important predators prevailing in most parts of the country are members of coccinellids, chrysopids, syrphids, mantids and spiders. They attack pests from different orders (e.g., Hemiptera, Thysanoptera and Lepidoptera). Among such listed species, *H. variegata* and *C. carnea* showed their wide distribution and highest abundance all the year round as key bio-agents for various pests, particularly aphids and whiteflies. On the other hand, *C. carnea* and spiders were potent enemies of tingid bugs and lepidopterous insects. This suggests the importance of the two predators in regulating these pests on various crops. These predators should receive great attention to enhance their role in pest management programs.

Important parasitoids

Regarding the parasitoids, table (2) listed the most important species associated with pests of vegetable and field crops. The whitefly seems to be fairly controlled with two parasitoids (viz., *Encarsia lutea* and *Eretmocerus mundus*), especially in areas of low pesticidal usage. These two species were encountered throughout the year on different host plants, hence, they were recommended for further studies to be utilized efficiently in biocontrol. Similarly, a number of larval-larval and larval-pupal parasitoids were reported to attack leaf miners (*Liriomyza* spp.) at variable levels on various crops as well as on different wild plants. Some of these parasitoids were found to exert high levels of parasitism on *Liriomyza* larvae attacking economic vegetable and field crops like cotton, okra, beans, peas, cucurbits, solanaceous crops and others. So, they reflect high potentiality to be tested for the biocontrol of these devastating pests. However, parasitism on leaf miners was found to be higher at Dongola area in northern Sudan (may reach > 81%) than at the Gezira area, which attributed to very limited insecticides usage in the former region (Ibrahim *et al*., 2004).

Parasites reported for *Chilo partellus* are; *Vipio deesae* and *Euvipio* sp. as larval parasites, and *Hyperchalcidia soudanensis*, and *Pediobius* sp. as pupal parasites. On the other hand, the egg parasite, *Platytelenomus hylas*; the larval parasites, *Apanteles ruficrus*, *Apanteles sesamiae* and *Bracon brevicornis*, and the pupal parasites, *Brachymeria sesamiae* and *Pediobius furvus*, were recorded for *Sesamia cretica*. However, nine parasitic insects were recorded for *Helicoverpa armigera* (Schmutterer, 1969; Balla, 1986, and Kranz *et al*., 1997), a major pest

of various crops in the Gezira area. A recent study in Khartoum State showed a number of parasites on the three previous pests, with the highest parasitism (> 62%) being recorded on *H. armigera* by *Apanteles* sp. (Satti, 2007). The latter parasite and spiders' predators were the dominant bioagents in this area. However, in agricultural schemes of central Sudan (e.g., New Halfa) *Diplazon laetatorius* and tachinid flies *Tachina* sp. are the dominant parasitoids on *H. armigera* (Mohamed, 2011). Winter season manifested higher impact of natural enemies on these pests than the other seasons.

Table (2). The important parasitoids attacking most insect pests of vegetable and field crops in Sudan.

In spite of what have been mentioned regarding those abundant natural enemies, no recent studies are found considering biological control of economic pests in the country. The indigenous natural enemies reported yet for most insects are so encouraging to continue forward in studying their potential role in IPM, particularly those of aphids, whiteflies, African bollworm and cereal pests like stem borers. In contrast, it is clear that some economic pests like jassids (*Jacobiasca lybica*), flea beetles and some other major pests have no promising parasitoids known. Therefore, Kleks and van Lenteren (1991) who reviewed the situation of jassids recommended that the role of local natural enemies in controlling *J. lybica* should be clarified firstly before attempting introduction of any natural enemies to the country. Nevertheless, they suggested *Anagrus atomus* as the most promising parasitoid to be considered for importation. Also, a number of parasitoids listed in the table were reared from different pests, but they lack sufficient investigations to understand their real contribution in natural control. More research is needed to cover the various bio-ecological aspects of such enemies and to evaluate their importance in combating different pests.

Conclusion

Abundant predators and parasitoids of agricultural pests are found in Sudan. Some species showed potential role in combating certain major insect pests like aphids, whiteflies, tingid bugs, leaf miners, bollworms (particularly *Helicoverpa armigera*) and cereal stem borers. Areas of higher pesticide application showed apparent negative impact on the populations of natural enemies. However, most of the recorded species lack sufficient evaluation regarding their potential role in pest control. Hence, the paper stressed the importance of studying these bio-agents for better exploitation in integrated pest management.

COMPOSITION ANALYSIS OF THE SELECTED FOOD SUPPLEMENTS

Małgorzata SKARBEK

Wroclaw University of Environmental and Life Sciences, Students Scientific Society of Market Analysis, Institute of Economics and Social Sciences, Poland
*Corresponding author: skarbek.gosia@gmail.com

Abstract

Rapid pace of life, exposure to stress and diet based on highly processed foods, make people want to enrich their food by appropriate supplementation. For this reason in many highly developed countries (also in Poland), dietary supplements market is developing very dynamical and it is mostly powered by non-pharmacy sales. There are no specific regulations on the components of dietary supplements other than vitamins and minerals it makes the market for these products is characterized by considerable diversity. We often hear of undervalued quality dietary supplements. Particularly big problem with maintaining quality supplements are extracts from plants. In this study author described the results of own research on composition of supplements containing omega-3 fatty acids and supplements containing extract of Ginkgo biloba. In first group of analyzed products the content of EPA was mostly in line with the declaration of the manufacturer and pharmacological requirements were fulfilled. (quality, safety and effectiveness of use) The fatty acids of the dietary supplements transfer into methyl esters (FAME) and analyzed by using gas chromatography (GC). The analysis was made in triplicate. In case of supplements with extract of Ginkgo biloba, some products had correct level of standard extracts of Ginkgo biloba and had fulfilled pharmacological requirements. But in this group were also products with too low amount of standard extracts and elevated ginkgolic acids (this is potentially toxic substance for human).
Keywords: *food supplement, dietary supplements, omega-3, plant's extracts, Ginkgo biloba*.

Introduction

Dietary supplements market in Poland is developing very dynamically and it can be bought not only in pharmacies, but also in supermarkets, drug stores, what makes go up the sale of these preparations. Last year society in Poland spent on them more than 2.8 billion zł. According to the surveys this amount in upcoming years will grow by 9-10 percent per annum. Dietary supplements are mostly foodstuffs that are intended to supplement our diet with vitamins, minerals or other substances having a nutritional. These preparations can be purchased in the form of capsules, dragees, sachets of powder, tablets or ampoules with liquids and other similar liquid forms and powders designed to be eaten in small, measured unit quantities, excluding products which have the properties of a medicial product within the meaning of pharmaceutical legislation (Dz. U. 2010. No. 136, pos. 914 as amended). (Krasnowska and Sikora, 2011) Chief Sanitary Inspector in Poland is in charge of a supervision of dietary supplements. The introduction of these products on the market requires less research and fewer demands than in the case of drugs. So why so many people are willing to use for these products? All of this is caused by because magic of the advertisements, in which producers have taken care of the supplements to be associated more with medicine, which can easily, cheaply and quickly improve our health. According to the Regulation of the Minister of Health from 2007 supplements may include vitamins or nutrients, but also other additional substances that do not always have a positive effect on our body and are not strictly specified by pharmaceutical law. According to a European Commission report the number of substances used in the manufacture of food supplements is approx. 400 from this amount as

50 percent of the market of these formulations in the European Union are the vitamins and minerals.

Materials and methods

In 2014, as a part of scientific extra classes OrgChem author had performed 7 months analysis of the composition of dietary supplements with contains omega- 3. In research author used not only dietary supplements containing omega- 3 for adults but also for children and pregnant women. Work was performed with 15 different products, which were the main source of fish oil, fish oil and algae. The names of supplements that are used for testing are 1 Möller 's Tran Omega-3 DHA Biovilon 2. 3. Lupicol DHA, 4. Olympus Gold Omega -3, Omega -3 5. mite, 6. Omegamed Pregna DHA, 7. Pregna 250 DHA, 8. Prenatal DHA from algae, 9. Rekinal, 10. Tran, 11. Omega -3 Forte, 12. Ecomer, 13. Olimp Gold Omega 3 Forte, 14. Omega -3 Platinum, 15. Doppel Herz activ mama. The fatty acids of the dietary supplements transfer into methyl esters (FAME) and analyzed by using gas chromatography (GC). The analysis was made in triplicate. The results of the research conducted on Gingo biloba have been taken from the literature.

Results and discussion

Omega-3 and omega-6 are polyunsaturated essential fatty acids (WNNKT). They are not synthesized by the human body and thus must be supplied in the diet. The ratio of omega-3 to omega-6 should be 1:2 or 1:5. Omega-3 acids are: alpha-linolenic acid (ALA), eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Shahidi and Wanasundara, 1998). The human body is able to change linolenic acid into EPA and DHA. The first of these acids is rooted in flaxseed, hazelnuts, rapeseed oil and soy. In contrast acids DHA and EPA are mainly found in fish, seafood, as well as algae. The greatest amount of omega-3 is located in salmon (1.2 g / 100j of the product) (Breivik, 2012). In order to ensure proper absorption of polyunsaturated fatty acids ingestion should be accompanied by vitamin E, which is a natural antioxidant (Kolanowski, 2007). Diet has a huge impact on human health. Cardiovascular diseases are the leading cause of death in many countries. Reducing the consumption of saturated fatty acids and an increase in polyunsaturated is an effective way to reduce cholesterol levels in the blood. Consuming omega-3 has anti-atherosclerotic effect, anti-cancer effect, limits the development of diabetes type 2, regulate lipid metabolism and have a positive effect on the condition of skin that becomes more moist and supple. Moreover, DHA is essential for the proper development of the brain and retina (Falinska and Bascoul-Colombo, 2012).

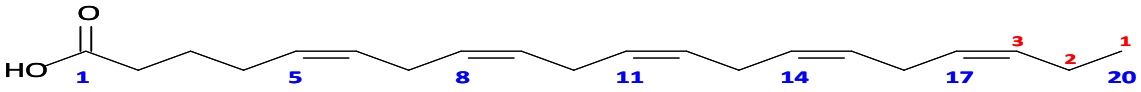

Figure.1. Docosahexaenoic acid.

Figure.2. Eicosapentaenoic acid.

Consumers are increasingly turning to supplements, which may provide them with the right amount of omega- 3 because fish from unknown sources contain increased amounts of heavy metals such as lead and mercury. Also, pregnant women decide to supplement the diet with these acids to prevent retinopathy of premature of in babies and to ensure proper brain development in children (Siddiqui and Zerouga, 2006; Anna Walczewska and Tomasz Stępień, 2011).

Test results for DHA. The analysis results were quite surprising. None of the supplements contained the declared content of the acid. In most cases, the manufacturer stated the higher amount, so the client received gratis from producer. Only in a few cases the content was lower than the under stated the amount of, we were deceived, and the manufacturer took a given amount of product. Most additional component in the form of DHA is in products: 2. Biovion DHA DHA 6. Omegamed Pregna and 7 Pregna 250 DHA, are products for supplementation of pregnant women and children under 6 years of age. However, in products: 8 Prenatal DHA from algae, Ecomer 12 and 14. Omega-3 Platinum most of the acid was stolen. It may also result from the fact that the sources of these supplements are mainly sea algae containing small amounts of DHA. In other cases, the deviation was within the normal range.

Figure 3. Check the manufacturer’s assurances for DHA

The test results for acid EPA. For the EPA acid is the same analysis as for DHA was performed. According to the data given on the packages in three formulations: 3.Lupicol DHA DHA 6.Omegamed Pregna, 7. Pregna 250 DHA EPA does not exist, as confirmed by analysis. These preparations are meant to be for pregnant women and for children under 6 years of age. The biggest surprise was for the preparation 12. Ecomer because analysis showed a trace amount of acid in the preparation. Understated ingredient content was also observed in formulations such as: 1. Möller 's Tran Omega -3, 8 Prenatal DHA from algae and 14. Omega -3 Platinum. The two latter products also contain DHA acid content understated . We may be given some gratises when buying producks: 2. Biovion DHA, 4. Olimp Gold Omega -3 and 13. Olimp Gold Omega 3 Forte .

Research on nutritional supplements containing Japanese ginkgo biloba were made by scientists from the University of Life Sciences in Poznan. It has been tested as many as 11 of ginkgo biloba preparations. Main active compounds and toxic compounds were determined in these foodstuffs. The research included qualitative analysis and determinated the content of flavonoid compounds, and terpene lactones ginkgolic acids. After hydrolysis, the content of flavonoids formulations was similar to the declarations of manufacturers as well as to the requirements of the pharmacopoeias. Only in four products the content of quercetin and kaempferol (flavonoids) coincide with the data on the packaging, in other supplements the amount of quercetin was higher and the amount of kaempferol was lower, which indicates that the supplements do not contain the full value of ginkgo leaf extract. However, high levels of acids tested ginkolie in 4 dietary supplements (in one case the standard has been exceeded 1,600 times) may result from the use of of non-standardized extracts in production. Increased amount of ginkgolic acid content is considered potentially toxic.

Dietary supplements containing vitamins, minerals, fatty acids, amino acids, probiotics and prebiotics, of course, we can take in moderate doses , in states of increased demand. Instead, we must be careful with products containing vegetable raw materials outside Europe. They contain substances of different from those used traditionally in our latitude. These plants grow in different soils, are used among the population, which otherwise he eats, it has a different metabolism. What for people in Asia or South America is good can be devastating for us. According to the EFSA guidance, supplements containing plant materials previously not used as food or used for other purposes, shall undergo examinations proving the safety of their use. According to the law, for the safety of supplements is the responsibility of the manufacturer. This is a large pharmaceutical company that has implemented GMP system, we can assume that the product is of sufficient quality. But if you do not know anything about the manufacturer, it is such certainty we no longer have.

Conclusion

Dietary supplement, as the name suggests aren’t a medicinal product. It can be helpful in addition to certain missing elements or vitamins in the body, but must be used in moderation and preferably under the supervision of a specialist - a doctor or pharmacist. Given the abundance of available, often contradictory information on dietary supplements, patients need help in getting to reliable sources about dietary supplements and proper nutrition. Analyzing the content of dietary supplements can be assumed that they do not meet the requirements of

the manufacturer. Often the component that is less expensive or more easily extracted is present in greater amounts / concentrations in the product. Given the supplements on the package does not match the actual composition after analysis.

THREE SUCCESSIVE TIMELY WORK MASKED GENES SAVING OF VIRULIFEROUS INSECTS AND COORDINATED WITH ZYMV RESISTANCE GENE IN SQUASH.

Abdulbasit A. AL JANABI

Ministry of Science and Technology, Agriculture Research Office, P.O.Box765 Baghdad, Iraq
*Corresponding author: abd_lbasit@yahoo.com

Abstract

Binary and ternary hybridization among three pure lines previously isolated having different kinds of white silvery colors were done to know how the saving genes of *Zucchini Yellow Mosaic Potyvirus* (ZYMV) viruliferous insect will react with each other's, and to compare some new parameters of different genes included genotype. Characters efficiency (a ratio between the saving period and the character appearance period) measuring revealed that they were 92.8, 94.4, 76.6%, for the full leaf silvery color, netty white, white spotted respectively, and for all characters jointly was 63.3%. The Saving period (summation of the lasting days of the genotype first infection after control and the number of days of full infection dissemination in the genotype unite) of pure lines, binary and ternary hybrids were also estimated. Results were 13.0-20.0, 25.0-29.0, and 39.0 days respectively. The Saving degree (a ratio of the different between the saving period of the genotype and the dissemination period in control to the saving period of the genotype) was 0.46 - 0.65, 0.70 – 0.75, and 0.79 The Saving efficiency (the saving degree multiplied by the character constant) was 46.0 – 65.0, 70.0 – 75.0, and, and 79.0%.There were an interaction and operation sequences of the three characters appearance (the previous covered or masked the post), where the beginning with full leaf silvery color followed by netty white and then white spot. More over in quaternary hybrid that has three of saving genes (characters) and one of ZYMV resistant. Resistance degree (the different between the highest resistance degree (1.0) and the genotype infection degree) was 0.83. The Resistance efficiency (the resistance degree related to 100%) was 83%. Protection efficiency (summation of saving efficiency and resistance efficiency related to 200) was 182/200.

Key words: *Vegetable breeding, plant virus resistance, masked gene, squash leaf coloration.*

Introduction

Zucchini yellow mosaic Potyvirus (ZYMV) causes considerable losses of cucurbitaceous vegetables grown nearly all over the world; indeed, the commonly planted cultivars are highly susceptible to ZYMV (Svoboda et al., 2013). Genetic resistance is the best manner to control viruses especially that of insect transmitting. Aphid transmitted many viruses infected squash (*Cucurbita spp*) (Boyhan, 1999; Davis and Shifriss, 1983; Shiffriss, 1981; Shiffriss, 1982; Smith et al., 1964) causing 100% high severity infection and high yield losses most times. Insecticide controlling of virus victor commonly is not effective manner to reduce virus infections (Boyhan, 1999). Reflective mulches have been used to reduce plant insect visitations and so virus infections (Hrpaz, 1982; Kring, 1964; Kring, 1969; Kring, 1969; Moore et al., 1972; Wyman et al., 1979), but it is expensive, difficult to apply, and mostly be ineffective when plants cover the ground surface or in state of the vector pressure is too high (Davis and Shifriss, 1983). In the same way white silvery leaf coloration of squash have been shown to reflect light and so it alter aphid flight activities and repel them, or reduce the attractiveness of the landing site (Davis and Shifriss, 1983; Shiffriss, 1981; Shiffriss, 1982).

Squash leaf coloration is a compound character appears in several forms for limited periods. They may interact with each other shortly. They have a role of saving squash plants of virus vectors insect. They differs in their density, size or power of expression depending on genotype, environment factors (sun solar intensity, temperature, and relative humidity), or they affect by the insect pressure and injury severity (Davis and Shifriss, 1983; Shiffriss, 1981; Shiffriss, 1982).

In fact the saving or resistance traits be in different levels, but there were not grades express by accurately reflect degrees of resistance or saving to differentiate characters within one genotype or one character among different genotypes. So needing arose to use precise measurements and developed a new mathematical relations to compare different aspects of coloration saving, or resistance to ZYMV in one or different genotypes by giving every coloration shape the degree or ratio of saving or resistance extremely, and to get the real saving or resistance efficiency in each genotype, or to compare resistance strains or hybrids included than that free, or any other breeds or varieties possess some level of resistance or to evaluate the performance of any material against any disease.

Material and Method

Four strains of squash different form coloration, full silver leaf 2020A, netty white 2020B, white spotted 2020C, and control free of coloration (full green leaf) 2020D, also binary, ternary hybrids among these lines, and quaternary with ZYMV resistance strain were planted in rows of 5m length, distance between one and another 2 m, and 0.75 m between the plant and the last, with three replications, in three sites within 5 km between site and another, according to randomized complete block design. Plants in each replicate were left for natural infection from sensitive squash plants that were mechanically infected by ZYMV in transverse lines of 4m long at a distance 5m on top of each replicate as a source of infection by insects of peach green aphid (*Myzus persicea*) that were put and left to proliferate on each plant. These insect were previously tested to their free of any virus by put on susceptible squash plant. To see the indirect impact of the presence of each shape of coloration to delay the initial infection and the naturally dissemination of ZYMV in the field, the period from the appearance of each character of coloration to disappearance were recorded, as well as from begin of the initial infection to complete distribution on plants of each strain in each duplicate. Saving period, Saving degree, Saving efficiency, and Health yield percent for each coloration form in each line separately, and in binary, ternary crosses of these genotypes, more over to correct comparison between the coloration forms in different genotypes, in addition to extract the real values of these parameters it has developed a new mathematical relation as following:

Character constant (Character efficiency) = $\frac{Character\ saving\ period}{Character\ appearance\ period\ mean} \times 100\%$

Control lasting period = $No.of\ days\ to\ first\ infection + No.of\ days\ to\ full\ infection\ dissimination$

Genotype saving period = $No.of\ days\ to\ first\ infection\ after\ control + No.of\ days\ to\ full\ infection\ dissimination$

Genotype saving degree = $\frac{genotype\ saving\ period - control\ lasting\ period}{genotype\ saving\ period}$

Genotype saving efficiency = $saving\ degree \times character\ constant$

Health yield percent = $\frac{Health\ yield}{Total\ yield} \times 100\% = \frac{period\ of\ health\ yield}{period\ of\ total\ yield} \times 100\% = \frac{yield\ savig\ period}{period\ of\ total\ yield} \times 100\%$

As well as in quaternary hybrid of the three coloration form with the resistant strain, disease severity was divided into the following grads of disease scale: 0 = No symptoms of injury, 1= leaf mottle or mosaic, 3= complete yellow mosaic and blisters on leaves and fruits, 4= leaf curl or simple deformation of leaf and fruit, 5= leaves turning into high strings or strong leaves and fruit deformation. Infection degree, resistance degree, resistance efficiency, and prevention efficiency, were calculated by used the following relations:

$$Genotype\ infection\ degree = \frac{\max grade\ of the\ genotype\ infection}{No.of\ grades\ of disease\ scale}$$

$$Genotype\ resistanc\ degree = Absulute\ degree\ of\ resistance - Genotype\ infectio\ degree$$
$$= 1 - \ Genotype\ infectio\ degree$$

Genotype Resistance efficiency $= resistance\ degree \times 100\%$

$$\text{Prevention efficiency } = \frac{saving\ degree \times 100\% \ + resistance\ degree \times 100\%}{200}$$

Results and discussion

The white silvery coloration traits of squash leaves have been separated into three different forms pure line in a previous study (Fig 1). Results of appearance of each form individually or upon entry into different hybrids (Table 1) revealed that these periods were differed from one format to another; as they have ranged between 8.2-41.0 days in pure lines, and the longest visible was spotted white. In hybrids appearing periods were doubled by adding period of any shape to the others interred with it in the hybrid, where in binary hybrids has increased to range between 20.0 - 69.0 days, and the longest period was the hybrid (netty white × spotted white) for collect two coloration forms entrants in it, and have increased more in ternary hybrids to 35.4 - 83.7 days for periods of three forms gathered together. That's mean as the greater the number of formats increased in the genotype the appearance period increased of being appeared in sequence and not in the same time. This represents the max aim of the collection of shapes in hybrids.

Fig (1) Different squash leaf coloration form and their short interference through sequential appearance in hybrids.

But although the appearance periods have increased in these hybrids approximately to the age of plant that of 100 days, the real periods of saving represented by the initial infection lasting and periods of infection dissemination did not exceed in the maximum, but only to the half age of plant or two third of productivity period almost, where the Initial infection lasting periods (Fig 2) has ranged in the pure lines 7.0 -11.0 days and the best was in the hybrid (netty white × spotted white), and more increased in ternary hybrids to 15.0 days, as well as of infection dissemination periods in experimental units ranging in the pure lines of the coloration forms between 7-13 days and the highest being spotted white, and in binary hybrids between 15-18 days and the best was (netty white × spotted white) as well, and arrived in ternary hybrids to 24 days. This has served the saving periods to increase from 13-20 days in the pure lines and 24-29 in the binary hybrids and to 39 days in ternary hybrids.

Table 1. Relation of character, saving, prevention efficiency, and health yield ratio with the appearance and saving period

Genotype coloration	Period of Character appearance (day)	Period of first infection lasting (day)	Period of Disease Dissemination (day)	Saving (lasting) period (day)	Character Constant %	Saving Degree	Saving Efficiency %	Prevention Efficiency /200	Health yield %
No coloration (Control)	0.0	4.0	3.0	7.0	0.0	0.0	0.0	0.0	0.0
Full silver leaf	8.2 – 20.2	6.0	7.0	13.0	92.8	0.46	46.0	46.0	25.0
Netty white	10.0 – 26.0	9.0	8.0	17.0	94.4	0.58	58.0	58.0	28.3
White spotted	11.2 – 41.0	7.0	13.0	20.0	76.6	0.65	65.0	65.0 .	33.0
Binary hybrid: Silver Full leaf ×netty white	20.0 – 49.2	10.0	15.0	25.0	84.1	0.70	70.0	70.0	42.0
Binary hybrid: netty white ×white spotted	23.2 – 69.0	11.0	18.0	29.0	64.1	0.75	75.0	75.0	48.0
Ternary hybrid:netty white × white spotted×Silver Full leaf	35.4 – 87.8	15.0	24.0	39.0	63.3	0.79	79.0	79.0	65.0
Quaternary hybrid:nettywhite × white ×spotted×SilverFullf×resistant	29.4 – 87.8	15.0	24.0	39.0	63.3	0.79	79.0	182.0	100.0

Every number in table represents the average of three replicates in three sites.

There was a difference between the appearance and the real saving period belong to more than reason, since the appearance period the longer the greater chance of injury, and the insects may discover its secret if the period elongated and not feared, so the change in the form of characters collected in hybrids (as it sequence changes from one form to another through a time organizer of the work of controlling genes) is one of the necessities of sustaining its impact in order to not easily discover by insects and be less efficiency, In addition, each form or character have a functioning efficient of their own (ratio between the saving period and the appearance period), which descended up appearing period in the pure lines, where the highest being the efficiency of the netty white that appears as a net, so insects might saw as a spider net and so repel from it and that raising its saving efficiency to 94.4%, then the full silver which might seemed like reflective mulches coated in silver, which was found that it alienated insects and delayed their visit to the plant (2, 4, 7, 9, 10) and thus its efficiency reached 92.8%, then the white spotted that appears as bright spots which might cluttered vision in front of the insects and did not saw the green color of the leaves clearly or it alter the flight behavior of aphids as (Kring, 1972) was found , but its efficiency had declined to 76.6% for the length of its appearance, as well as in hybrid the best efficiency was the binary hybrid (full silver × netty white), amounting to 84.1% because it combines two competent forms, and

it had dropped to 63.3% in the ternary hybrid (netty white × white spotted × full silver) for being the longest appearance period. The saving efficiency from virus vectors insect injury (which represents the degree of saving multiplied the character efficiency) has also varied depending on the form of increase coloration. The character efficiency was on the contrary has increased with the appearance to range between 46.0 - 65% in pure lines and the white spotted was the best because it was the longest period, and increased in hybrids to range between 70.0 -79.0 % and the best was the ternary hybrid (netty white × white spotted × full silver) because of its longer appearance.

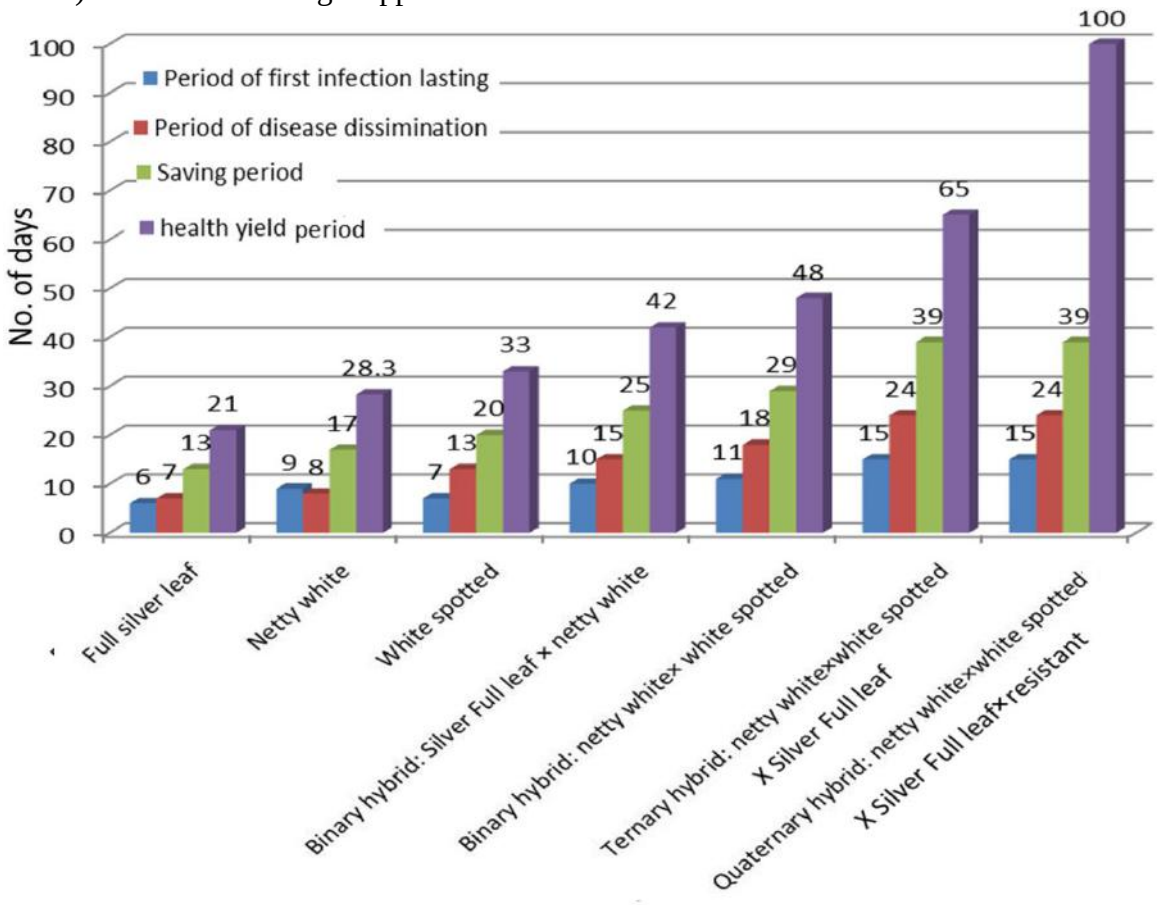

Fig .2. Periods of lasting, dissemination, saving of infection and health yield in different coloration form and their increasing with the number of form in hybrids

These ratios of efficiency of characters and saving reduce the efficiency of saving and therefore the period of saving if they were less than the maximum value 100%. Beside that there was a natural delay period to infect comparative plants deducted from saving period to obtain the real value of saving of each coloration form resulting in reduced appearance period and so saving degree and thus the saving efficiency of the form. It is clear from these results that the more time appearing the less character efficiency, but on the contrary, the saving efficiency has increased up period to appear. This reflected on the rate of health fruiting production in pure lines and hybrids (except quaternary hybrid) ranging between 25% to 65%, or between a quarter and two-thirds of the total yield or overall productivity period amounting to 60 days approximately, while the saving period has ranged between 13.0 to 39.0 days, which also covered a quarter to two-thirds of the overall productivity period, that if the injury coming agree with the beginning of the fruiting production and not before or after (this little obtain) and saving efficiency must be of 100%, but this efficiency has been ranged between 46.0 to 79.0%. In other words there was a decrease in the saving period of approximately one fifth to half, though, the health production period have increased and surpassed the real saving

period as there was an increase not decrease in saving period that covering the time difference between the two periods. This increase in the period of health production due to that the symptoms of injury not seen on fruits or the fruits were not deformed immediately after the plant injury, and might late for few days more than a week. Therefore, the real values of the saving period, degree and efficiency, or periods of health production of every coloration form in pure lines and hybrids were calculated to avoid these differences.

It can be seen from the foregoing that although of the extension of saving periods to the end of plant life through hybridization between pure lines of the coloration forms, but the low efficiency of characters and saving prevented access of the plant saving from insect injury throughout their life, especially through the intensification of virus infection or increase the density of viruleferose insect or appropriate environmental conditions for both as (Shiffriss, 1981, 1982) found , so to reach this object it has remained the needing to resistance strains to enter with saving strains, and that what has been done in quaternary hybrid (netty white × white spotted × full silver × resistant strain), which included three coloration forms plus resistant strain, that has a resistance efficiency of 83.0%. Thus the overall efficiency of this hybrid or the prevention efficiency as we called that combines the saving efficiency and resistance efficiency becoming 182\200, so they complete each other, whereas this resistance gene does not function but only when the existence of virus infection, where this strain induced resistance lead to healing plants shortly after the injury, but when injury repeated in frequent intervals, it prolongs the recovery period, and leading to symptom appearance on fruits, however, the presence of saving with resistance characters reduce insect injury repeating, a result that led to save plant from virus infection throughout the period of their life, except a short period between their infection and recovery, however the fruits remained intact 100% through the production period for non-injury symptoms appearance. This was a very major cognitive to collect genes of saving or resistance, or both in the construction of a hierarchy of resistance to plant diseases.

Conclusion

Appearance period of various coloration shape of leaves in squash differed from one format to another in pure lines and in their hybrids, the work of coloration character was marked with several properties by existence with some others in hybrids, notably the independence of the controlling genes, where the shape or character has independently appeared and every form, including kept a period of appearances own it took a solo in pure lines, where the appearance of each form were not affected by the existence of others such in the hybrids, on the contrary appearing periods were doubled by adding the period of each format to the other interred with it in this hybrid, as well as the sequencing appearance of forms, where there have been a succession appearance of coloration form and did not all appear at once, and a constant succession started its with full silver, then netty white, and then spotted white. Moreover there was a coordination between the controlling genes of traits as if organized chronologically or sensor controlling them and works to stimulate the appearance of following form shortly before disappearance of its predecessor, or as if the concentration of the stimulator is controlling this process which is which stimulates specific character appearance sequentially and constantly with its predecessor, as well as having a short interference between characters, where the character appear after a brief overlap with that preceded it, as well as with that followed. In other meaning that these traits covering each other for a short time according to the appearing sequence, where the full silver covers netty white, and netty white covers the white spotted, and this added for every two sequential coloration forms an extra period of survival ranged between 2-3 days as a period of overlap between them. This had been got benefit by the communication between coloration characters, and not gets a time gap between two sequential forms appearance that may allow access injury of virus vector insects. That

may explain that the genes had worked independently and continuously. More over these features have been obtained with economy of energy, where the genes controlling these traits did not work at the same time but only for a short period interfere of sequential characters, and if they work together that would costs plant cells extra energy without added benefit, whereas the characters would covering some others, appear one and disappear two with three character energy consumption, this did not happened and the characters appeared one after one, and so got benefit by the extension of character appearance periods longer durations and so lengthened the term of saving in hybrids. More over the sequential changes of shapes prevent their secret to be discovered by insects, and those utmost to be of hybridization, otherwise that are considerably less saving and efficiency of this process.

Abstract

Herbicide application in some cases could lead to plant damage and yield loss. This problem is especially often in maize seed crop. In Serbia, herbicides are not registered for use in maize inbred lines. So, safe herbicide application requires maize lines sensitivity testing. The aim of this study was to test five maize inbred lines to sulfonylurea and triketons herbicides.

Three year experiment on the experimental field of the Maize Research Institute Zemun Polje, Belgrade, Serbia. Rimsulfuron and foramsulfuron as sulfonylureas, as well as mesotrione and topramezone as triketone herbicides were applied in recommended and double dose (dose for hybrid maize). Visual plant demages, plant fresh mass and grain yield were measured. Obtained data was statistically processed by ANOVA and differences between means were tested by LSD test.

Sulfonylurea herbicides caused higher plant damages compared to triketons. Injury symptoms were followed with decrease of fresh matter content, especially 2-3 weeks after herbicide application. Double dose of foramsulfuron in higher percentage decreased fresh matter on three maize lines. Sulfonylureas decreased grain yield in four lines. On the other hand, triketons induced slightly injuries according to first evaluating, while no injury symptoms were recorded during second evaluation. Mesotrione and topramezone did not influence on fresh mass and grain yield of maize lines.

Key words: *maize lines, sulfonylureas, triketons*

Introduction

One of the most profitable activities in agriculture is seed maize production. Every production have negative effects that can limit production. In seed maize one of the most important pests are weeds. Due to homozigous, maize lines often have a smaller hatibus with uneven growth than hybrid maize. Those conditions create a microclimate in seed maize where weeds are best adapted (Stefanovic et al., 2007). If weeds are not controled, higher percentage of grain yield can be lost. Homozygosis of maize linis carries other negativness, like higher susceptibility to various biotic and abiotic factors. Herbicides are first on the list that can negatively effect maize lines (Stefanović et al., 2010). So, on one hand we need to apply herbicides to control weed in maize lines crop, while on the other hand we need to safe apply those herbicides to prevent possible crop demages and injuries. Herbicides in Serbia are not registrated for use in maize seed production, so companies that product seed maize need to test their own genotypes.

Herbicides can negatively effect by growth delay, reduction in plant leaf area, plant height, leaves deformations, and in the worst case by yield loss or totaly plant demages and death. Carvalho et al., (2007) concluded that if plant are able to overcome herbicide application – it is temporary stress, while in case they can not overcome herbicide application – it is permanent stress. Permanent stress is mostly associated with greather plant demages, reducing grain yield or complete plant destruction, where a plant death is occured.

The aim of this study was to test five maize inbred lines to sulfonylurea and triketons herbicides.

Material and Methods

Three year field experiment (2010 – 2012) was set up on chernozem soil type in experimental field of the Maize Research Institute „Zemun Polje“, Serbia (44° 52´ N, 20° 19´ E, 18 asl). Five maize lines, parental components of commercial ZP hybids were tested to rimsulfuron and foramsulfuron as sulfonylureas and mesotrione and topramezone as triketons. Each herbicide was applied in two doses – recommended and double for hybrid maize. Herbicides were applied when maize lines had 5-6 leaves, what is 15-16 leaf stage according to BBCH scale. The four-replicate trial was set up according to split-plot arrangement. The main plots encompassed one 10 m row of each maize line in four replication, while subplots included herbicides and a control – without herbicides application.

Visual plant demages were estimated two times: in period of 2-3 weeks after herbicides application and 2-3 weeks after firts estimation. Visual demages were estimated according EWRC scale (0 - no plant demages and 9 – planth death; Feldfersuche Manual, 1975). For measuring plant fresh matter content, plant samples (four plant per replication) were collected also two times: first in the same period as first visual estimation and second in maize flowering stage. At the end of the vegetation cycle grain yield was estimated and calculated at 14% of moisture. Obtained data was statistically processed by ANOVA and differences between means were tested by LSD test.

Meteorological data for experiment was presented in table 1. In first vegetation cycle weather conditions were good for maize production with good distribution of percipitacion. On the other hand, second and third year had a lower quantity of percipitation with a drought period in third year.

Table 1.Precipitation and average air temperatures for the period April-September

Months	Precipitation (mm)			Temperature (°C)		
	2010	2011	2012	2010	2011	2012
April	44.0	14.9	64.2	13.2	13.4	14.45
May	64.1	89.6	66.4	17.5	16.8	17.9
June	167.3	26.2	17.5	21.0	21.5	24.56
July	35.6	44.0	30.7	23.2	23.3	27.08
August	68.2	66.0	5.8	23.1	23.9	26.21
September	68.0	32.6	26.0	17.6	21.6	22.14
Average	447.2	273.3	210.6	19.3	20.1	22.05

Results and Discussion

All tested lines had higher damages with application of sulfonylurea herbicides. First two lines had moderate to tolerable damages in first visual estimation, while other lines had light to very light demages. In second evaluation only L1 had significant demages with sulfonylureas. Other lines did not had significant demages. Triketones herbicides also did not cause significant damages in both evaluation (table 2). According to Malidža (2007) and Stefanović et al., (2007) introduction of sulfonilurea herbicides have led to lower crop tolerance and higher susceptibility of certain maize lines. In our experiment, first two lines which belong to early maturity group, have been shown as sensitive.

Table 2. Visual damages of maize lines (first and second evaluation)

1st eval.	Herbicides

Fresh matter content varied also only with application of sulfonylureas. First two lines, that had the highes injuries, had significantly lower fresh matter content at all treatments with sulfonylureas. Double dose of foramsulfuron significantly reduce fresh matter content in L3 in first evaluation. Other lines did not have significant reduction with herbicide application, while triketons also did not cause plant fresh matter reduction. Similar results were obtained in second evaluation, where first two lines did not recover from herbicide application. Only recommended dose of rimsulfuron did not cause fresh matter content in L3. Triketons did not cause variation in second evaluation (table 3). Green and Urlich (1994) stated that variation of fresh matter content is a good indicator of maize susceptibility to herbicides. Brankov et al., (2015) stated that application of rimsulfuron and foramsulfuron caused reduction in fresh matter content in maize lines.

Maize grain yield was significantly lower only with sulfonylurea herbicides. First two lines, L1 and L2, at all treatments with sulfonilureas had significantly lower grain yield. Double dose of foramsulfuron decrease grain yiled of L1 down to 60%. Double doses of rimsulfuron and foramsulfuron caused significantly grain yield reduction in L3 and L5. Grain yield of L4 did not vary with herbicide application. On the other hand, mesotrione and topramezone did not affect maize lines grain yield (table 4). Brankov et al., (2012) stated that application of sulfonylurea herbicides cause significant grain yield reduction. Similar results were obtained by Dragičević et al., (2011).

Table 4. Maize grain yield (t/ha)

	Herbicides

L1 - PL38; L2 - PL39; L3 - L335/99; L4 - L375/25-6; L5 - L155/18-4/1 RfVg; L1 - PL38; L2 - PL39; L3 - L335/99; L4 - L375/25-6; L5 - L155/18-4/1 RfVg; RD – recommended dose; DD – double dose; * - significant at 0,05 level, ($p<0,05$).

Conclusion

According to obtained data, mesotrione and topramezone showed good selectivity towards tested maize lines and these herbicides can be safely use in seed maize production. On the other hand, rimsulfuron and foramsulfuron showed lower selectivity towars tested maize lines and for their application special attention is required.

Abstract

Anise (*Pimpinella anisum* L. fam. *Apiaceae*) is important medicinal plant and a popular aromatic and spice crop. Aniseed is rich in essential oils and is used in the food industry, as well as for medicinal and cosmetic purposes. Its production has increased in Serbia in the last decade. The aniseed were collected the locality Pančevo during 2012-2013. Using conventional mycological seed testing, according to the ISTA rules, different fungal species were isolated. Monosporial representative isolate BS-1 was used for morphological and molecular identification. The fungal colonies grew rapidly in PDA media, reaching a diameter of 4 to 10cm following incubation at 25°C for 8 days on potato dextrose agar. Colonies were dark olive and slight cotton-like, totally covered by short conidiophores, with three to five black conidia in their apex. The reverse side of the colony was dark olive. Conidia size ranged from 40 to 117μm long and from 18 to 27μm wide, with 4 to 12 pseudosepta. They were usually straight (90%), ellipsoid, with round edges, rarely curved (10%), medium brown to dark brown in color. Conidiophores were between 170 to 280μm in length. The total DNA was extracted from fungal mycelium with DNeasy Plant Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. The rDNA internal transcribed spacer (ITS) regions of one isolate were amplified using polymerase chain reaction (PCR) with universal fungal rDNA primers ITS1 and ITS4. The sequence analysis of the ITS region revelated that isolate BS-1 (GenBank Accession No. KR866080) shared 100% nt identity of many *Bipolaris / Drechlera sorociniana* (Sacc in sorok.) isolated deposited in the Gen Bank from different region of the word. To confirm pathogenicity, a suspension of 2×10^6 spores/ spores/ml from the 14 days old culture were used for inoculation of the seeds. The level of root necrosis was calculated after 30 days, according to the scale from 0-3. On the basis of fungal macroscopic and microscopic characteristics, pathogenicity testing, and the ITS region sequence, this fungus was identified as *Bipolaris/Drechlera sorociniana*.

Key words: *aniseed, pathogen, identifications*

Introduction

Anise, *Pimpinella anisum*, is a herbaceous annual plant in the family Umbelliferae grown primarily for its fruit which is used as a spice in cooking or as a confectionery flavouring. The leaves can be eaten in salads.

Mycopopulation of anise seed are not investigated thoroghly. Only a few fungal species have been reported in the world as anise seeds pathogen: *Alternaria alternata* (Strandberg, 2002), *Puccinia pimpinellae* (Ghoneemet et al., 2009), *Erisyphe heraclei* and *Peranospora umbellifarum* (Davis, 2004).

The mycobiota of seeds of medicinal plants is well documented, but data on fungal species associated with anise seeds missing in Serbia. Consequently, the mycobiota of anise seeds were studied in 2012 and 2013 at the cultivating plantation of the Institute for Medicinal Plants Research "Dr Josif Pančić". The aim of this research was to determine mycopopulation of anise seeds for the first time in Serbia.

Material and Methods

Seed sampling, fungi isolation and pathogenicity test

Four hundred seeds (4 trials, each with 100 seeds) were sterilized with NaOCl for 2 minutes and then rinsed with sterile water and transferred to the filter paper and PDA medium on Petri dishes (Mathur and Kongsdal, 2003). After the fifty-day incubation at 25°C, parts of the mycelia taken from well - developed colonies was transferred to the PDA in order to be further examined**.**

Morphological examination of the eight selected isolated fungi (BS-1, BS-12, BS-17 from 2012 and BS-6, BS-8 and BS-16 from 2013 year) was conducted using monosporial cultures (Dhinger and Sinclair, 1986). The following characteristics were monitored: the appearance of aerial mycelia, presence of pigmentation, the appearance of conidiophores and conidia and the manner of conidia formation on the 15 old days fungal isolates. A hundred conidia were measured in every isolate.

Identification of the isolated fungi species was based on morpho-physiological characteristics and the cultivation of the fungi tested (Bockus et al., 2010).

The pathogenicity test of six isolates was confirmed by the modified method of Molot and Simone (1967). A total of ten anis seeds, surface-sterilized with sodium hypochlorite per isolate were inoculated in the suspension containing 2×10^6 spores/ml from the 14 days old culture. The control seeds were immersed in the sterile water. The inoculated and control seeds were transferred to the pots containing a sterile organic soil in greenhouse condition. The level of root necrosis was calculated after 30 days, according to the scale from 0-3 (0- not pathogenic; 1 - low pathogenicity; 2 - moderate pathogenicity; 3 - very high pathogenicity).

DNA extraction and PCR

The total DNA was extracted from fungal mycelium with DNeasy Plant Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. The rDNA internal transcribed spacer (ITS) regions of one isolate were amplified using polymerase chain reaction (PCR) with universal fungal rDNA primers ITS1 (5'TCCGTAGGTGAACCTGCGG3') and ITS4 (5'TCCTCCGCTTATTGATATGC'3) designed by White et al. (1990). Amplification reactions (25 µl) contained 10×PCR buffer, 5 U/µl Taq polymerase (Kapa Biosystems), 0.4 mM dNTPs, 25 mM $MgCl_2$ (Fermentas), 0.5 µM of each primer and 10 ng of genomic DNA per reaction mixture. PCR was performed in a Thermal Cycler PCR system 2720 (Applied Biosystems, USA). Initial denaturation at 95°C for 2 min was followed by 36 cycles at 94°C for 1 min, 57°C for 1 min (primer annealing), 72°C for 1 min (primer extension). A final extension at 72°C for 10 min was incorporated into the program, followed by cooling to 4°C until recovery of the samples. PCR products were visualized using UV light and separated in 1% agarose gel following staining with Midori Green DNA Stain (Nippon Genetics).

Sequence analyses

Sequencing in both directions was performed on an automated sequencer (ABI 3730XL Automatic Sequencer Macrogen, Korea). Sequence generated in this study was deposited in the National Center of Biotechnology Information (NCBI) GenBank database. Sequence of the Serbian isolate (BS-1) was compared with the respective fungi sequences available in the GenBank database (http://www.ncbi.nlm.nih.gov/ BLAST/) using the ClustalW program (Thompson et al., 1994) and MEGA5 software (Tamura et al., 2011).

Results and discusion

Analysing results of the collected anis seeds mycopopulation enabled different species from genus: *Alternaria, Phoma Fusarium, Bipolaris/Dreschlera, Epicoccum, Penicillium,*

Aspergillus and *Rhysopus* to be indentified. *Bipolaris sorokiniana* (Sacc in sorok.) (Fig. 1) was a predominant pathogen species on anes seeds, accounting for 8 and 15% in 2012 and 2013, respectively.

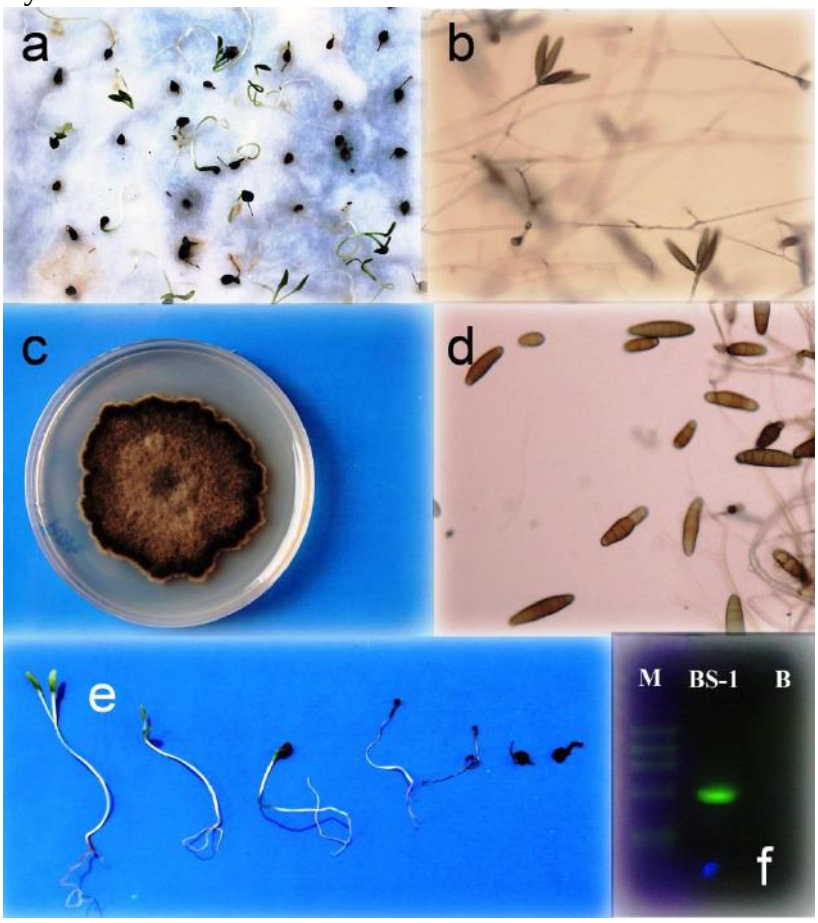

Figure 1.*Bipolaris/Drechlera sorociniana*.- a) pathogen on germinating anise seeds, b) and d) apearance of conidia, c) a colony on PDA, e) seedlings of artificially infected aniseed (left-seedling from a non-inoculated seed), f) Electrophoretic analysis of PCR products obtained using primer pair ITS1/ITS4. Lanes: M- Mass-Ruler^{TM}DNA ladder, Mix (Fermentas Life Sciences GmgH, Lithuania); 1- isolate BS-1; B- negative control (PCR mix with Rnase-free water)

Pathogenicity of tested isolates *Bipolaris sorokiniana.*

All six investigated isolates of *B.sorokiniana* caused root and leaf necrosis of seedlings (Tab.2). There were no significant differences between the isolates, but the isolate BS-1 showed the highest pathogenicity in comparison with the other five. All isolates showed a degree of pathogenicity.

Table 2. A degree of pathogenicity of *Bipolaris sorokiniana* on the anise seedlings in laboratory conditions

Isolates	Pathogenicity
BS-1	3
BS-12	2
BS-17	2
BS-6	1
BS-8	1
BS-16	2
Control	0

0- not pathogenic
1- low pathogenicity
2- moderate pathogenicity
3- very high pathogenicity

Morphological characteristics

After eight-day incubation on filter paper on the surface of the investigated anise seeds individual straight, shape conidiophores were observed measuring 170 to 280 (average 210 μm), tooped located three to five radially arranged conidia. On the potato dextrose agar medium a compact, initially olive brown, and subsequently black mycelium was formed. Conidia were usually straight or slightly curved, 40-117 x 18-27 μm in lenght, and golden brown, with 12 pseudosepta. These morphological and cultural characteristics are similar to *Bipolaris sorokiniana* already described by Ellis (1971), and Pidopličko (1977). Although the germination of conidia was mainly bipolar, lateral germination was observed sometimes.

Molecular detection and identification

Electrophoretic analysis of the PCR product showed that the fragment was of the expected length of 560-bp. In a BLAST search analysis, the sequence of the Serbian isolate BS-1 (Acc.No. KR866080) showed the highest nt homology of 100% with 16 *B. sorociniana* isolates deposited in GenBank from Italy (KJ909776), India (HM195250-60), Brazil (KF765399, KF765404, KF765404), China (KJ026137) and Canada (GU934504).

Bipolaris sorokiniana is an aggressive pathogen, transmitted by seeds that causes spot blotch, root and crown rots, node canker and head and seedling blight (Zillinsky, 1983). *Bipolaris sorokiniana* (Sacc in sorok.) is already known as causal agent of spot blotch of barley (*Hordeum vulgare*) and a common foliar pathogen worldwide. It has a wide host range and it is economically important wheat pathogen (Marthre, 1982, Nutteret al., 1985). *Bipolaris sorociniana* on oats in America secretes toxins and enzymes that destroy the plant (Agrios 1997).

This study represents the first attempt to characterize pathogens of *Bipolaris sorokiniana* in anise seeds in Serbia. Mycopopulation of anise seed is insufficiently known.

The different species from genus *Fusarium* (Pavlović et al., unpublich data) and *Alternaria alternata* **(**Stanojković-Sebić et al., 2014) have been detected on anise seeds previously in Serbia. Ghoneen et al., (2009) has reported *Puccinia pimpinellae* on anise seeds.

Conclusions

According to the cultural, macroscopic and microscopis characteristics, selected isolates from anise seeds were identified *as Bipolaris sorokiniana* (Sacc in sorok.). The representative isolates B-1 showed the highest nt homology of 100% with 16 *B. sorociniana* isolates

deposited in GenBank from Italy, India, Brazil, China and Canada. *Bipolaris sorokiniana* was a predominant pathogen of anise seed during 2012 and 2013. *B.sorokiniana* caused root and leaf necrosis of anise seedlings. To the best of our knowledge, this is the first report of *B.sorokiniana* being isolated from naturally infected anise seeds in Serbia.

Abstract

Diversity of leafminers in region of East Sarajevo, was examined in 2011. and 2012. in intensive plantations (locations Vojkovici and Kula), in semi-intensive plantations (locations Tilava and Petrovici) and in extensive plantation (location Kasindo). In Kula, examination was done on the following cultivars: „Viljamovka“ (Bartlett/Wiliams), General Le Clerc, „Passa Crasana“, Abe Fetel and Poire de Curé.

Six species of leafminers from four families was determined. Family Lithocolletidae is presented with three species: spotted tentiform leafminer miner (*Lithocoletis blancardella* Fabricius), hawthorn red midget moth (*Lithocoletis corylifoliella* Haworth) and garden apple slender (*Calisto denticulella* Thunberg), family Nepticulidae with one: apple pigmy (*Stigmella malella* Stainton) and from the family Lyonetiidae, two species was found: pear leaf blister moth (*Leucoptera malifoliella* (Costa (1836)) and *Coleophora hemerobiella* Scopoli from family Coleophoridae.

The highest number of damaged leaves was found in the semi-intensive plantations, in localities Tilava and Petrovici, where *S. malella* and *C. denticulella* were dominated species. In intensive plantations, in the locality Vojkovici, only *S. malella* was found. In the locality Kula, except *S. malela* which was the most numerous on pear cv. the Williams, *L. blancardella* was also determined. In extensive orchards, in the locality Kasindo, the most common species was *C. denticulella*.

Keywords: *leafminers, pear, East Sarajevo.*

Introduction

Leafminers from order Lepidoptera are economically important pests in areas where pears are grown. The damage are caused by larvae that are feed on the leaf parenchyma below the epidermis, leaving empty couloir, or "mine" of different shapes and sizes. The presence of mines on leaves reduces assimilation and transpiration surface, which adversely affects the yield, fruit quality and, in general, physiological condition of plants. Importance of these pests and their negative impact on fruit production, started increasing during end of the 60´s in the XX century. Leafminers became a serious problem, particulary in plantations in most European countries (Dimic, 1964, 1968). The presence and importance of different species of isn't the same in all areas of their distribution.

In Europe, more than 20 species of leafminers from genera: *Coleophora, Leucoptera, Stigmella, Lyonetia, Lithocolletis, Incurvaria, Recurvaria* and *Calisto* were detected on the pear (Hering, 1957). The most important species on the pear are: *Lyonetia clerkella, Leucoptera malifoliella, Lithocolletis blancardella, Lithocolletis corylifoliella and Callisto denticulella* (Almasi et al., 2004). In Turkey, for example, three species was identified on pear: *Lyonetia prunifoliella* (Hubner, 1796), *Lyonetia clerkella* and *Leucoptera malifoliella* (Seven, 2006).

After *Lithocolletis blancardella* was introduce in North America from Europe, it became an important pest (Corrigan and Bennett, 1987), and a increasing problem in plant production, because of its resistance to organophosphorus insecticides, especially azinphos-methyl (Hogmire and Beavers, 1998).

In Romania, in pear orchards, the most important species are *L. blancardella* and *Lithocolletis corylifoliella* (Frasin et al., 2008; Vasian et al., 2013).

In the former Yugoslavia, a mass phenomenon leafminers occurred in the late 70´s in XX century, when they became a serious problem. For example, eight leafminer species were detected on the pear in Slovenia: *Lyonetia clerkella, Lithocolletis corylifoliella, Lithocolletis cerasicolella, Calisto denticulella, Stigmella pomella, Stigmella piri, Stigmella plagicollella, Stigmella prunetorum.* In Serbia and Croatia were registered five leafminer species: *Leucoptera malifoliella, Lyonetia clerkella, Lithocolletis corylifoliella, L. blancardella* and *Stigmela malella* (Krnjaić and Grujic, 1982). Distribution and harmfulness caused by leafminers were studied in Bosnia and Herzegovina during the 60´s, when a rapid increase in population density and damages were registered. In that period, a total of 45 species of leafminers were found, out of which in Sarajevo and its wider area 5 species was recorded on the pear: *L. corylifoliella, L. mespiliella* Frey, *Lyonetia clerkella, Cemiostoma scitella and Coleophora hemerobiella.* In that period, according to the intensity of the attack, the most harmful was *L. corylifoliella*, especially on young trees (Dimic, 1964, 1968).

The area which now includes the East Sarajevo presents a part of the Sarajevo region and there are not enough data regarding harmful leafminers on pears. The tendency of increasing the production of pears in this area in the last 10 years, resulted in establishment the new, intensive plantations. Having in mind that leafminers are economically important pests of pear, the aim of this study was to register their diversity, to detect the most numerous species, as well differences in their number, both in plantations where different growing tehniques are aplied, as well between the cultivars.

Materials and methods

The examination was realized in 2011. and 2012. in the field (locations Vojkovici, Kula, Tilava, Petrovici, Kasindo) and in the laboratory of the Agricultural faculty in East Sarajevo. Samples of pear leaves were taken four times from June to the end of October for leafimers presence in all inspected locations. Every time 100 randomly sampled leaves were taken from pear trees (total of 400 leaves per each locality), except in the locality Kula, where 400 leaves of each variety was sampled.

All sampled leaves were observed in laboratory for presence of mines as well the type of mines. Number of damaged leaves was calculated. The before adult stadium of insects who located in the mines, were reared to adult stadium. The rearing was in plastic containers and Petri dishes with a layer of cellulose wadding on the bottom of which is occasionally yeast in order to maintain the freshness of the list. Determination of species was based on morphological characteristics of the adults and shapes of mines, folloowed by keys and appropriate entomological literature (Balachowsky 1966, Hering, 1957).

Results and discussions

Two-year research of diversity of leafminers on pears in the area of East Sarajevo, resulted in six detected species from four families. From family Lithocolletidae, three species were found: *Lithocoletis blancardella* Fabricius, *Lithocoletis corylifoliella* Haworth and *Calisto denticulella* Thunberg. From family Nepticulidae results of our examination showed presence of *Stigmela malella* Stainton, from family Lyonetiidae it was *Leucoptera malifoliella* (Costa (1836)), while *Coleophora hemerobiella* Scopoli which belongs to family Coleophoridae, was found only in certain leaves. The number of damaged leaves, varied by the species of leafminers and inspected cultivars (Table 1).

Regarding the total number of 323 damage leaves, found in all inspected localities, the most numerous species was *S. malella*, whose mines were registered in 125 leaves or 38,69%, followed by *C. denticulella* (97 leaves or 30,03%) and *L. blancardella* with 74 damaged leaf

or 22,91%. The lowest number of damaged leaves was caused by *L. corylifoliella* (20 leaves or 6,19%) and *L. malifioliella* (7 mined leaves or 2,16%).

Table. 1. The number of mined leaves on pear by species of leafminers and localities

Species of leaf miners / Locality	*Leucoptera malifoliella*		*Lithocoletis blancardella*		*Lithocoletis corylifoliella*		*Stigmela malella*		*Calisto denticulella*		Total number of mined leaves in localities
	Number of mined leaves	%	Number of mined leaves	%	Number of mined leaves	%	Number of mined leaves	%	Number of mined leaves	%	
Vojkovici	**-**	**-**	**-**	**-**	**-**	**-**	**13**	**3,25**	**-**	**-**	**13**
Kula	**-**	**-**	**11**	**37,93**	**-**	**-**	**18**	**62,06**	**-**	**-**	**29**
Tilava	**7**	**5,69**	**26**	**21,13**	**9**	**7,32**	**45**	**36,59**	**36**	**29,26**	**123**
Petrovici	**-**	**-**	**18**	**23,68**	**11**	**14,47**	**21**	**27,63**	**26**	**34,21**	**76**
Kasindo	**-**	**-**	**19**	**23,17**	**-**	**-**	**28**	**34,15**	**35**	**42,68**	**82**
Total number of leaves mined by species	**7 (2,16%)**		**74 (22,91%)**		**20 (6,19%)**		**125 (38,69%)**		**97 (30,03%)**		**323**

The highest number of mined leaves was found in the locality Tilava were 123 leaves in total were damaged or 30,75%. Out of total number of leaves with „mines“ from this locality, it was found that the most abundant was *S. malella* which damaged 45 or 36,59% leaves, *C. denticulella* with 36, or 29,26%, and *L. blancardella* with 26, or 21,13% of damaged leaves. Leaves were damaged the least by *L. malifioliella*, 7 or 5,69%, while *L. corylifoliella* damaged 9 or 7,32% leaves.

In the locality Petrovici, out of the total number of examined leaves, 76 leaves or 19% were damaged.

The most abundant species was *C. denticulella* which damaged 26, or 34,21%, and is followed by *S. malella* with 21 or 27,63%, *L. blancardella* with 18, or 23.68%, while the *L. corylifoliella* was of lower presence with 11, or 14,47% damaged leaves.

In locality Kasindo, the most abundant species was *C. denticulella* with 35 or 42,68% damaged leaves, and *S. malella* with 28, or 34,15%, while the lowest number of damaged leaves was caused by *L. blancardella* (19, or 23,17%).

In the locality Vojkovići, only *S. malella* was found and damaged 13, or 3,25% leaves.

In the locality Kula, 29 damaged leaves were registered. Out of these, *S. malella* caused damage on 18, or 62,06% leaves, with the highest number of mined leaves on cv. Williams (8), then the cv. „Passa Crasana“, 4, while on the cultivars, Abe Fetel and General Le Clerc 3 damaged leaves were found. Apart form *S. malella*, it was also detected presence of, *L. blancardella* which damaged 11 or 37,93% leaves. Of these, on the cultivars Wiliams, was found 5 mined leaves, cv. Abate Vettel 4, and the cv. of General Leclerc, 2 leaves.

As results of the analysis on presence of leafminers in different locations, it is evident that the most abundant species is *S. malella* which is also dominant species in many European

countries since 1950. in apple orchards. On the other hand, there is no enough information about it's harmful effects on the pear. Besides *S. malella*, numerous species was *C. denticulella* which is not considered economically important pest and is mainly present in the extensive orchards according to the literature data (Almasi, 2004). Literature data about the rare presence of *L. malifoliella* in Europe and Asia (Jenser et al., 1999; Radoslav et al., 2001; Magud, 2002) are in correspodence with our results because this species was represented only with 2,16% in comparision with the other species of leafminers.

Conclusion

In pear orchards in the area of East Sarajevo, six leafminer species were found: *Lithocoletis blancardella, Lithocoletis corylifoliella, Calisto denticulella, Stigmella malella, Leucoptera malifoliella* and *Coleophora hemerobiella*.

In relation to the total number of mined leaves in all localities, the most numerous species was *S. malella*, which was found on 38,69% leaves and the least numberous was *Leucoptera malifoliella* and is detected only in 2,16% mined leaves.

In the intensive orchards, in the locality of Kula and semi-intensive orchards in the locality Tilava, *Stigmella malella* was the most abundant, as well the only identified species in intensive plantation in the locality Vojkovici. In semi-intensive orchards in the locality Petrovici and extensive plantation in locality Kasindo, the most abundantspecies was *Calisto denticulella.*

The highest number of mine were caused by *Stigmella malella*, established at the cv. Williams, and the lowest number on cv. Abe Vetel and General Le Clerc.

Abstract

Lavender yields of depend on the age of the plantations. It takes 8-10 kg of fresh flowers to gain one kilogram of pure dry flowers. Biannual yields of fresh lavender flowers range from 600 to 800 kg/ha or 3-6 kg/ha of aromatic oils. Lavender flowers on an existing four year old plantation can achieve yields of fresh flowers which range between 3,500 and 4,000 kg/ha, or 20-26 kg/ha of aromatic oils. The yields of fresh hybrid lavender flowers on a two year old plantation range from 1,000 to 1,500 kg/ha or 10-15 kg/ha of aromatic oils. Plantations older than four years can produce flower yields of 5,000-7,000 kg/ha. Seed yields are between 200-300 kg/ha.

The subject of analysis in this paper is the profitability of organic lavender oil production grown on one hectare an area. The aim of the research is to determine economic viability of lavender over the profitability of oil production using production results On average, from 2008 to 2012, the analyzed production of lavender oil and one hectare lavender yields the total production costs which amounted to 5.926,23 €. Gross earnings amounted to 3.810,52 €. After the representation of the total costs, costs of materials participated with 20.65%. The calculated cost of Maillet oil hybrids is on average 60.00 €/kg. There is a total profit of 1.018,77 €/ha, which means that organic farming and production of lavender oil is a highly profitable business.

Keywords: *lavender oil, variety of Maillette, costs of production, profit*

Introduction

Thanks to its geographical position, climate and soil, respectively, the territory of Bosnia and Herzegovina (BH) is suitable for cultivation of agricultural crops, among others, medicinal, aromatic and spice plants. Land, usually unfavorable because of its physical, chemical, biological and other characteristics – for example arable crops would not achieve satisfactory production and economic results, can be used for the cultivation of medicinal and aromatic herbs. Total production of lavender oil depends on the activity, capacity and number of flower parts containing oil (calyx) and the number of flower heads, branches and the number of plants per hectare. Therefore, managing processes of plants for a maximum contribution of oil need to focus on the flower and growth, so as to reach the maximum number of healthy plants with thick branches and leaves per hectare. The soil and climate conditions greatly affect the yields and quality of the oil. The soil should therefore be analyzed regularly; it is recommended every 3 to 4 years, and if necessary, make appropriate improvements. The maximum potential production and quality of the oil depends on the choice of the variety and its genetic potential. Lavandins have higher oil yield than L. Angustifolia, which is why most lavender oil in the world is made from lavandin.

In BH, lavender was previously grown on plantations covering large areas and thus there are no adequate data on yields. Among the first scientists who described the lavender was Coulper (1952), and in BH it was Devetak (1949). The research by Peco (2009), established the biological productive traits of hybrid lavender grown on the principles of organic production; yields and lavender flower oil obtained by distillation, the differences that exist in

the respective characteristics of a hybrid, as well as the differences in the characteristics of two hybrids. Accordingly, the subject of the research is establishing the economic effects of the cultivation of lavender.
The aim of the research is to determine economic viability of lavender over the profitability of oil production using production results.

Materials and Methods

Authors used data from analytical and accounting records of lavender growers in the municipality of Mostar (BH) for this research. In addition, different websites and various publications from domestic and foreign authors have been consulted. By applying statistical calculations and methods, significant economic indicators and the evaluation of the economic viability of production are determined. The results are presented in tables and graphs along with appropriate comments.

Results and Discussion

Biological and technological properties of lavender

Lavender has a long history of cultivation worldwide. Lavandula (common name lavender) is a genus of 39 known species (https://www.en.wikipedia.org/wiki/Lavandula). This is a perennial plant. According to Jancic (1990), lavender grows in the form of a hemispherical bush height and diameter of 100 to 150 cm. The root is branched and woody. The tree is branched and bushy with many branches. Lavender leaves are flat, elongated and lanceolate, 0.5 cm wide and 5 cm long. Young lavender plants are of gray-green color and age green. The flowers are grouped in earlike blossoms. The color of flowers varies from deep purple, lilac, blue, pink to white, depending on the hybrid. One inflorescence has 6 to 10 flowers. Lavender blooms from July to August. There are about 20 different hybrid lavender plants. The name lavender comes from the Latin word "lavare" which means "to wash" (Houdret, 1999).
The scale of production of medicinal and aromatic herbs, including lavender, in Europe and the world has undergone significant changes in recent years. There was an intensification of production in order to increase labor productivity and production volume, as well as to improve product quality. Production of organic lavender has derived from such a concept. Organic production currently represents the best compromise between the demands of agriculture (quantity and quality) and the requirement to protect the environment and produce food that is safe enough and health-wise for consumers (Milic and Lukac-Bulatovic, 2013).
The selection of varieties in the production of lavender is an important issue to be solved before plantation. Long period of exploitation and a large number of hybrids of different economic and biological characteristics stress out even more significant problems for the proper resolution of assortments. Mistakes made in the selection of new cultivars can later be difficult to remove, and if there are certain possibilities, it is necessary to allocate additional financial resources (Milic and Radojevic, 2003). In the first year, in late May, lavender is pruned to 8 or 10 cm, to form a dense compact shrub. During the second year it is re-trimmed to a height of 15 to 18 cm. The old lavender plantation after six to eight years is rejuvenated by cropping plants during dormancy at a height of 10-15 cm by special machines. The plantation will give a full yield year after pruning. This way, the crop can be rejuvenated two to three times during the lifetime of proper lavender. Old branches of hybrid lavender that do not provide new bursts rejuvenate as proper lavender (Oliver, 1996).

Photo 1: Lavender Maillete

Flower stalks are cut to the height below the first pair of leaves. Improper pruning reduces the quality of the plant. For smaller areas, reaps are most usually manual while on larger areas special machines that can be drawn or self-propelled are used.
Lavender inflorescences are harvested at the stage when 50-75% of flowers are in bloom. One worker can manually collect 100-150 kg lavender flowers or 300-500 kg of hybrid in ten hours. Special machines collect crop off of 0.1-0.3 hectares in an hour. After harvesting, inflorescences are dried at ventilated places in the shade. Before winter, shrubs are cleaned of subsequently grown or overly ripen blossoms.
Lavender is grown for aromatic oils. According to Dorfer et al. (1990), the first distillation of aromatic lavender oil in Europe was performed in Frankfurt in 1582. The oil is obtained by distillation from the flowers of Lavandulae Flos (formerly Flores Lavandulae). Lavender flowers contain 0.6-1.4%, while hybrid 0.9-5% of essential oils and about 10% of tannin. Aromatic oil - Lavandulae Aetheroleum (formerly Oleum Lavandulae) is colorless and of bitter taste. The main constituents of the essential oil are: linalyl acetate (35-62%), linalin, geraniol, hydroxycoumarin and others. Lavender has a broader application in home medicine for problems with headache, appetite, bloating, in repulsive reaction to food, in dizziness, nerve problems, gall bladder, problems with the liver and spleen.
As for the aromatic oil, lavender is said to be the "mother of the oils." It has a sweet, honey-floral scent. It is mild and does not irritate the skin. Any packaging must accurately say the Latin name Lavandula Officinalis or synonyms Lavandula Angustifolia or Lavandula Vera. Unfortunately, some producers sell counterfeit lavender oil under this Latin name. In addition to written Latin name, sellers possess a chemical certificate. The detailed chemical analysis must be made for every quality aromatic oil on the market. Such an analysis easily reveals retailers and distributors who sell counterfeit lavender oil.
The yields per unit area in the plantation production of lavender significantly dependent on natural conditions, silvicultural form, selected varieties, applied agricultural technology etc. Their incompatibility can cause yield reduction and the achievement of unfavorable economic results. Yields depend on the age of lavender plantations. According to *Tanovic (2002),* full yield is achieved only in the fifth or sixth year of cultivation.

Photo 2: Condenser for the production of lavender oil

8-10 kilograms of fresh bloom are needed for 1 kg of pure dry bloom. Yields of two year old fresh lavender blooms range from 600 to 800 kg/ha or 3-6 kg/ha of aromatic oils. On older plantations, up to four years of age, yields of fresh blooms range between 3,500 and 4,000 kg / ha or 20-26 kg / ha of aromatic oils. Yields of blooms of two year old fresh hybrid lavender range from 1,000 to 1,500 kg/ha, or 10-15 kg/ha of aromatic oils. On older plantations, up to four years of age, yields of 500-700 kg/ha of aromatic oils can be achieved.
McNaughton (1994) gives a special place to lavender and its use. Proper lavender oil, made of all kinds of lavender, has a very calming effect. It helps with nervousness and insomnia, and relaxes tense muscles after a day of work, stress and physical activity. Aromatic oil of broadleaf lavender (L. Spica L. Latifolia) has a mild smell, a refreshing touch, and compared with aromatic lavender oil, it smells less sweet. This aromatic oil has the most beneficial effect on skin. It has an excellent regeneration effect on oily, dry and damaged skin. Oil from broad lavender is the most effective on mild burns.

Economic results of lavender growing

The production value is the market value of the products obtained at the farm during a business year. As for the reference period of 2008-2012, the yields of Maillete hybrids oil stood on average at 1,736.25 kg or 115.75 kg/ha. The economic result of the production unit depends on the amount of cash value that is achieved through the realization of products and the amount of the costs. The greater the positive differences between these values, the more favorable economic results are of the operations. Due to its production and technological features of modern plantation, cultivation of medicinal and aromatic plants should be a highly intensive production based on high investments of capital and labor per unit of production capacity. The basic requirement for successful production is the achievement of economic optimum, from both points of view the scope and structure of production, and within the end from the investment point of view.
As for the period of 2008-2012, in the analyzed production of lavender, overall production costs on average amounted to € 5,926.23/ha (Table 1). As for the total costs, variable costs (fertilizer, fuel and other materials) account for 53%. The calculated cost price is approximately 60.00 €/kg. The profit amounted to 1,018.77 €/ha, which is very acceptable.
In terms of competition, the goal of every manufacturer is to offer, not only a greater quantity, but also lower costs. Manufacturers go for better financial result, which imposes the need for a reliable prediction, monitoring and comprehensive analysis of the components of costs.

Table 1: Economic indicator of Maillet sort in the period of 2008-2012

I n d i c a t o r s	*Amount (€/ha)*	*The structure of the total cost (%)*
1. Value of production	*6,945.00*	-
2. Variable cost	3,134.48	53.00
3. *Gross margin (1.-2.)*	*3,810.52*	-
4. Fixed cost	2,791.75	47.00
5. Total cost (2.+4.)	*5,926.23*	100.00
Profit (1.-5.)	***1,018.77***	-

As for the economic production of lavender, it is expressed through the relationship between the output and the value of the funds spent and the work or the costs of production. If the cost effectiveness ratio is greater than one, we have a more economical production and vice versa. Since the coefficient of economy of production in the examined period is 1.16, it shows that the production of Maillet lavender is profitable activity.

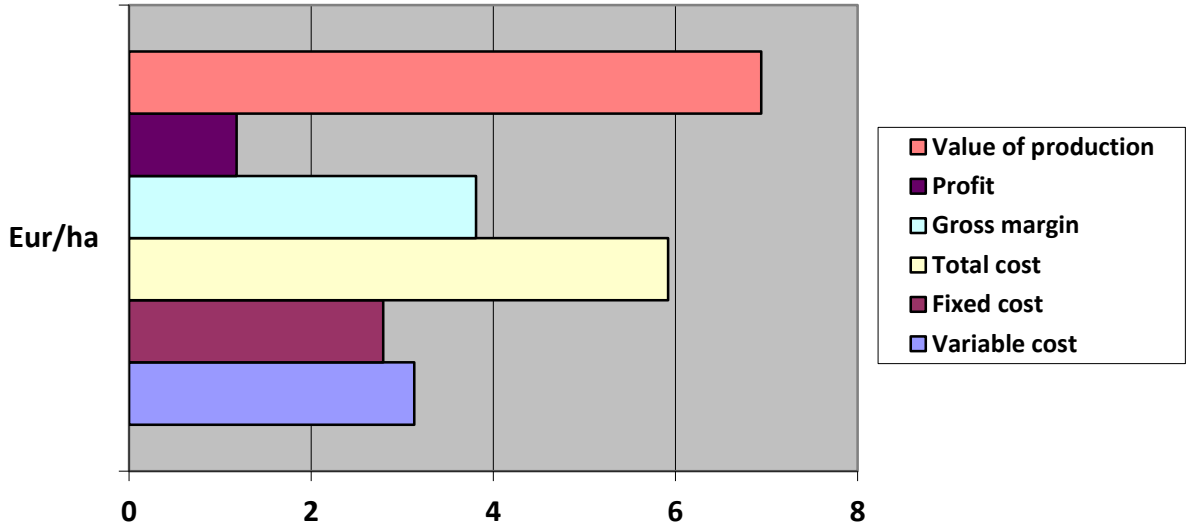

Chart1: Graphic indicators display of oil production in the (000) EURO per 1 ha of lavender oil.

One of the indicators of economic efficiency of production is also the profitability of production. The rate of return indicates the amount of profit for every 100 € of the market value of production. Determined profitability for the production of Maillet hybrid amounted to 16.56 €.

Conclusion

Project of lavender plantation started in 2001 in the research company and it brought along the latest technology and methods in lavender growing. It was necessary to implement a lot of knowledge, experience and funds. One of the many requirements is to provide security of products for the final consumer. The company management certifiers the production at the world-famous certification company Soil Association, which provides the opportunity to access the most demanding consumers. The calculated cost price of Maillet hybrids oil is, on average, 60.00 €/kg. Recorded total profit on a 15 ha plantation is € 5,926.23, which is very

acceptable. Production efficiency is 1.16 which indicates that the production is a profitable activity. The profitability of Maillet hybrid lavender amounted to 16.56 €.

IMPACT OF VARIOUS HERBAL EXTRACTS ON YIELD OF LETTUCE (Lactuca sativa)

Srdjan LJUBOJEVIC

Independent University of Banja Luka, Faculty for Ecology, Bosnia and Herzegovina
*Corresponding author: ljuboje@blic.net

Abstract

The paper presents results of a large-scale experiment dealing with the impact of various herbal extracts on yield of lettuce (*Latuca sativa*), conducted at the laboratory of plant physiology. Plants were grown on hydroponic with half-strength Hoagland`s solution. The following characteristics were measured: number of leaves, length of the green parts of plants, root length, total weight, together with visually assessed plant vigor. Trial included 12 treatments with 30 repetitions each, and that were: leaf extract of comfrey (*Symphitum officinale*), leaf and root extract of nettle (*Urtica dioica*), leaf and root extract of dandelion (*Taraxacum officinale*), extract of above-ground part of horsetail (*Equisetum arvense*), flower extract of yarrow (*Achillea millefolium*), extract of above-ground part of lemon balm (*Melissa officinalis*), root extract of valerian (*Valeriana officinalis*), root extract of burdock (*Arctium lappa*), extract of above-ground part of squirting cucumber (*Ecballium elaterium*), commercially produced gibberellic acid, commercially produced plant growth regulator (PGR) based on seaweed extract and control group.

The results point out the differences in size and direction of impact of various extracts on lettuce`s yield, where some of them behaved even as a retardant. On the basis of this experiment and previous findings, special herbal preparation was composed with the strength of PGR. It`s capacity was tested on lettuce and cabbage in commercial agricultural production with satisfactory results.

Keywords: *herbal extracts, lettuce, yield, PGR*

Introduction

The extracts of wild growing herbs, above all medicinal, are widely used as components of medicinal and cosmetic preparations, as well as various products of the food industry. They are also applied in organic agriculture as mild fertilizers and plant protection means.

A specific type of application of herbal extracts is the production of plant growth regulators (PGR). Here as the raw material most often occur seaweed extracts. The majority of commercially produced extracts derives from brown seaweed, whose representatives are *Ascophyllum nodosum* and species of the genus *Fucus*, *Laminaria*, *Sargassum*, and *Turbinaria* (Calvo et al., 2014). Recently the seaweed extracts are reassigned to the newly formed, broadly structured category - biostimulants. Seaweed used for their production contain auxins, cytokinins and some other hormone-like substances (Bulgari et al., 2015). Beside the extract of seaweed, active dry yeast extracts are in use as well (Hanafy et al., 2012).

Additionally to this raw material base, PGRs can be obtained from extracts of wild growing medicinal herbs. Grounds for such approach are numerous, ranging from the classical authors of Greece and Rome, through Paracelsus, to allelopathy founder Hans Molish and many of his contemporaries, not forgetting biodynamic agriculture practitioners and followers of pure organic gardening.

In ancient times it was already well known that plants contain and release extracts which can produce both positive and negative effects on other plants. The ancient concept of sympathy and antipathy eventually grew into a modern concept of allelopathy (Willis, 2007).

In the Middle Ages, Paracelsus (1525) was among the first to speak about the positive impact of medicinal plants (presumably he was referring to St. John's wort (*Hypericum peforatum*) on the development of other cultures, in the chapter entitled, "About St. John's herbs ".
At the beginning of the 20th century Coupin (1911) studied the effect of herbal ingredients, among them the extract of lemon balm. Molish, founder of the term "allelopathy" demonstrated that flowers and fruits contain many other substances that prove physiological effects on young plants (1937). Ulman (1940) in his doctoral thesis discusses the impact of extracts of yarrow and valerian on the growth of young plants in length. Knapp et Thyssen (1952) undertook a large-scale experiment in which they studied the relationships between 60 species of medicinal plants, grown on experimental plots. The authors have identified three aspects of the plant on the plant impact - 1. stimulating, 2. favorable and 3. adverse effect.
Rudolf Steiner (1993), the father of Anthroposophy and founder of the so-called biodynamic method of agriculture, recommends the following set of species for nutrition and plant protection: - for nutrition: dandelion, English oak bark, nettle, yarrow, valerian;
- for nutrition and protection: comfrey, fern (genus *Telypteris*; syn. *Dryopteris*), great yellow cress, tansy, wormwood. Practitioners of organic farming still use the extracts of elder and rhubarb (Omahen, 1985; Stickland, 1989).
In addition to the above listed, to the present day a large number of plants was recorded whose extracts affect growth, development and the appearance of vegetables and floricultural crops, such as common corn-cockle (Anon., 1986), rape pollen (Thompson, 1981), sage (Ljubojević, 1998) and many others.
Working on the development of special preparations as an alternative for mineral fertilizer to be used in fragile agricultural ecosystems, such as catchment areas of underground drinking water reservoirs, particularly protected area of Vrelo Bosne near the town of Sarajevo, the author conducted a series of experiments aimed at finding the optimal formulation for pre-defined target group of plants. One of the indicative experiments, concerning the testing of different herbal extracts influence on the growth and development of lettuce in early stages, are shown in this paper.

Material and methods

Seed of lettuce (*Lactuca* sativa L.) cv. "Majska kraljica", produced by „Seme", Belgrade (Serbia & Montenegro), were sown at the end of December 1996, at the laboratory of plant physiology in the Agyos Athanasios Industrial Estate, Limassol, Cyprus, on sandy boxes; this leafy vegetable crop showed very high ability in growth during early growth stages (Tei et al., 1996). The bed was regularly watered after sown to ensure proper emergence. When the plants from seed stage entered into cotyledon stage, plants were carefully taken out from sandy boxes and transferred into close hydroponics systems. The nutrient solutions were half-strength Hoagland solution. In the beginning the level of the solution was found to be just above the root hair. After two weeks in the solution the half length of the root was submerged, while the other half was in direct contact with air. The change of the nutrient solution was conducted every four days. Containers with solution were shaken every 12 hours and on every 24 hours fresh air was injected by using the hand pump. In order to provide equal access to light, plants were for 14 hours per day exposed to artificial light which consisted of a couple fluorescent lamps (2 x 60 W) at a distance of 60 cm. Room temperature was maintained at 22 ° C and humidity at 65%.

The moment when the plants from cotyledon stage entered in the seedling stage with the first true leaves, 360 plants were selected and totally randomly distributed in 12 experimental groups with 30 plants in each. In the same way, each group was associated with some of the 11 treatments and one control group. Eight medicinal plants were selected for treatments, which are widespread in our country and a similar climate (Ljubojević et al., 2000, 2014). Considering that the experiment had been carried out on Cyprus, experiment was extended

with a locally widespread plant species, squirting cucumber. Rational basis for this choice lies in the chemical composition of its active constituents and in practice of local rural population to spray fruits and vegetables with a liquid feed diluted with water. Two treatments have the role of rappers. The first one as a strictly specific PGR based on hormonal (gibberellic) effect, and the other as a widely used PGR with various features (seaweed extract). In all treatments and control group, nutrient solution concentration was reduced to 50 % of the standard solution so as to avoid morphological and physiological changes on young plants due to overdose of macro- or microelements.

The treatments were the following:

T1 - Standard nutrient solution (SNS) + water extract of dried comfrey leaf (*Symphyti folia*),
T2 - SNS + water extract of dried nettle leaf and root (*Urticae folium et radix*),
T3 - SNS + water extract of dried dandelion leaf and root (*Taraxaci folium et radix*),
T4 - SNS + water extract of dried aboveground part of horsetail (*Equiseti herba*),
T5 - SNS + water extract of dried aboveground part of yarrow (*Millefolii herba*),
T6 - SNS + water extract of dried lemon balm leaf (*Melissae folium*),
T7 - SNS + water extract of dried valerian root (*Valerianae radix*),
T8 - SNS + water extract of dried burdock root (*Bardanae radix*),
T9 - SNS + water extract of fresh aboveground part of squirting cucumber (*Ecballium elaterium*),
T10 - SNS + water solution of „Giberlex“ – natural plant growth regulator (PGR),
T11 - SNS + water solution of „Original Seaweed Extract“ – natural PGR,
T12 - SNS - half-strength Hoegland solution.

In the foreground of application extracts, all plants were recorded on the following features: the number of true leaves, the length of aboveground parts, root length, total weight. Afterwards four control measurements were carried out during the rosette stage. The experiment was completed before entering the cupping stage, given that the optimal conditions for plants development were not secured in present and subsequent stages of growth.

The impact of treatment on the size of the observed feature is represented by the size of changes with respect to the initial state and their comparison with the control group. The statistical significance of observed differences was evaluated through two-sample t-test, where both samples are small ($n_i \leq 30$) and have equal number of elements. Ranks were assigned using dense ranking.

Preparation and application of treatments

The raw material for preparation of aqueous extracts in treatments T1-T8 consisted of herbal drugs originating from wild medicinal plants, as follows: T1 - comfrey (*Symphitum officinale* L.), T2 - nettle (*Urtica dioica* L.), T3 - dandelion (*Taraxacum officinale* Web. et Wigg.), T4 - horsetail (*Equisetum arvense* L.), T5 - yarrow (*Achillea millefolium* L.), T6 - lemon balm (*Melissa officinalis* L.), T7 - valerian (*Valeriana officinalis* L.), T8 - burdock (*Arctium lappa* L.). The raw material originated from "Herbogal" Svrljig, Serbia, "Krka" d.d., Novo Mesto, Slovenia and "Ulrich" S.p.A, Genoa, Italy. From each plant drug 50 g were taken by and dipped in 450 g of previously softened water, preheated to 65 °C. After 24 hours the mixture was filtered off and stored in a refrigerator. During the application phase the extract concentration in the nutrient solution was 4.76% (1 part of aqueous extract is mixed with 20 parts of nutrient solution).

For the preparation of treatment T9, 150 g of fresh aboveground parts of squirting cucumber was taken (which is equivalent to 50 g of dried herb) and submerged in 450 g of softened water. All other activities remained the same as in the treatment T1-T8. The raw

material was collected in the vicinity of the premises where the laboratory of plant physiology is located (Agios Athanasios Industrial Estate Area, Limassol, Cyprus).

Treatment T10 consisted of the preparation "Giberlex" in the form of tablets, produced by “Fine Agrochemicals Ltd”, UK. One tablet of the preparation contains 1 gram of gibberellins comprising not less than 90% of gibberellic acid and not more than 10% of other biologically active gibberellins. In practice it dissolves with 1,000 litres of water. The same ratio was maintained in the experiment. During application the concentration of previously diluted preparations in the nutrient solution was 4.76% (1 part of pre-diluted mixture was mixed with 20 parts of nutrient solution).

Treatment T11 consisted of the preparation "Liquid Seaweed (Kelp Extract)", derived from fresh Norwegian kelp (*Acrophyllum nodosum* (L.) Le Jolis), produced by “Maxicrop International Ltd.” U.K. One part of mixture was diluted with 400 parts of water. During application the concentration of previously diluted preparations in the nutrient solution was 4.76% (1 part of pre-diluted mixture was mixed with 20 parts of nutrient solution).

The control treatment (T12) consisted of the standard nutrient solution - half-strength Hoagland solution, of the following formulation: N (as NO_3) - 103 ppm, P (as H_3PO_4) - 30 ppm, K - 140 ppm, Ca - 110 ppm, Mg - 24 ppm, S (as SO_4) - 32 ppm, Fe – 2,5 ppm, B – 0,25 ppm, Mn – 0,25 ppm, Zn - 0,025 ppm, Cu – 0,01 ppm, Mo - 0,005 ppm.

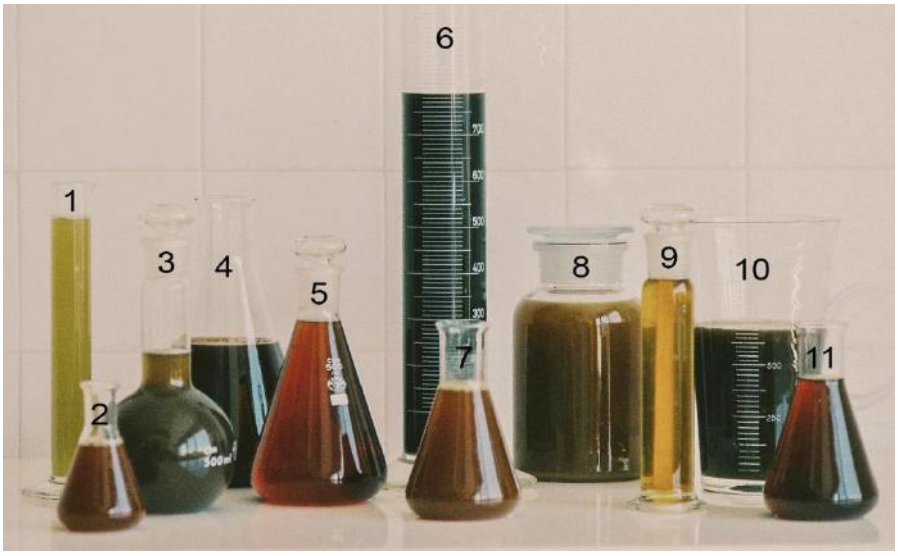

Photo 1: Water extracts used in experiment: 1. of aboveground part of squirting cucumber, 2. of lemon balm leaf, 3. of nettle root, 4. of valerian root, 5. of dandelion root, 6. of aboveground part of yarrow , 7. of nettle leaf, 8. of burdock root, 9. of aboveground part of horsetail, 10. of aboveground part of yarrow, 11. of comfrey leaf

Results and discussion

Number of leaves on the plant

Application of plant extracts did not contribute to a significant increment in the number of leaves on plant compared to the control group. Treatments with comfrey and horsetail led to slowing the development of new leaves, and the differences arising in the reporting period were statistically significant (Table.1). Based on these results we can cautiously conclude that the extracts of comfrey and horsetail act as retardants, when it comes to the number of leaves in the early growth stage of lettuce.

Notice: */ test statistic $t_o > t_1$ (significance level equal to 0.05)

Length of aboveground part of the plant

Application of nettle, yarrow, lemon balm, valerian, burdock and squirting cucumber extracts contributed to increment in length of aboveground part of the plant in comparison to the control group, however, only in the case of lemon balm the observed differences were statistically significant (Tab. 2). On the contrary, with dandelion application the growth of aboveground part of the plant was significantly slowed down. However, the biggest increment in length of above ground part of lettuce has been achieved in treatments with “Giberlex”, while treatments with seaweed extract were lower than the control group.

Root length of the plant

Application of nettle, yarrow, valerian and squirting cucumber extracts contributed to increasing the length of roots in comparison to the control group, however, the observed differences were not statistically significant. On the contrary to this, application of comfrey, dandelion and horsetail extracts showed that root growth in length was significantly slowed compared to the control group (Tab. 3). The treatment with lemon balm extract did not affect the root’s growth in length of those intensity as that they did in case of above ground parts. In the case of treatment with "Giberlex" and seaweed extract, root growth trend was slower than the control group.

Fresh weight of the plant

Application of nettle, yarrow, lemon balm and squirting cucumber extracts contributed to the increased growth of fresh plant compared to the control group, however, the observed differences were not statistically significant. On the contrary, treatment with comfrey, dandelion and horsetail gave significantly lower results compared to the control group. From the recordings based on these indicators, we can cautiously conclude that the extracts of comfrey, dandelion and horsetail act as retardants, when it comes to fresh lettuce weight in the early growth stages.

Conclusions

The observed plant extracts show contrasting growing patterns in the observed period – at the early growth stages of lettuce. Comfrey extract acts as an inhibitor because it slows down the formation of leaves, development of above ground and underground part in length and conclusive increase of fresh biomass. Similar actions exhibit the extracts of dandelion and horsetail. Nettle extract stimulates the growth of above ground and underground parts of plants, but not to the extent of considering observed changes as statistically significant. An identical conclusion applies to extracts of yarrow, valerian and squirting cucumber. Extract of lemon balm has significant impact on the growth of above ground portions of the plant. Burdock extract does not contribute to a significant increase in above ground and underground parts, but also does not slow down its growth, i.e. does not have the inhibitor characteristics. None of the studied extracts did induce a significant increase in fresh biomass compared to the control group. Nevertheless, the effect of the extract is promising. The majority of extracts has showed without any upgrades the same, if not even better activity than of commercially produced extracts from seaweed. Also, in contrast to the "Giberlex" preparations, whose effect is strictly specific (induces only above ground parts growth), herbal extracts act simultaneously on the above- and underground part of the plant.

CHEMICAL COMPOSITION AND ANTIOXIDANT POTENTIAL OF ESSENTIAL OIL AND METHANOL EXTRACT FROM MINT (Mentha piperita L.) GROWING IN MACEDONIA

Ljupcho MIHAJLOV*, Sanja KOSTADINOVIĆ VELIČKOVSKA

Faculty of Agriculture, University “Goce Delčev”, Krste Misirkov bb, 2000 Štip, Macedonia
*Corresponding author: ljupco.mihajlov@ugd.edu.mk

Abstract

The chemical composition and antioxidant potential of essential oil and methanol extract from Macedonian *Mentha Piperita L.* was object of this study. The plant was organically produced from for the first time at south-east region of Macedonia (41º49`N, 21º 59`E) on the overlapping area of two climate types: the Mediterranean and Continental climate.

The GC-FID and GC-MS analyses of essential oil indicated menthol and menthone as the most abundant compounds with 48.05 and 20.4% respectively. The other identified and quantified compounds such camphene, sabinene, *p*-cymene, *β*-pinene, limonene, *cis*-carvon, menthol acetate, piperitone and piperitone oxide were presented in the levels below 10%.

The total phenolic compounds and total flavonoids were presented at higher level in methanol extract with abundance of 22.42±1.14 mg of gallic acid equivalent/g DM and 0.79±0.34 mg luteolin/g DM respectively, in comparison to essential oil with the levels of 10.12±0.89 mg galiic acid equivalent/g DM and 0.54±0.11 mg luteolin/g DM.

The antioxidant potential measured by two radicals DPPH and ABTS indicated higher values for methanol extract in comparison to essential oil.

Keywords: *Mentha piperita L., essential oil, phenolic compounds, flavonoids, antioxidant potential*

Introduction

The aromatic plant *Mentha piperita L.* belonging to the family Lamiaceae which is grown in regions of Eurasia, South Africa, the north, west and east portions of Europe, as well as Turkey and Russia.

The chemical composition and antimicrobial activity of different varieties of Mentha plant were object of study of many researchers. In the work of Arman et al., the essential oil from *Mentha mozaffarianii* had significant antimicrobial activity against gram positive bacteria *Bacillus subtilis, B. pumulis, Staphylococcus aureus* and *S. Epidermidis* as well as moderate activity against gram negative bacteria such *Escherichia coli*, *Klebsiella pneumoniae*) and no activity against *Pseudomonas aeruginosa, Aspergillus niger*. The major components of the oil were piperitenone (59.5 %), *cis*-piperitenone epoxide (14.9 %), and pulegone (8.5 %), (Arman et al.2011). Chemical composition and antimicrobial activity of *Mentha pulegium* from Iran was studied by Morteza-Semnani et al. (2011). According to their findings, the major constituents of this essential oil were pulegone (54.6 %) and menthone (15.1 %). Carvone-Rich Essential Oils from *Mentha longifolia (L.) Huds. ssp. schimperi Briq*. and *Mentha spicata L.* grown in Sudan had oxygenated monoterpenes comprised 81.5% and 88.7%, while monoterpene hydrocarbons comprised 14.7% and 9.2% (M. H. Younis and S. M. Beshir 2011). Zeinali et al. (2005), reported fifteen principal components in the oils of 12 variety of Iranian mints accessions. The oils obtained from Mint variety Mzin 9 and Mzin 10 contained the highest value of *p*-cymene with the levels of 48.9 and 48.6%. In the mint oils from variety Mzin 5 and Mzin 11 was quantified cis-carveol over 70%. Carvon oxide was the most dominant compound in Mzin 4 with the level of 52.5%. Rissanen et al. (2002), stated that oil

yield and composition of *Mentha piperita L*. depends of plant density and growing season. According to their findings, the highest oil concentrations were present in highest plant densities in the first growing season.

The chemical composition and antioxidant potential of essential oil and methanol extract from Macedonian organically produced *Mentha Piperita L.* was object of this study.

The plant was organically produced, described in details in research of Mihajlov et al. (2015), from for the first time at south-east region of Macedonia (41º49`N, 21º 59`E), on the overlapping area of two climate types: the Mediterranean and Continental climate.

Materials and Methods

Oil isolation and analysis: A sample of 250 g of dried leaves and stems was mixed with 500 mL of tap water in flask and water distilled for 2 h using a Clevenger-type apparatus (Fig. 1). The oil content was measured based on mL oil per 100 g dry matter (mL/DM). The oil compositions were analyzed by GC (FID) and GC/MS. Gas chromatography was carried out with an Agilent HP 6890 gas chromatograph equipped with flame-ionization detector (FID) and quantitation was carried out by addition of pure standards as well as area normalization and neglecting response factors.

The analysis was conducted using a HP-5 (5% Phenyl Methyl Siloxane) fused silica capillary column (30 m x 0.50 mm, film thickness 0.32 μm, J &W Scientific Inc., Rancho Cordova, CA). The operating conditions were as follow: injector and detector temperature: 250°C, carrier gas: helium; inlet pressure: 35.4 kPa. Oven temperature program was 50 - 220°C at the rate of 4°C/min. Quantitative data concerning the percentage contribution of each constituent were taken with this system. GC/MS analysis was carried out using an Agilent HP 6890 gas chromatograph fitted with the same column as described above, coupled to quadrupole 5973 MSD, which was operated at an ionization potential of 70 eV and electron multiplier energy 2000 V. The temperate program started at 50°C during the split injection and then programmed to 220°C with increment of 4°C/min. The oil components were identified by comparing their retention indices and mass spectra data (NIST 14 Standard Reference Database 1A) with those of authentic samples and published data: M. H. Younis and S. M. Beshir (2011), S. Kostadinović Veličkovska (2013), and S. Kostadinović et al. (2010).

Determination of total phenolic compounds and total flavonoids: 0.5 mL of the methanol extract and 0.5 mL of essential oil were dissolved in 5 mL distilled water and mixed with 0.5 mL of 10 times diluted Folin-Ciocalteu’s reagent. 1 mL of saturated sodium carbonate (35 %) was added to the mixture and it was topped up to 10 mL distillated water. After three hours, the total phenolics were measured spectrophotometrically at 725 nm.

Determination of flavonoids: in the extract and essential oil was performed by method of Oomah et al, (1996). Methanolic extract and essential oil (10 μL) was three times dissolved in distillated water. Furthermore, 200 μL of diphenylboric acid 2-aminoethyl ester solution was added in the mixture and solution was measured at 404 nm. Luteolin as standard for calibration curve was used in the range from 0.1 to 10 mg/L.

Antioxidant assays: DPPH and ABTS: For DPPH assay, the antioxidant activities of the extract and essential oil were expressed as percentage of decolorization of a solution of the stable radical DPPH (2,2-diphenyl-1-picrylhydrazyl radical) at 517 nm.The Trolox equivalent antioxidant assay (TEAC) employed in this study gives a measure of the antioxidant activity of methanol extract and essential oil under study. For this purpose 10 mL of ABTS (2,2'-azino-bis (3-ethylbenzothiazoline-6-sulphonic acid) solution was prepared from 39.23 mg of ABTS and 7.17 mg of potassium thiosulphate disolved in Nanopure water to volume.

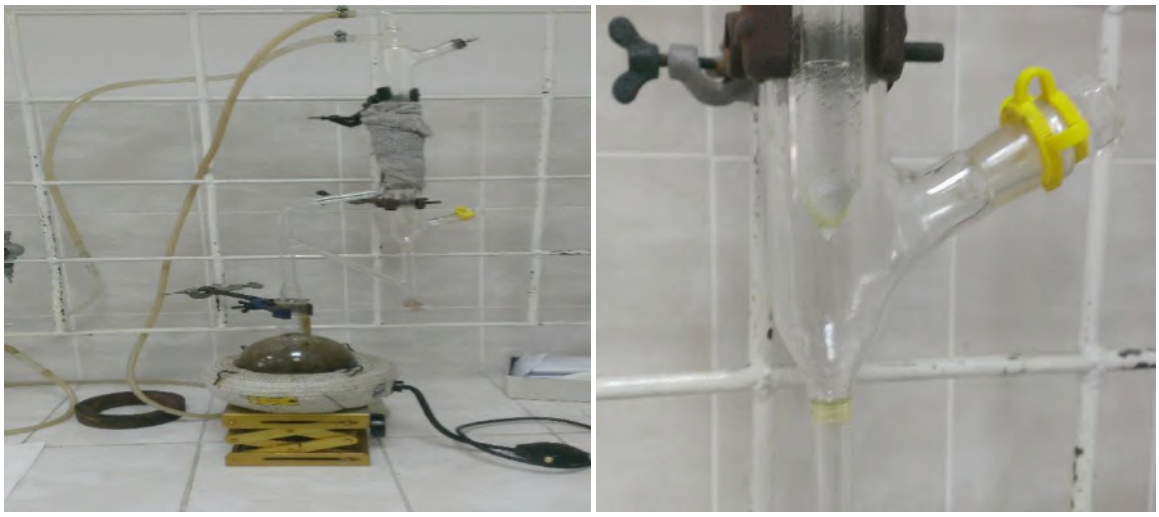

Fig. 1. Isolation of essential oil from *Mentha piperita L.* by hydrodestilation.

Results and Discussion

The qualitative and quantitative compositions of the essential oil obtained from Macedonian organically produced *Mentha piperita L.* was presented in Table 1. Twelve components were identified with total abundance of 85.96%. Four compounds had the highest abundance from all identified compounds, in particular: menthol (48.05%), menthone (20.4%), piperitone (8.3%) and piperitone oxide (4.9%). The relative percentages of all other compounds were in the level below 2.5%. The level of total phenolic compounds and total flavonoids for methanol extract and essential oil of organically produced *Mentha pipperita L.* as well as antioxidant activity were presented in Table 2. As we can see from the results, the total phenolic compounds expressed as gallic acid equivalent had higher abundance in comparison to total flavonoids expressed as mg of luteolin/g of dry matter.

On the other hand, menthanol extract had higher level of both classes of polyphenolics in comparison to the level of the same classes of polyphenolics in distillated essential oil. Furthermore, the level of total phenolic compounds for mentanol extract was more than double in comparison to total phenolics found in essential oil. However the difference for flavonoids was around 30% in favor to methanol extract. The higher antioxidant potential by two radicals (ABTS and DPPH) had methanol extract. More precisely, methanol extract had higher antioxidant potential than essential oil which was in good agreement with the results from total phenolics and total flavonoids. On the other hand, TEAC assay showed higher antioxidant potential for both samples in comparison to DPPH assay. If we compare the results from DPPH and ABTS assay for methanol extract and essential oil presented, we can concluded that results are more than double in favor to ABTS assay.

Table 1. Chemical composition of essential oil from *Mentha piperita L.* from Macedonia by GC-FID and GC-MS

	Compound	RT	Area (%)
1.	camphene	947	0.05
2.	sabinene	974	0.10
3	*p*-cimene	1025	0.05
4.	β-pinene	1027	0.01
5.	limonene	1034	1.2
7.	**menthone**	1110	**20.4**
8.	**menthol**	1175	**48.05**
9.	*cis*-carveol	1180	2.2
10.	menthol acetate	1183	0.7
11.	piperitone	1185	**8.3**
12.	piperitone oxide	1199	**4.9**
	Total		**85.96**

Table 2. Total phenolic compounds, total flavonoids and anthioxidant activity of methanol extract and essential oil from Mentha piperita L.

	Total phenolic compounds (mg GAE/g DM)	Total flavonoids (mg Luteolin/g DM)
Methanol extract of *Mentha piperita L.*	**22.42±1.14**	**0.79±0.34**
Essential oil from *Mentha piperita L.*	10.12±0.89	0.54±0.11
	DPPH assay (mg Trolox/g DM)	TEAC assay (mg Trolox/ g DM)
Methanol extract of *Mentha piperita L.*	12.98±1.05	**27.14±2.24**
Essential oil from *Mentha piperita L.*	7.14±0.87	**13.31±0.04**

Conclusion

We concluded that the region of South-east Macedonia had good potential for production of high-quality organically produced *Mint (Mentha piperita L.)* described in details in published surveys of Mihajlov et al. (2015), with appreciable amount of menthol and menthone.
Further investigations will include antibacterial, antifungal and antimicrobial activity of essential oil from different varieties of Mentha plants.

ECONOMIC CHALLENGES OF ORGANIC FARMS IN POLAND

Wioletta WRZASZCZ, Józef St. ZEGAR

Institute of Agricultural and Food Economics – National Research Institute, Poland
*Corresponding author: wrzaszcz@ierigz.waw.pl

Abstract

Agricultural holdings are facing many challenges, which they must meet. These challenges are conditioned, on the one hand by macroeconomic factors, such as progressing globalisation and growing consumers awareness concerning the quality of agricultural products, as well as the need to respect natural environment. On the other hand, farms as enterprises must be ruled by the microeconomic conditions, namely the agricultural production volume and value, as well as satisfactory level of agricultural income. There is common understanding, that only conventional farms can cope with the microeconomic and global challenges.

The purpose of article is verifying, basing on the microeconomic account, if organic farms are able to meet the economic challenges. The article focuses on the analyses of production and economic results of organic farms compared to all private farm covered by agricultural accountancy system in Poland – Farm Accountancy Data Network (FADN) 2012. The study was conducted taking into consideration agricultural land and farming types that indicate specialization of agricultural production. There were calculated the main indicators, namely: land and labour productivity, as well as profitability, using the following categories: total agricultural output, gross farm income, agricultural farm income.

Conducted research in static approach indicated, that organic farms have smaller ability to meet the economic challenges than conventional ones, however, in the long term and with full economic account including the externalities, these relations would probably be opposite in favour of sustainable form of agriculture. On the basis of the relatively unfavourable economic results of organic farms, it can be concluded that the financial support under governmental programmes targeting such a system of farming is inadequate.

Keywords: *Organic farms, microeconomic account, Poland, FADN data*

Introduction

The increasing liberalisation of markets in terms of structural supply surpluses puts competitiveness on a pedestal, meeting of which is essential for the achievement of the economic objectives of agricultural holdings. Competitiveness cannot be achieved at the expense of the natural environment or the food quality. These requirements try to reconcile the organic form of agriculture, which becomes a part of the concept of sustainable agriculture. The key feature of organic agriculture is the use of such methods of agricultural production, which comply with the requirements of soil fertility, plants and animals, with simultaneous care of the other environmental components (Nachtman, 2015; Runowski, 2012; Sołtysiak, 1994).

The development of organic farms is dependent on economic relations and national policy (Wrzaszcz and Zegar, 2014a; Wrzaszcz and Zegar, 2014). Organic production, on the one hand, should not affect the ecosystem sustainability, on the other hand, must meet economic challenges. Meeting these challenges may occur in the way of normal market rules – *via* higher prices and possibly lower costs of production – or (and) targeted support of governmental institutions, primarily in the form of subsidies. The first one is observed for example in American agriculture, while the other in the agriculture of the European Union countries, including Poland.

This article aims at verifying, basing on the microeconomic account, if organic farms are able to meet the economic challenges.

Material and methods

The analysis considered 10,589 farms covered by the Farm Accountancy Data Network in Poland in 2012. The article focuses on the production and economic results of organic farms compared to all individual (private) farms covered by FADN. The guiding principle in the organic system is to cultivate plants in compliance with the standards of the *Good agrienvironmental practices* with due attention to the phytosanitary condition of plants and soil protection. Such farms are obliged to keep an area of permanent grasslands and landscape elements not used for agricultural purposes[8].

For analysed groups of farms, there was presented their number and the basic characteristics of the production potential, measured by the following indicators: the area of agricultural land (AL ha), the labour input (AWU[9]), the stocking density (LU[10]) and the standard gross margin (ESU[11]). The study was conducted taking into consideration farming types that indicate specialization of production, namely: specialised in field crops (type: I), in permanent crops (III) and in rearing grazing livestock (IV), non-specialised with mixed crops (VI), with mixed livestock (VII) and with mixed crops and livestock (VIII).

Subsequently, the economic efficiency of farms was assessed by means of the following indicators: land productivity (Total Output/Agricultural Land; Gross Farm Income/Agricultural Land); labour productivity (Total Output/Annual Work Unit; Gross Farm Income/Annual Work Unit); land profitability (Family Farm Income/Agricultural Land); labour profitability (Family Farm Income/Family Work Unit). *The Total Output* of a farm indicates the economic result of farming. It is the outcome of the sum of the crop and livestock production value and other activities. *Gross Farm Income* is the result of difference of total output and the total intermediate consumption (total specific costs – including inputs produced on the holding – and overheads arising from production in the accounting year), adjusted for the outcome of the balance of current subsidies and taxes. It accounts the impact of the agricultural policy on the economic situation of farms by means of the system of subsidies and taxes (Goraj, 2009). Net value added adjusted for the cost of total external factors and the balance of subsidies and taxes on investments indicates *the level of Family Farm Income* (Bocian and Malanowska, 2014). *Family Farm Income* is the primary economic goal of farmer's agricultural activity and it is an essential determinant of a farmer family living standard, and hence it may be an important indicator of farm efficiency in agriculture. The issue of factor productivity is especially significant in the context of food security, thus profitability factor has particular importance in the evaluation of labour remuneration and farmer`s family general income. The volume of income illustrates the level of compensation for the involvement of their own factors of production in the farm's operations and for the risk taken by a farm manager in a given financial year.

[8] The list of legal regulations in the field of organic farming system can be found on the website of the Ministry of Agriculture and Rural Development: (http://www.minrol.gov.pl).

[9] 1 AWU (Annual Work Unit) is equivalent to full-time own and paid labour, i.e. 2,120 hours of work a year. 1 FWU (Family Work Unit) is the equivalent of a full-time labour of a farming family member.

[10] 1 LU – Livestock Unit is a conventional unit of farm animals with a mass of 500 kg.

[11] Sum of standard gross margins – the difference between output and specific (direct) costs of all activities occurring on the farm – indicates the economic size of the farm, otherwise the productive potential of the farm. 1 ESU is equivalent to EUR 1,200. The standard gross margin is the average gross margin by region. Standard gross margin on a particular crop or animal is a standard (average of three years in a particular region) value of production obtained from one hectare or from one animal minus the standard direct costs necessary for production.

Results and discussion

Organic farms constitute a small fraction – 4% of FADN farms` population (Table 1). The average area of the organic farms amounted to 37 ha, just like the size of an average individual one. Only 40% of organic farms had an area of at least 50 ha, whereas every second farm had such an area (Chart 1a). The level of labour inputs was slightly lower in the case of organic farms. The average size of a herd of animals in the individual farm in question amounted to 27 LU. In comparison to that, the organic farms significantly deviated from the average (14 LU). Every fifth individual farm didn't conduct animal production, whereas among organic ones it was every fourth. Such a result is not justified for organic farms. The main idea of organic production is to keep a closed circuit of nutrients within a farm, which should lead to mixed agricultural production. The presented data confirm the discrepancy between theory and practice in agriculture[12]. The differences in the livestock population of the selected groups of farms were reflected in the total value of their assets. Organic farms were characterised by the lowest value of the assets (ca. ¼ as compared to an average individual farm). The standard gross margin made it possible to synthetically evaluate the economic potential of the identified groups of farms. Organic farms differ in this respect from the average individual farm – the result was lower by 38%. This result is a proof of the importance of animal production and diverse crop production for the value of the standard gross margin. Multifunctionality of agricultural production and diversified crop structure contributes not only to the assurance of environmental benefits, but also tangible economic benefits.

Table 1. Production potential of analysed farms` groups (average per farm)

No.	Specification	Total farms	Organic farms (ECO)	ECO/Total (%)
1	Number of farms	10 589	422	3,9
2	Agricultural land (ha)	36,8	37,4	101,5
3	Labour input (AWU)	2,01	1,89	94,0
4	Livestock units (LU)	27,3	14,4	52,6
5	Total assets (thousand EUR)	294,3	214,5	72,9
6	Standard gross margin (ESU)	21,7	13,5	62,2

Source: Prepared on the basis of FADN 2012 data.

About 60% of the analysed farms` population are specialized holdings – mainly focused on field crops (I) and rearing grazing livestock (IV, Chart 1b). Among the non-specialized farms – with the so-called mixed-production – dominate the holdings, with mixed crops and livestock (VIII). However, organic farms are more likely to lead a specialized agricultural production.

The value of agricultural production is predominantly determined by the total output value. The relatively largest importance of the other kind of production can be seen in organic farms (3% of total output value), which results from slightly different organisation of such farms. In the case of many organic farms, agricultural production is supplemented for instance with agri-tourism based on the assets of a farm. Land productivity on an average individual farm amounted to EUR 1,691/ha[13] (Table 2). Compared to that, organic farms deviated from the average individual one in particular – their result was lower by 58%. The presented figures confirm lower land productivity on farms that provide services for the natural environment – of course if we measure it in static terms. It is very likely that in the long term and with a full

[12] Studies have demonstrated, that there is a growing problem involving not only limiting the scale of animal production on organic farms, but even giving up such production (Nachtman, 2014; Wrzaszcz and Zegar, 2014a).

[13] The exchange rate in FADN 2012: EUR 1 = PLN 4,3177.

account of the costs and benefits – of the externalities – these relations would be the opposite. Organic farms – just like in terms of land productivity – had significantly lower results in **labour productivity** (with the difference amounting to 54%).

Source: Prepared on the basis of FADN 2012 data.

Total intermediate consumption on an average individual farm amounted to EUR 1,003/ha (Table 2). In this respect, farms that provide services for the natural environment were characterised by a lower production intensity. Organic farms distinguished themselves in this respect in particular, which results from the specifics of this production system that is based on small and justified use of external means of production.

The Common Agricultural Policy instruments that are currently under implementation determine the opportunities for obtaining financial support by agricultural producers through environmental restrictions and for compensating the services provided for the environment. These determinants have the form of regulations, such as cross-compliance, that are linked to

direct payments, refer to diversification of that type of payments depending on the chosen plant species and animals production and include the activities for the sustainable development in the form of e.g. environmental programmes[14]. The implementation of these measures by farmers is confirmed by the level of subsidies they receive. An account drawn up in accordance with the FADN methodology distinguishes the category of the balance of subsidies and taxes connected with current productive activity. The category indicates the direction of the transfer of funds to a farm when it adopts a positive value. For organic farms, this category was significantly higher than the average result for the population of the analysed farms (48%). About one third of current subsidies are organic subsidies, that accounted 90% of agri-environmental payments of organic farms. These differences indicate that the measures taken for the environment are compensated by the state with funds, however there is still a question whether they are sufficient.

Gross farm income on an average individual farm amounted to EUR 904/ha. The conducted static analysis indicates that organic farms are incomparably lower than the other farms in terms of produced volume of agricultural production (31%), and policy instruments compensate for such differences only to a certain degree. Despite a high share of the balance value of current subsidies and taxes in the gross farm income in the case of organic farms (51%), their results are still below an average one.

Land and labour profitability in family farms are illustrated in table 2. On average, the use of 1 ha of utilised agricultural area made it possible to generate income amounting to EUR 633/ha. Organic farms still have a significant *economic delay* compare to other analysed farms (EUR 425/ha, the difference 33%). The presented results may be a sign of insufficient *legal and financial protection* of that production system because they compensate for a small part of the low profitability of the production factors. One full-time worker of family labour on an average individual farm (that indicate labour profitability) achieved the result of EUR 13,363/FWU. Unfortunately, organic farms are still placed on unsatisfactory position (EUR 10,334/FWU, the negative difference amounting to 23% compared to the average FADN farm), which strengthens previous conclusions on this system of farming.

In the analysed population, farms specialized in permanent crops (III) characterised with the highest **land productivity and profitability**, while on the opposite place, holdings specialized in field crops are located (I, Chart 2a). Regarding organic farms, specialized ones generate less satisfactory production and economic results than non-specialised (Chart 2b). This result is promising in the light of sustainable development – diverse organic production not only provides relatively greater environmental benefits, but also economical ones. However, organic farms remain far behind average individual holdings in terms of land productivity and profitability (the difference in the case of total output, gross farm income and family farm income per hectare of AL, was appropriately 58%, 31% and 33%).

Farms with mixed livestock (VII) characterize with relatively less surface of agricultural land, resulting in a higher production outcome per hectare. While the level of unit costs (intermediate consumption measured per unit area) is nearly twice higher in those farms compared to entities specialised in field crops (I), simultaneously having lower subsidies to current activity. The level of subsidies, connected with, among other, with providing environmental services as a part of the Rural Development Programme, was a significant factor determining the higher profitability of farms specialized in field crops (I).

Organic farms – like in terms of land productivity and profitability – significantly deviate from all individual farms *in minus* in the range of **the labour productivity and profitability** (the difference in the case of total output, gross farm income and family farm income per work unit, amounts appropriately to 54%, 25% and 23%, Chart 2c,d). Regarding the farming

[14] www.minrol.gov.pl.

type, agricultural holdings specialized in field crops (I) achieve the best results in this range, in contrast to those with mixed crop production (VI). This relationship is maintained also in the case of organic farms. In the case of organic farms, the attention is put towards agricultural holdings specialized in permanent crops (III), where in spite of relatively lower unit value of total output per annual work unit, unit gross farm income and family farm income exceed the average result for all organic farms. The national system of agri-environmental subsidies particularly prefers this farming type, that is reflected in the presented economic account (Table 3).

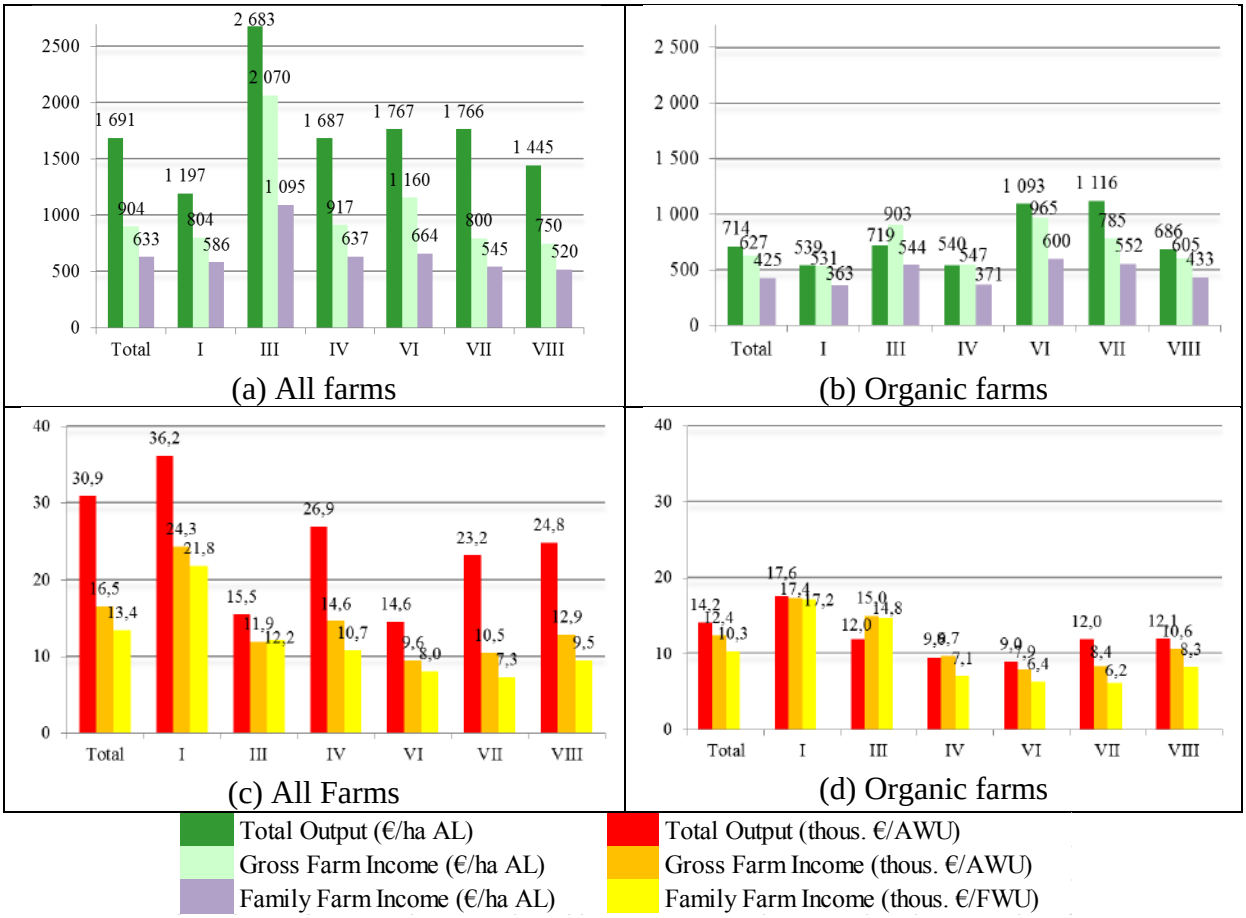

Chart 2a-d. Land (a, b) and labour (c, d) productivity and profitability of all and organic farms
Source: Prepared on the basis of FADN 2012 data.

Table 3. The level of agri-environmental subsidies in total and organic farms

Subsidies	Total	I	III	IV	VI	VII	VIII
Agri-environmental subsidies (€/ha AL)	22,3	25,4	57,9	15,5	26,9	18,2	24,0
Organic subsidies (€/ha AL)	4,0	3,6	56,6	4,3	11,8	1,3	2,4
Agri-environmental subsidies/Family Farm Income (%)	3,5	4,3	5,3	2,4	4,0	3,3	4,6
Organic subsidies/Family Farm Income (%)	0,6	0,6	5,2	0,7	1,8	0,2	0,5
Subsidies	**Organic**	**I**	**III**	**IV**	**VI**	**VII**	**VIII**
Agri-environmental subsidies (€/ha AL)	112,6	96,0	258,3	107,5	139,0	98,0	89,1

Agri-environmental subsidies/Family Farm Income (%)	26,5	26,5	47,5	29,0	23,2	17,8	20,6
Organic subsidies/Family Farm Income (%)	23,7	25,3	46,9	22,6	22,0	16,0	18,6

Source: Prepared on the basis of FADN 2012 data.

Conclusion

The number of organic farms is not numerous. Production and economic results of organic farms are significantly lower than for the average individual farm, both in terms of livestock population, assets and the generated standard gross margin. This result is a proof of the importance of animal production and diverse agricultural production for the value of the standard gross margin.

Organic farms do not match the other farms in terms of the generated production volume and land productivity.

Organic farms could not match the average ones in the range of land and labour profitability. Unfortunately, also in this regard, organic farms generate worse economic effects. On the basis of the relatively unfavourable economic results of organic farms, it can be concluded that the financial support under governmental programmes targeting such a system of farming is inadequate.

Regardless the farming type, economic efficiency of organic farms is lower compared to the average individual farms.

Regarding the farming type, in particular, organic farms specialised in field crops (I) and in rearing grazing livestock (IV) generate significantly lower results in terms of land productivity and profitability in relation to average individual farms of mentioned types.

Conducted research in static approach indicates, that organic farms have smaller ability to meet the economic challenges than conventional ones, however, in the long term and with full economic account including the externalities, these relations would probably be opposite in favour of sustainable form of agriculture.

THE POSSIBILITY OF USING WASTE BIOGAS PLANT (DRY RESIDUE AND PELLETS) AS FERTILIZER

Natalia NIKITSKAYA

Perm State Agricultural Academy, Russia
*Corresponding author: natali_nikitska@mail.ru

Abstract

Increased requirements to protect the environment from pollution, ever increasing cost of waste rekindled interest in the anaerobic digestion of biomass in biogas plants. Fermented sludge from biomass is a valuable fertilizer, since the fermentation process is stored in the organic or ammonium form almost all of the nitrogen. It does not contain pathogenic microflora and viable weed seeds, suitable for aerobic composting or direct use as a fertilizer in the form of solids or pellets. The purpose of the study - to explore the possibility of using waste biogas plant as fertilizer in a laboratory experiment. The most effective stimulation of the fertilizer for growth and weight of aboveground parts of barley are pellets at a dose of 2.20 g / kg 4.28 g / kg and a dry residue at a dose of 1.36 g / kg. The least effective option turned making pellets at a dose of 1.12 g / kg. This is because the sawdust pellets contained in conifers has a high ratio of carbon to nitrogen, for supplying negative microorganisms which does not compensate for the nitrogen contained in the pellets in a minimum dose. Making pellets and solids at all doses increased cellulolytic activity to 79-91 % in the case of pellets (with increasing doses reduced activity) to 82-90 % in the case of the dry residue (increasing doses led to an increase in activity). Most cellulolytic activity observed when making pellets at a dose of 1.12 g / kg solids in a dose of 5.42 g / kg.

Keywords: *biogas, pellets, organic fertilizer, barley, laboratory experience.*

Introduction

Annually Russianlivestock farms produce 200-250 million tons of manure and about 600 million tons of liquid effluents. Organic waste without recycling can significantly pollute the environment. The chemical composition of manure is a valuable secondary resource. Therefore the main objective of its use is the use as organic fertilizer on agricultural land.

The first of the ecological problems of industrial livestock production is the transformation of potentially hazardous environmental contaminant – manure, relatively strong, fast, and complete organic fertilizer, rich in nutrients. You need to look for new ways of processing that would meet the following requirements: disinfection, ensuring long-term storage with maximum retention of nutrients, elimination of waste, polluting the environment. At the same time, it is important that they are economically justified. For the processing of manure can be applied biotechnology and by regulating the activity of microorganisms, to obtain high quality products, while preserving the environment (Orlova, 2009).

Increasing requirements to protect the environment from pollution, increasing the cost of recycling has revived interest in the anaerobic digestion of biomass in biogas plants. The biogas plant not only lower the hazard class of livestock waste and contribute to production of organic fertilizers, which are due to the anaerobic treatment is easily absorbed by plants, but also allow to obtain electrical and thermal energy (Lysenko, 1998). The fermented material slurry after processing of biomass is a valuable fertilizer, as in the fermentation process and stored in the organic or ammoniums form almost all of the nitrogen. It does not contain pathogenic microorganisms and viable weed seeds suitable for aerobic composting or direct use as fertilizer in the form of solids or pellets.

The aim of the study was to explore the possibility of using waste biogas plants as fertilizer laboratory experience.
In accordance with the aim, the following tasks were set:
1. Agrochemical analysisof soilis making for laboratorial test.
2. Influence assessment of different forms and doses of fertilizers from cattle manure in comparison with urea on growth of the aerial parts of barley.
3. Influence assessment of different forms and doses of fertilizers on biometrics of barley.
4. Influence assessment of different forms and doses of fertilizers on the effect size of phytostimulation.
5. Influence assessment of different forms and doses of fertilizers on the cellulolytic activity of the soil.

Materials and methods

The objects of study are the dry residue and pellets.The dry residueisobtainedby separation from cattle manure. Pellets are made by line LCC-500 from the enterprise "Integrated recycling system" the city of Orenburg (Russia). Line for the production of fertilizers in the form of pellets required for the production of fuel pellets from the solid fraction of the biogas plant. These pellets can be used as fuel for heating. The heat transfer is several times higher than that of wood of wood for 1 kg of fuel: allocated 4400 kcal of heat energy. However, it is worth noting that the granules of litter and manure are almost unusable to pellet boilers. They long to ignite, has a bad smell and the combustion temperature is ineffective. Nevertheless, the experimenter said, “It is best to use granular manure as fertilizer, not for burning”. The company "Energorezhim" (the city of Perm (Russia)) on the enterprise "Integrated recycling system" the city of Orenburg (Russia) in 2012 launched a line of pellet production from cattle manure. This product can be used in dry form as a soil fertilizer in recommended doses. The same can be soaked in water. This gives an aqueous solution of an organic fertilizer with all necessary nutrients.
According to research conducted by the Testing laboratory FGPAS "Orenburg" the content of basic nutrients in dry matter: organic matter is 57.5%, total nitrogen – 5.53 %, total phosphorus – by 1.4 %, total potassium was 8.8 %, nitrate nitrogen – 10388 mg/kg ammonium nitrogen – 82946 mg/kg, movable copper – 3.6 mg/kg, movable zinc – 17.4 mg/kg, movable iron to 78.3 mg/kg.
The content of basic nutrients in the pellets: total nitrogen – 6.7%, total phosphorus – 1.1%, total potassium of 7.0%, sawdust coniferous trees – 20.0% by weight.
For comparison we used nitrogen fertilizer urea $CO(NH_2)_2$ with a nitrogen – 46.2%.
The experiments were performed in the chemical laboratory of ecology Department of the Perm state agricultural Academy in the 2012-13 year. Soil for laboratory experiences taken in Krestyanskih – farm SP Raszyn. Soil is sod-podzolic heavy loam.
Agrochemical analysis was performed according to standard procedures. Determination of phytotoxicity was carried out by means of seedlings. The method is based on the reaction of the test culture, when applied to the soil or other compounds, which reveals the toxic effect or a stimulating effect of introduced substances. As the test object was used germinated seeds of barley varieties Rodnik Prikamya. Calculation of doses of fertilizers produced on the active substance (nitrogen) per 1 kg of soil.
Options: without fertilizer (control), urea 0.16 g/kg, urea 0.32 g/kg, urea 0.64 g/kg, dry residue of 1.36 g/kg, residue is 2.71 g/kg dry residue 5.42 g/kg, pellets of 1.12 g/kg, pellets 2.20 g/kg, pellets to 4.28 g/kg.
The experiment was conducted in triplicates. In a plastic container with a volume of 500 cm^3 was placed 400 g of the prepared substrate is pre-wetted to 60% of moisture capacity. In each vessel planted 15 seeds of the studied culture. On the fourth day the container was placed on a

rack with lighting within 24 hours. In the course of the experiment was maintained constant humidity. Length of experience is 14 days. When experiment plants were cleared from the ground and dried. Then experimenters determined the height of seedlings of barley, root length, weight of aerial parts and roots (Orlov, 2002).

The effect of phytostimulation (FS) was calculated according to the weight of aerial parts and roots of the following equation:

$$FS, \% = (M_H - M_K)/M_X \text{ ,where}$$

M_K is the mass of plants in the control vessel, g;

M_X is the mass in the vessel of the investigated variants, g.

To determine cellulolytic activity of the soil in the Petri dishes were taken 100 g of soil, with subsequent irrigation of up to 80% of full soil water content. 10 pieces of linen fabric 1x1 cm evenly placed in cups with soil. After that, the cups were covered with lids and left for 30 days at room temperature. The experiment was conducted in four replications. Options experience is similar to previous experience.

Results and discussion

To conduct the study and determine the optimal doses of fertilizer selected sod-podzolic heavy loam soil in farm SP Raszyn, which is located in the village of the Katishi of Krasnokamsk district of Perm Krai. Next table shows results of agrochemical analysis of soil.

Table - Agrochemical indicators of sod-podzolic soil

Humus, %	pH_{KCl}	Hr, mEq/100 g	S, mEq/100 g	PC, mEq/100 g	V,%	$N_{tot.}$, %	$P_2O_{5mob.}$, mg/kg
5.4±0.6	6.2±0.2	1.1±0.2	23.4±1.3	24.5	95.6	0.37±0.03	198±62

Humus contributes to the formation of stable soil structure, provides a favorable water-air regime, gives the soil buffering in relation to nutrients, especially nitrogen. High level of microbiological activity of soils is also supported by the high level of humus. Thus, the humus is an important indicator of soil fertility. The humus content in the studied soil was 5.4%, typical sod-podzolic heavy loamy soils (3-6%).

Actual acidity is due to the content of free hydrogen ions in the soil solution and is measured on the pH value of the aqueous extract from the soil. In the studied soil reaction is neutral environment (6.1-6.5).

The sum of exchangeable bases (S) – total amount of alkali and alkaline earth cations absorbed by the soil and is able to exchange, depends on soil texture and humus content. In the studied soil, the amount of exchangeable bases – 23, which exceeds typical of sod-podzolic soils a value of 15-20 mEq/100 g of soil.

The cation exchange capacity (PC) is the sum of all the cations absorbed by the soil. It depends on granulometric composition and content of humus. The heavier the soil, the higher PC. In the analyzed soil, the PC is moderately low (15-25 mEq /100 g of soil).

The degree of saturation of soil base (V) shows the percentage of exchangeable bases in the total absorption capacity. It used to evaluate soils in relation to the saturation of bases. In the analyzed soil is high (>90%).

Nitrogen is a part of the composition of organic matter of the soil. Total content of nitrogen in the surface layer of soils varies in the range of 0.10 to 0.85%.

The total content of phosphorus depends on the mechanical composition of the soil and humus. The heavier the texture, the higher the phosphorus content. The content of phosphorus, according to the classification Kirsanov high (151-250 mg/kg) (Kovda, 1988; Kovriga, 2010).

The influence of different forms and doses of fertilizers on the dynamics of growth of the aerial parts of barley. Measure the length of the aerial part was conducted a week after the

start of the experiment. At the first measurement with the lowest value of the length of the aerial part was observed when introducing solids at doses 2.71 and 5.42 g/kg, and 37.0 and 37.8 mm, respectively. The length of the aerial part in the control dimension is slightly above – 40.1 mm. The highest value when making with urea – 55.8 mm, 47.6 and 50.1 mm.

In the second measurement the minimum length of the aerial parts was observed in the control variant and in making pellets of 1.12 g/kg and dry residue 5.42 g/kg. The maximum length of the aerial parts was observed in the urea. The third measurementwas like the first two measurements. The fourth measurementshown the smallest length of the aerial part remained in the version with the introduction of pellets at a dose of 1.12 g/kg – 201.2 mm. The maximum length of options when introducing solids at a dose of 1.36 g/kg (254.1 mm) and control with urea in doses of 0.16 g/kg 0.32 g/kg, 0.64 g/kg – 269.3 mm, 291.2 and 267.5 mm, respectively.

The effect of different doses and forms of fertilizers on biometrics barley. Biometrics – the main parameters characterizing the growth and development of culture. These include the height of the aerial part, root length, weight of aerial parts and roots, etc. According to the data obtained the most effective fertilizer to stimulate growth and increase the weight of the aerial parts of barley are pellets in the dose of 2.20 g/kg, 4.28 g/kg and the dry residue in a dose of 1.36 g/kg. This effect may be caused by a more uniform distribution of solids in the soil, and consequently, the reduction necessary for plant nutrition dose.

The introduction of ureawasalso effective, which compares the use of waste biogas plant. These options have the greatest effect phytostimulation compared to the rest. The least effective dose for the posting turned out to be the pellets at a dose of 1.12 g/kg. This is because contained in the pellets sawdust of coniferous trees has a high ratio of carbon to nitrogen, adverse to food microorganisms, which does not compensate for the nitrogen contained in the pellet in a minimal dose.

The effect of different doses and forms of fertilizers on the effect of phytostimulation. The data indicate that the greatest effect on root length and their weight had pellets at a dose of 2.20 g/kg and the dry residue in a dose 5.42 g/kg. Large mass, but the smaller root length showed the options with the introduction of pellets per dose to 4.28 g/kg of dry residue in a dose of 1.36 g/kg, and the control variant and urea applied at a dose of 0.32 g/kg. The greatest effect of phytostimulation was observed in the variant with urea at a dose of 0.32 g/kg.

The influence of different forms and doses of fertilizers on the cellulolytic activity of the soil. Enzymatic activity of soil can be used as a diagnostic indicator of fertility of different soils, because the activity of enzymes reflects not only the biological properties of soil and their changes under the influence of agroecological factors. The cellulolytic capacity of the soil is one of the indicators of the total activity of soil microorganisms and soil fertility. It can serve as a characteristic of the transformation of organic matter, the involvement of hard to reach forms of carbon in the biological cycle and ultimately determines the level of soil fertility (Secondyou, 2010). According to the data obtained highest cellulolytic activity was observed when you make pellets at a dose of 1.12 g/kg and of dry residue in the dose 5.42 g/kg. Stimulation of activity destroys the cellulose microorganisms can be caused by the presence in these fertilizers movable of copper, zinc, manganese and iron. Lowest cellulolytic activity when urea 0.64 g/kg. Depressing effect of high doses of urea may be caused by excess nitrogen and lack of other nutrients for microorganisms.

Conclusion

On the basis of laboratory experiments with dry residue and pellets of cattle manure on sod-podzolic soil in the laboratory of ecology Department of the Perm state agricultural Academy (Russia), we can draw the following conclusions:

Investigated sod-podzolic soil, heavy granulometric composition, has much humus, a neutral reaction medium, moderately low cation exchange capacity, high degree of saturation with bases characterized by a high content of phosphorus.

The dynamics growth investigation of the aerial parts of barley showed that throughout the period of observation of maximum length reached the plants in the variants with the introduction of solids at a dose of 1.36 g/kg and urea, the lowest indices in the pellets at a dose of 1.12 g/kg.

Investigation of the effect of introducing different forms and doses of fertilizers on biometrics of barley showed the greatest effect on the length and weight of the aerial part from the making of the pellets at a dose of 2.20 g/kg and 4.28 g/kg, dry residue at a dose of 1.36 g/kg. Is also effective was the introduction of urea.The smallest effect on the height and weight of the aerial part had pellets at a dose of 1.12 g/kg. The length and weight of roots of barley greatest effect was influenced by the introduction of dry residue at a dose 5.42 g/kg and pellets at a dose of 2.20 g/kg. The smallest effect was from urea at a dose of 0.64 g/kg.

Investigation shown the greatest phytopromotionaleffect was when you make pellets at a dose 4.28 g/kg of dry residue in a dose of 1.36 g/kg. But, compared with urea, called this effect was less.

The most intensive decomposition of cellulose in the studied soil was observed when depositing pellets of 1.12 g/kg and dry residue 5.42 g/kg. Lowest cellulolytic activity when urea applied at a dose of 0.64 g/kg.

Abstract

Use of mineral fertilizers is one of the most important factors determining the size and stability of productivity of crops in Perm Krai. We conducted researches on studying of efficiency of mineral fertilizers and biological nitrogen on productivity and quality of barley at cultivation on a sod-podzolic heavy loam soil. Researches showed that the level of productivity of barley depended on mineral fertilizers and preceding crop. When using a clover of 2 years of use as the it is got the reliable increase of productivity in comparison with barley and a lupine. On a lupine, is traced only the tendency of increase in productivity of barley since the increase in comparison with barley made 0.45 t/ha ($LSD_{0.95}$ = 0.47 t/ha). Mathematical processing of results showed that productivity barley after on barley and on a lupine more depends on nitrogen. On the basis of the results received in experience are developed for each predecessor the production functions characterizing quantitative dependence between productivity of barley and doses of fertilizers. Quality of grain also depended on the studied factors. Best grain of barley is received after clover. Each kilogram of the application fertilizer provided depending on option from 0.3 to 29.7 kg of grain. The maximum payback (29.7 kg/kg) is noted in option with use one nitrogen after barley, additional introduction of phosphorus-potassium fertilizers reduces this indicator. The similar tendency is tracked and on the lupine predecessor. After clover payback of 1 kg of mineral fertilizers is much lower that is explained by a low increase of productivity barley of relatively control.

Keywords: *Mineral fertilizers, biological nitrogen, barley, sod-podzolic soil, yield*

Introduction

The current economic conditions in agriculture do not allow to apply the amount of mineral and organic fertilizers required for crops. Plowing the soil and replacement of perennial vegetation leads to a decrease in revenues of plant residues to the soil, humus mineralization and as a result the degradation of the soil (Mudrykh et al., 2014b). Consequently, one of the urgent problems of agriculture in our region is to find ways to increase the yield of grain by means of alternative sources of organic matter and other nutrients.

According to the Ministry of Agriculture and Food of the Perm region, sown area of barley is about 69 thousand hectares of the total area occupied by the spring grain crops. The average yield of barley in the Perm region in 2014 was 18-22 t/ha. This is a very low yield, as the potential yield of different cultivars of barley is 60-80 t/ha (The Ministry of Agriculture). Achieving this level is only possible if all the elements of barley cultivation technology are followed, while the most important element is to regulate the conditions of mineral nutrition. However, the use of fertilizers in the Perm region remains low. In 2013-2014 14-15 kg of fertilizers has been introduced per hectare of grain field, of which about 5.6 kg was nitrogen. This dose of nitrogen provides only the growth and development of plants in the initial phase. Based on the above statements, the relevant problem of agriculture in our region is to find ways to provide crops with nutrients throughout all the growing season.

The purpose of the research is to evaluate the effectiveness of mineral fertilizers and biological nitrogen on productivity and quality of barley under cultivation on sod-podzolic heavy loamy soil.

Materials and methods

The research was conducted in 2013. Field experiment is laid in a long-term stationary experiment on the field of federal state budgetary scientific institution Perm Agricultural Research Institute in accordance with standard procedure (Dospekhov, 1985) as follows:

Factor A – preceding crop:

A_0 – permanent barley;

A_1 – clover of the 2nd year;

A_2 – blue lupin.

Factor B – mineral fertilizers:

B_0– control (no fertilizers);

B_1 – N_{60};

B_2 – $P_{30}K_{60}$;

B_3 – $N_{60}P_{30}K_{60}$.

There was the triple replication of the experiment variants. Systematic plot allocation in 4 layers. Overall area of experimental plot for Factor A – 300 m^2 (25×12 m), registration plot area – 184 m^2 (23×8 m), for Factor B – 75 m^2 (25×3 m) and 46 m^2 (23×2 m) respectively.

The following fertilizers were used: ammonium nitrate, normal superphosphate, potassium chloride. All fertilizers were applied manually during presowing cultivation. Measurement of barley yield was carried out by a direct method in the phase of full ripeness of grain.

The mathematical processing of the research results was carried out using the Microsoft Excel, STATISTICA 7.0 and MINITAB 14 programs.

The researches were conducted on sod-podzolic heavy loamy soil. The content of humus in the soil varies from very low to low (1.89-2.67%), the pH index from low to medium acid (pH_{KCl} = 4.7-5.42). The content of labile phosphorus is very high (378.7-670.0 mg/kg of soil), exchange potassium from elevated to very high (161.2-428.2 mg/kg of soil).

Weather conditions play an important role in the intake of nutrients from the soil, which subsequently affects the productivity of the crop. Let us consider weather conditions during growing seasons of spring barley compared with the average long-term annual data (Fig. 1).

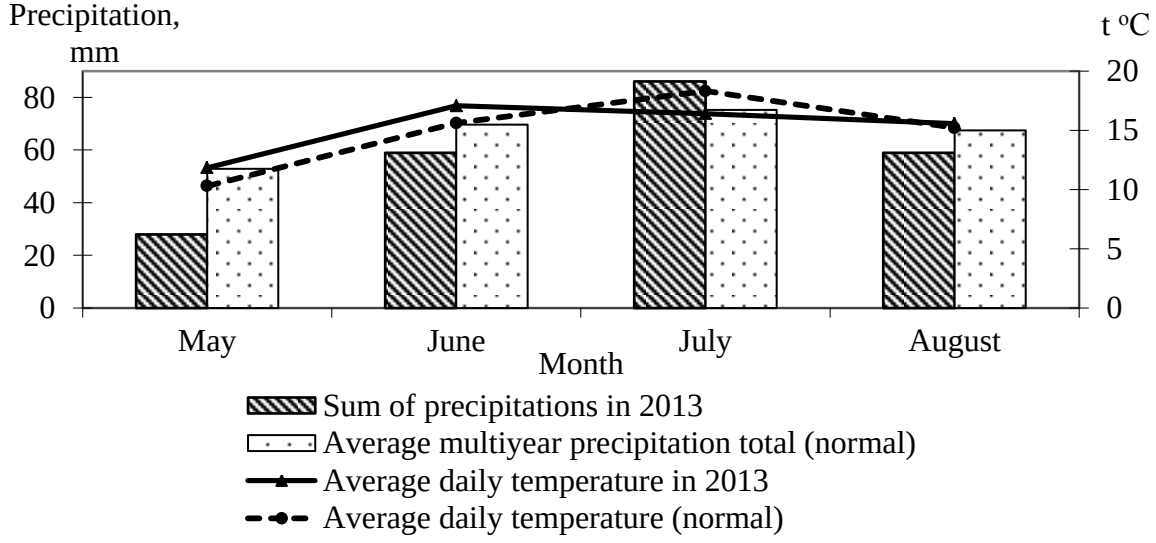

Figure 1. The dynamics of air temperature and precipitation in 2013 and average long-term annual data (according to Perm HMS)

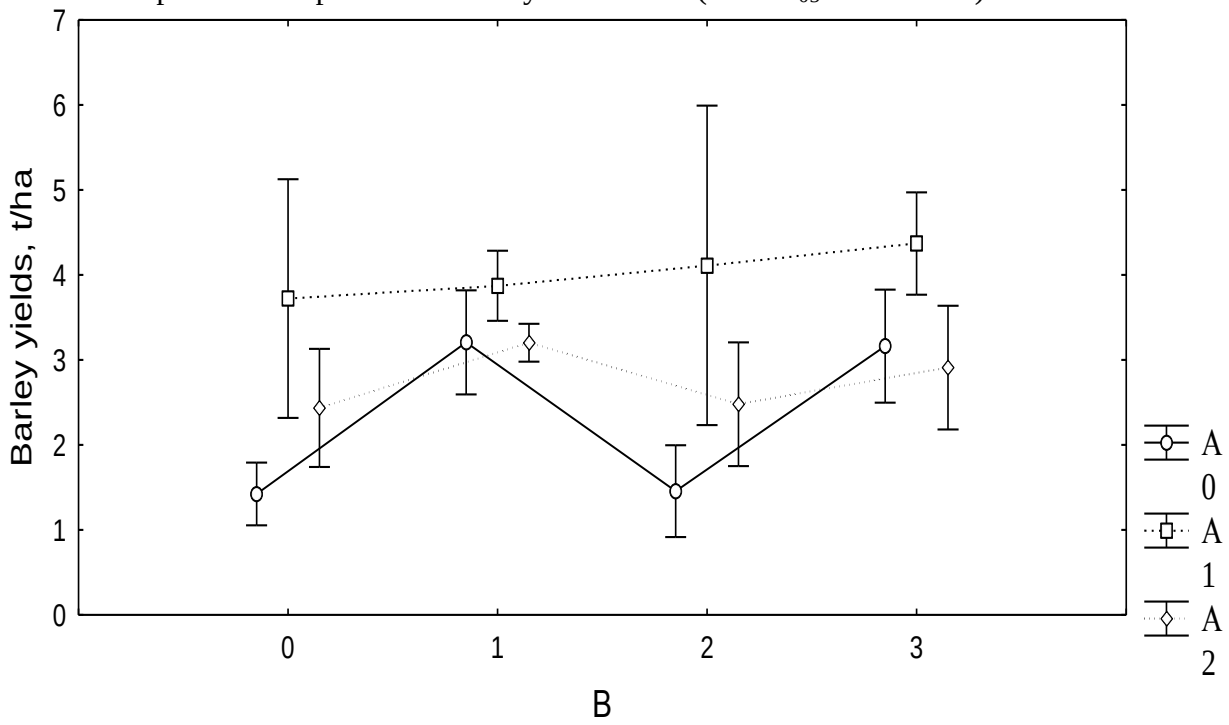
In the first decades of May 2013 there were low average daily air temperature and the abundance of rainfall, which led to the later emergence of seedlings and prolongation of

period from seedlings to tillering. In June, weather conditions were mainly quite favorable for plant growth and development. The tillering phase and establishment of generative organs proceeded in extreme conditions, namely high temperatures and lack of moisture, which further affected the yield of barley. July was characterized by erratic, mostly dry weather, which could lead to lack of grain at certain heads. There were often precipitation including the torrential rains. In this regard, the formation of the barley in July continued rapidly yet growth processes were slow. Weather conditions in August were favorable for harvesting barley. In general, the weather conditions of the vegetation period in 2013 can be described as satisfactory.

Results and discussion

Measurement of barley yield showed that it depends on the fertilizers and preceding crops (Fig. 2).

Considering the main effects of Factor A, we can say that using clover of 2nd year as a preceding crop we obtained significant yield increase compared to permanent barley and lupin. For lupin, in turn, only a tendency to increase the yield of barley can be traced, because increase compared to the permanent barley is 0.45 t/ha (at LSD_{05} of 0.47 t/ha).



Factor A: 0 – permanent barley, 1 – clover of the 2nd year, 3 – blue lupin. Factor B: 0 – control (no fertilizers), 1 – N_{60}, 2 – $P_{30}K_{60}$, 3 – $N_{60}P_{30}K_{60}$ (LSD_{05} for main effects of Factor A – 0.47 t/ha, Factor B and AB – 0.32 t/ha; particular I differences – 0.94, II differences– 0.55 t/ha)

Figure 2. Barley yields, t/ha

Considering the particular differences it should be noted that in the variants without nitrogen fertilizer bean preceding crops have provided a significant increase in yield of barley grain. For example, in the control group of permanent barley we obtained yield of 1.43 t/ha, in clover of the 2nd year – 3.72, in lupin – 2.44 t/ha. When applying nitrogen fertilizer, only clover of the 2nd year has shown significant increase in the version with complete mineral fertilizer.

Evaluation of the main effects of Factor B shows that phosphorus-potassium fertilizers did not provide a significant increase in yield of barley grain. Significant increment (0.8-0.9 t/ha) was

only observed with nitrogen fertilizer in comparison with both the control and with $P_{30}K_{60}$ variant.
Particular second-order differences indicate that the most pronounced increment due to nitrogen fertilizers was obtained by using them with permanent barley – 1.78 t/ha compared to the control and 1.70 t/ha with phosphorus-potassium fertilizers.
The mathematical processing of the results showed that both the permanent barley and lupine yields depend more on nitrogen. The correlation coefficient was 1.000 and 0.942 respectively. Yields of barley with these preceding crops were practically independent of the use of phosphorus-potassium fertilizers. By clover seam, yield was largely dependent on the phosphorus-potassium nutrition (r = 0.903) and to a lesser extent on nitrogen (r = 0.416).
Based on the results obtained in the experiment, production functions describing the quantitative relationship between the barley yield (t/ha) and doses of fertilizers were designed for each preceding crop. These models are as follows (Table 1).

Table 1. Regression models predicting yields of barley

Preceding crop	r	Regression models	R^2
permanent barley	0.96	$У^* = 1.44+0.0291X_1+0.00017X_2$	0.95
clover of the 2nd year	0.98	$У = 3.70+0.00342X_1+0.0148X_2$	0.96
blue lupin	0.65	$У = 2.52+0.100X_1-0.0042X_2$	0.57

*У – barley yield, t/ha; X_1 – dose nitrogen, kg/ha; X_2 – dose phosphorus, kg/ha.

Using these models, we can predict the level of yields of spring barley depending on doses of mineral fertilizers and preceding crops (Table 2).

Table 2. Trend of barley yields and deviation from it

Doses, kg/ha			Barley yields (fact.), t/ha	Trend of barley yields, t/ha	Deviation from trend, %
N	P	K			
Preceding crop – permanent barley (A_0)					
0	0	0	1.43	1.44	1.2
60	0	0	3.21	3.19	-0.6
0	30	60	1.46	1.45	-0.8
60	30	60	3.16	3.19	0.9
Preceding crop – clover of the 2nd year (A_1)					
0	0	0	3.72	3,70	-0,6
60	0	0	3.87	3,91	0,8
0	30	60	4.11	4,14	0,7
60	30	60	4.37	4,35	-0,5
Preceding crop – blue lupin (A_2)					
0	0	0	2.44	2,52	3,3
60	0	0	3.21	3,12	-2,7
0	30	60	2.48	2,39	-3,6
60	30	60	2.91	2,99	2,8

According to the obtained data, the deviation of calculated yield levels from the actual ones is low and ranges from -3.6 to 3.3 %. This indicates the high accuracy of the model, i.e. this model can be used to predict the level of barley yield depending on the preceding crops and used doses of mineral fertilizers.
The efficiency of fertilizer use is assessed by the agronomic and economic payback. To improve the economic efficiency of production it is necessary to reduce the cost of

production, increase quality and sales of products at a higher price. To reduce production costs it is necessary to apply modern production technology. Therefore, according to the problem of this study we shall define the efficiency of applying fertilizer on barley in various preceding crops in economic terms.

Significant yield increase due to mineral fertilizers was achieved in variants with doses N_{60} and $N_{60}P_{30}K_{60}$ at permanent barley, $N_{60}P_{30}K_{60}$ after clover of the 2nd year and N_{60} after lupin. Based on calculations, we can conclude that in the variant with the use of nitrogen fertilizers in dose N_{60} for the permanent barley the highest levels of net income (5826.72 rub.) and profitability (120 %) were achieved. In the variant with complete mineral fertilizer the profitability is lower due to increased costs for fertilizer use. The use of nitrogen fertilizer on barley after clover of the 2nd year was not profitable, as the cost of the use of fertilizers exceeds the value of increment. Introduction of nitrogen fertilizer on barley after blue lupine also led to obtaining a positive economic effect, but its profitability will be lower compared to the N_{60} version for the permanent barley. So, at the same cost of use of nitrogen fertilizer, the largest conditional net income from the use of nitrogen fertilizers was gained on the permanent barley – 5826.72 rubles. That is many times more than in the cultivation of barley after lupine.

The annual change in prices for the products and expense items does not allow comparison of payback for measures applied, so the efficiency of fertilizer use is determined by agronomic evaluation (Mudrykh et al., 2014a).

We calculated the agronomic payback, the results are shown in Table 3. The used fertilizers provided different barley grain yield increase, which affected the payback of 1 kg of active material.

Table 3. The agronomic efficiency of mineral fertilizer application

Variants	The yield, t/ha	Return 1 kg of NPK increase in yield, kg/kg	The costs NPK on increase yields grain, kg/t
Preceding crop – permanent barley (A_0)			
0	1.43	–	–
N_{60}	3.21	29.7	33.7
$P_{30}K_{60}$	1.46	0.3	3000.0
$N_{60}P_{30}K_{60}$	3.16	11.5	86.7
Preceding crop – clover of the 2nd year (A_1)			
0	3.72	-	-
N_{60}	3.87	2.5	400.0
$P_{30}K_{60}$	4.11	4.3	230.8
$N_{60}P_{30}K_{60}$	4.37	4.3	230.8
Preceding crop – blue lupin (A_2)			
0	2.44	-	-
N_{60}	3.21	12.8	77.9
$P_{30}K_{60}$	2.48	0.4	2250.0
$N_{60}P_{30}K_{60}$	2.91	3.1	319.1

Each kilogram of applied fertilizer, depending on the variant, provided from 0.3 to 29.7 kg of grain. Maximum payback (29.7 mg/kg) was observed in the variant with nitrogen only in permanent barley, the additional introduction of phosphorus-potassium fertilizer reduces the figure. A similar trend can be seen for lupine as a preceding crop. By clover seam, payback of 1 kg of mineral fertilizers is significantly lower due to the low yield increase relative to the control variant.

Due to the fact that when determining the fertilizer needs for the crop the fundamental parameter is the amount of nutrients required for the yield unit formation, we found it

necessary to determine this value (Table 3). The amount of fertilizers required for the 1 t increase of productivity also varied greatly depending on the variant, the range of variation was 33.7-3000 kg. The amount of fertilizer required to gain an increment of 1 t of barley yields has the same trend, but in the reverse order. At a higher payback of mineral fertilizer its consumption at the formation of the yield unit growth decreased.

Conclusion

Based on the conducted researches to study the effectiveness of mineral fertilizers and biological nitrogen on yield and quality of barley under cultivation on sod-podzolic heavy loamy soil of the experimental field of the state scientific institution "Perm Agricultural Research Institute", the following conclusions can be made:

1. For barley the best preceding crops is a red clover of the 2nd year and lupin.
2. Production functions allow to predict the level of productivity depending on the preceding crops and doses fertilizer.

Abstract

Eastern Serbia region, especially Homolje territory is an important natural resource of a great potential for organic sheep production. Its long tradition of sheep breeding and the quality of lamb meat and dairy products has become well-known. Svrljig type of Zackel sheep is traditionally reared in the hilly - mountain region of Eastern Serbia. It is well adapted to environmental conditions and sustainable breeding systems. Bearing in mind that autochthonous breeds are preferable for organic production due to the fact that they are well adapted to habitat and due to their genetic tolerance to diseases, the autochthonous Svrljig sheep population reared in Homolje territory was chosen for this research. Examination of health status, body score condition, reproductive traits in a population of 342 ewes and growth traits of 412 lambs reared in sustainable livestock farming was performed. Reproductive and lamb growth traits, litter size at weaning (LSW), total litter weight at birth (TLWB), total litter weight at one-month (1TLMW) and total litter weight at weaning (TLWW) were analyzed. Results of health status, basic ewe reproductive traits and lamb growth performance show that autochthonous Svrljig type of Zackel sheep has robust constitution and potential to be the breed of choice for organic production in the hilly - mountain region of Eastern Serbia.
Key words: *Zackel sheep, health status, production traits*

Introduction

One of the primary elements in the organization of organic production is the choice of suitable breeds. Each breed and strain of domestic animals were created through a process of interaction between genome and environment, along with adjustment imposed by man. According to the legal regulations of the methods of organic livestock production (2010), animal species and breeds that are adapted to local growing conditions and resistant to disease are envisaged to be used in organic production (Cojkić et al., 2014.; Savić et al., 2014). When choosing the animals, advantage is given to domestic (autochthonous) animal breeds and strains (Petrović et al., 2009.).

Autochthonous breeds, whose microevolution occurred under the influence of ambient selection factors represent a unique source of genetic variability that enable adaptation to the new conditions and may enable the survival of the population under adverse action of pathogenic microorganisms Organic production legal regulations set high standards which specify the conditions for breeding animals in self-sustaining systems. Animal breeding is based on physiological and ethological needs of the animals. But from the economic aspect of production, it is important to evaluate the reproductive and production potential of the breed.

Reproduction of animals in organic production is carried out through natural mating or artificial insemination. Other methods of biotechnology in reproduction such as embryo transfer, MOET and hormonal induction of estrus are not allowed.

Organic farming is a specific, innovative aspect of production, which brings significant innovations, especially the one relating to veterinary supervision. The regulation is quite strict when it comes to the prohibition of preventive treatment. Health care in organic livestock production is based on the principle of disease prevention. Legislation in this area emphasizes breeding of genetically resistant animals with the improvement of environmental conditions and care.

Economical use of well-adapted indigenous animals is achieved by preserving the diversity of domesticated animal species for the selection procedure and as a source of the gene pool that can confront unpredictable immune challenges.

A good adaptation of the animals to the local environmental conditions allows a maximal expression of their production potential. This is reflected in the quantity and quality of milk, meat, as well as reproductive features for a given species, breed or strain of animals. In sheep breeding the production is mainly focused on the production of meat. Consequently, the goal is to get a greater number of live, vital lambs per ewe, and for lambs to have some better feed conversion and therefore better growth.

This paper presents robustness-related traits of Svrljig type of Zackel sheep which are breeding in several municipalities of Eastern Serbia. The aim of this study was to investigate the potential of the locally adapted Zackel sheep, and the possibility of rational utilization and conservation of this strain of sheep as an important element for rural agro-economic development.

Materials and methods

Animals

In total, 342 ewes, 3 to 5 years old, and 412 lambs of Svrljig type of Zackel sheep breed, traditionally reared in Eastern Serbia, Homolje region, were examined for health status, body score condition, reproductive and lamb growth traits. The evaluation was performed during the winter and spring. During the spring and summer, the sheep were grazed on mountain natural pastures. On the other hand, during the autumn and winter the diet of ewes was based on hay and concentrate. The lambs remained with their mother until weaning at 90 days and fed ad libitum with hay and concentrate with 18% of protein.

Studied traits

Reproductive and lamb growth traits analyses included litter size at weaning (LSW), the sum of the birth weight of all lambs born per ewe lambed (TLWB- total litter weight at birth), the sum of the weights off all lambs on one month of age (1TLMW - total litter weight at 30 days) and the sum of the weights off all lambs weaned per ewe lambed (TLWW - total litter weight at weaning-90 days).

Statistical analysis

The software package Prism Pad v. 6.0 (Graph Pad Software Inc., San Diego, CA, USA) was used for statistical calculations. Reproductive and lamb growth traits were presented by descriptive statistical parameters. Student t-test was used to examine the differences of weight between male and female lambs, twins and single lamb of every measured period (TLWB, 1TLMW, TLWW).

Results and Discussion

The first stage in this study was the evaluating the body condition scoring of sheep. The results of this analysis have shown that all examined sheep were right BSC considering the stage of production.

Monitoring of sheep health carried out based on the Program of animal health protection measures. Based on that, animals are monitoring for Brucellosis (B. melitensis, B. ovis), transmissive spongiform encephalopathy (TSE) and the diagnostictestsin case ofabortions. Percentage of abortionsin the herdwas not asignificant. No one abortionwas notcaused byinfectiousdisease (brucellosis, leptospirosis, listeriosis, and Q fever). Analysis of the reproductive characteristics of Svrljig sheep shown regular fertility. Reproductive traits were in accordance with breed standards.
The results of the constitutional and reproductive traits of ewes as well as body weight of lambs at birth (TLWB), on 30 days (1TLMW) and 90 days (TLWW) are shown in Table 1.

Table 1. Summary of descriptive statistics for constitutional, reproductive and lambs growth traits.

	Lambs			**Ewes**	
	TLWB (kg)	1TLMW (kg)	TLWW (kg)	Body weight (kg)	LSW (lamb)
$\bar{x} \pm SE$	3.39 ± 0.03	8.90 ± 0.04	26.62±0.11	56.25 ± 0.17	1.20 ± 0.02
SD	0.58	0.78	2.16	3.42	0.40
IV	2.0 – 4.7	6.9– 13.0	22.0 – 35.0	48.0 – 67.0	1.0 – 2.0
CV	17.28%	8.78 %	8.10%	6.09%	33.47 %

TLWB- total litter weight at birth, 1TLMW- total litter weight at one-month age, TLWW - total litter weight at weaning, LSW - litter size at weaning

The average TLWB, 1TLMW and TLWW were 3.39 kg, 8.90 kg and 26.62 kg, respectively. In the study of Caro Petrović et al. (2012), performed on the Svrljig type of Zackel sheep, the average birth weight of lambs and weight at 30 days was higher than in our study. On the other hand, the average weight of lambs at 90 days was lower. Indirect lamb selection based on TLWW could be efficient for the studied traits (Roshanfekr et al., 2015).
The mean body weight of ewes on lambing, measured was 56.25 kg. The result is in agreement with study which reported that birth weights of lambs depend on the weight of ewes (Petrović et al., 2011).
In this study litter size at weaning, LSW was 1.20, which is an agreement with Zackel breed characteristics. Differences in reproductive performance could be explained by many factors like genetics, maternal behavior of ewes at different ages, nursing and the differences in maternal effects (Roshanfekr et al. 2015).
The influence of sex of lamb, birth type and lambs` body weight are presented in this study.

Table 2.The differences in body weight of lambs, based on sex and birth type

	Male lamb (n=38)	Female lamb (n=374)	Singles (n=274)	Twins (n=138)
TLWB	4.14±0.39^{AA}	3.01±0.55^{AA}	3.76±0.27 ^{BB}	2.64±0.23 ^{BB}
1TLMW	10.14±1.22 ^{AA}	8.78±0.60 ^{AA}	9.05±0.79 ^{BB}	8.60±0.67 ^{BB}
TLWW	30.73±2.72 ^{AA}	26.14±2.00 ^{AA}	26.66±3.01	26.15±1.91

TLWB- total litter weight at birth, 1TLWM- total litter weight at one-month age, TLWW - total litter weight at weaning: AA, BB - ($P < 0.001$)

In the Table 2. The average body weight at birth (TLWB), at one month of age (1TLMW) and at weaning (TLWW) of both sexes of lambs and birth type were presented.
The differences in TLWB, TLW1 and TLWW between male and female lambs were statistically significant ($P < 0.001$). Likewise, the differences in TLWB, 1TLMW between singles and twins were statistically significant ($P < 0.001$). On the other hand, there was difference in TLWW between birth type, but not statistically significant ($P > 0.05$).
This is in agreement with the results of the other researchers (Abdullah and Tabbaa, 2011.). Gamasaee et al. (2010) stated that the effect of birth type was significant on birth weight of lambs and can be explained by limited uterine space and nutrition of lamb during pregnancy. The difference in weight between single and twin lambs increased from birth to weaning, which could be attributed to that singles were more capable of suckling their mothers than twins. The growth traits are important in productivity and are the major selected traits in sheep breeds. They are influenced by genetic and environmental factors as shown in numerous studies (Behzadietal., 2007, Dass et al., 2008.).

Conclusion

Homolje territory is an important natural resource of great potential, with specific characteristics of HNV (High Nature Value) region. Flora and fauna of Homolje region is particularly rich and abundant in many plant and animal species which, some of them being relict. Under agricultural land is 36 880 ha or 48% of the territory. Of that 42.9% of meadows, 26% of pastures and 31.1% is arable land. Meadows and pastures represented from the lowest level parts to the highest parts of the mountain ranges, which is a great potential for organic sheep production.
Considering the results Svrljig sheep is identified as a good potential for further development of organic sheep husbandry in East Serbia hilly mountain ecoregions. Svrljig sheep reared in a sustainable production system, and since it uses well natural pastures and meadows, its diet is based on existing plant resources. For achieving better productive results of Svrljig sheep, an integrated approach is necessary. The approach must contain all aspects of sheep keeping, feeding, breeding and disease prevention, as well as pasture management.

SEASONAL CHANGES OF MICROBIAL POPULATION IN MAIZE AND SOYBEAN RHIZOSPHERE UNDER CONVENTIONAL AND ORGANIC GROWING SYSTEMS

Dragana BJELIĆ*, Nastasija MRKOVAČKI, Jelena MARINKOVIĆ, Branislava TINTOR, Ivica ĐALOVIĆ

Institute of Field and Vegetable Crops, Maksima Gorkog 30, 21 000 Novi Sad, Serbia

Abstract

The aim of this study was to compare abundance of microorganisms in the rhizosphere of maize and soybean grown under conventional and organic management. The trial was set up on the chernozem soil at the experimental field of Bački Petrovac, Institute of Field and Vegetable Crops, Novi Sad. Rhizosphere samples were collected in two sampling terms during 2014 (July 7 and August 14) and analysed by the indirect dilution method followed by plating of soil suspension on selective nutritive mediums: soil agar for the total number of microorganisms, meat peptone agar for the number of ammonifiers, Waksman-Carey medium for the number of cellulolytic microorganisms, synthetic medium for the number of actinomycetes, Czapek Dox agar for the number of fungi, and N-free medium for the number of azotobacters and free N-fixers. The results showed significant differences in microbial abundance between plant species, growing systems and sampling terms. Significantly higher number of microorganisms was found in rhizosphere of soybean compared to maize, as well as in organic growing system compared to conventional. Significant differences between sampling terms were recorded for the number of ammonifiers, azotobacters, fungi and actinomycetes, while the number of most tested microbial groups was higher in the second sampling term.

Keywords: *maize, microbial abundance, organic and conventional growing system, rhizosphere, soybean*

Introduction

Agricultural intensification as one of the greatest threats to global biodiversity, leads to large-scale ecosystem degradation and loss of productivity in the long term (Convention on Biological Diversity, 2010). Management practices (tillage, cropping rotation, use of pesticides and mineral fertilizers, irrigation) strongly influence the quality and fertility of agricultural soils and consequently, the size, composition, and function of the soil microbial community (Shannon et al., 2002). In turn, despite of their small volume in soil, microorganisms play a definitive and very useful role in soil fertility through the cycling of carbon, nitrogen, phosphorus, sulfur, and decomposition of organic residues (Nannipieri et al., 2003; Singh et al., 2011). In addition to the effect on nutrient cycling, microorganisms also affect the physical properties of the soil via production of extracellular polysaccharides and other cellular debris, and thereby help in maintaining soil structure as well as soil health (Bastida et al., 2008).

Conventional farming systems have been associated with loss of soil fertility, soil erosion and ground water pollution (Pimentel et al., 2005). Low-input systems such as organic farming, substantially reduce the use of synthetic fertilizers, pesticides, energy and mechanic stress, and mitigate these negative impacts in order to improve sustainable production (Gomiero et al., 2011). Earlier studies have shown that incorporation of organic amendments increase biomass, activity and diversity of soil microorganisms (Gelsomino et al., 2004; Girvan et al., 2004). According to Hartmann et al. (2015), fertilization scheme, the application and quality

of organic fertilizers in particular, is the major determinant of microbial diversity. The addition of animal or green manures on organic plots provides a significantly greater input of organic carbon which increases microbial population (Reeves, 1997).

Microbial processes within the rhizosphere of crop plants are crucial to agriculture. The relation of soil microbial community to cropping system, yield, and soil quality is unclear at present. Seasonal inputs of crop roots, rhizosphere products, and crop residues significantly altered soil microbial biomass and mineralizable C and N of this soil, illustrating the dependence of N dynamics on short-term C inputs and association of soil C/N ratio with changes in microbial community composition across different treatments (Carney and Matson, 2012). Beside management practices and soil environmental factors, the diversity and composition of microbial community in the rhizophere also depend on several other factors including plant species (Mahmood et al., 2005). Plants can influence composition and stimulate activity of soil microorganisms by producing labile carbon compounds through root exudation (Marschner et al., 2004). Valid evaluation of soil quality requires better understanding of short- and long-term responses of key biochemical and microbiological soil properties to seasonal changes and types of management practice in the cultivation of various crops.

Therefore, the aim of this study was to examine the seasonal changes in rhizosphere microbial population of maize and soybean grown under conventional and organic growing systems.

Materials and Methods

The trial was set up on the chernozem soil at the experimental field of Bački Petrovac, Institute of Field and Vegetable Crops, Novi Sad. Rhizosphere samples were collected in two sampling terms during 2014 (July 7 and August 14) and analysed by the indirect dilution method followed by plating of soil suspension on selective nutritive mediums: soil agar for the total number of microorganisms (dilution 10^7), meat peptone agar for the number of ammonifiers (dilution 10^6), Waksman-Carey medium for the number of cellulolytic microorganisms (dilution 10^5), synthetic medium for the number of actinomycetes (dilution 10^4), Czapek Dox agar for the number of fungi (dilution 10^4), and N-free medium for the number of azotobacters (dilution 10^2) and N-fixers (dilution 10^6) (Jarak and Đurić, 2006). Incubation temperature was 28°C, while incubation time depended on the tested microbial group. All microbiological analyses were performed in three replications, and the average number for all samplings was calculated per 1.0 g of absolutely dry soil. The results were analyzed in accordance with three–way model of analysis of variance (ANOVA) using Statistica software (StatSoft Inc. 2012), followed by mean separation according to Fisher's LSD test (Steel and Torrie, 1980).

Results and Discussion

In a long-term field trial in which organic and conventional growing systems were compared, a significant influence of organic agriculture on microbial biomass, diversity and microbial community structures was reported (Esperschütz et al., 2007). Our research focused on comparison of microbial abundance between rhizosphere of maize and soybean grown under conventional and organic management.

At the first sampling term, the number of examined microbial groups in soybean rhizosphere was higher in the organic farming system. Significant differences between systems were recorded for the total number of microorganisms, number of ammonifiers, free N-fixers and cellulolytic microorganisms. At the second sampling term, higher microbial abundance was also obtained in the organic farming system, except for total and free N-fixers, while significant differences were observed within the number of ammonifiers, azotobacters and cellulolytic microorganisms (Table 1). In study of Das and Dkhar (2012), addition of organic

amendments affected the soil physicochemical properties, which in return affected the microbial characteristics in soybean rhizosphere.
The number of microorganisms in maize rhizosphere, was higher in organic management system at the first term of sampling, while significant differences between the systems were recorded only for the number of ammonifiers.
At the second sampling term, for all tested groups except ammonifiers and free N-fixers exhibited the highest number in the organic management system, while significantly higher number between systems was recorded only for the number of actinomycetes and cellulolytic microorganisms (Table 1). Similar results were reported by Orr et al. (2010), indicating that the larger number of free nitrogen-fixers in conventional system was obtained due to higher concentrations of phosphorus from mineral fertilizers. On the contrary, Buyer and Kaufman (1997) showed that total number and diversity of microorganisms in maize rhizosphere were not significantly different for conventional and low-input systems suggesting that conventional agricultural practices may maintain high indices of microbial diversity in the rhizosphere.

Table 1. Number of microorganisms in rhizosphere of soybean and maize

Number of microorganisms in 1 g of absolutely dry soil (CFU g^{-1})					
Microbial group	Growing system	Organic		Conventional	
	Sampling/Plant	I	II	I	II

Cellulolytic microorganisms x 10^5	Soybean	30.39^{a}	31.22^{a}	8.16^{c}	14.95^{bc}
	Maize	5.73^{c}	24.46^{ab}	5.55^{c}	6.62^{c}

Means with the same letter are not significantly different at the P = 0.05 level of significance

This research showed significant differences in microbial abundance between plant species, growing systems and sampling terms (Table 2). Higher microbial number was recorded in soybean rhizosphere compared to rhizosphere of maize. Significant differences in microbial abundance were found between plant species, for all microbial groups except actinomycetes. These results are in agreement with those of Carney and Matson (2012) who revealed that microbial community composition differed between plant species. Similarly, significant differences in the soil microbial biomass were not visible during the wheat growing season, as a result of application of mineral and organic fertilizers, whereas fertilizer application significantly increased this parameter during the maize growing season (Mahmood et al., 2005).
Growing system demonstrated a significant impact on the total number of microorganisms, number of ammonifiers, free N-fixers, actinomycetes and cellulolytic microorganisms.

Significantly higher number of microorganisms in the organic farming system compared with conventional was also determined by Mrkovački et al. (2012).
However, their study reports the higher number of microorganisms in rhizosphere of maize compared to soybean, which is contrary to our results, and indicates that variations in the number of microorganisms depend on the year of research. Studies of Kong et al. (2011) confirmed the highest total microbial biomass in the organic management, and similar values between the conventional and low-input systems, while Bettiol et al. (2002) obtained similar effects of organic and conventional growing system on soil microbial populations. Various findings confirmed that stimulative effect of organic amendments on biomass, activity and diversity of soil microorganisms depends on numerous factors, such as soil type, plant species, soil management practices and other environmental variables. Franzluebbers et al. (1994) indicated that crop management strategies can affect the short-term dynamics of the active C and N pools of soil organic matter by altering the timing, placement, quantity, and quality of crop root and residue input, as well as nutrient status and environmental conditions. Fließbach and Mäder (2000) also interpreted higher microbial biomass in soils of the organic systems as an enhanced decomposition of the easily-available light fraction pool of soil organic matter with increasing amounts of microbial biomass.

Table 2. Effect of plant species, growing system and sampling term on microbial population

Number of microorganisms in 1 g of absolutely dry soil (CFU g^{-1})						
Microbial group	Plant species		Growing System		Sampling term	
	Soybean	Maize	ORG	CON	I	II

	**		***		NSD	

NSD indicates no significant difference at the P = 0.05 level of significance; *, ** and *** indicates significant differences at the P < 0.05, P < 0.01 and P < 0.001 levels

Significant variations in microbial number in relation to the growing season were recorded for the number of ammonifiers, azotobacters, fungi and actinomycetes, while higher abundance was obtained at second sampling term. Shi et al. (2013) recorded seasonal fluctuations in soil microbial biomass C and N, in dehydrogenase and alkaline phosphomonoesterase activities, and in total phospholipids fatty acid (PLFA) level under different tillage and phosphorus management practices, concluding that soil environmental factors and tillage had a greater effect than fertilization on microorganisms (biomass and activity) and community structure. Bossio et al. (1998) observed sustained increases in microbial biomass resulting from high organic matter inputs in the organic and low-input systems that were significantly different during growing season. Same authors ranked the relative importance of various environmental variables in governing the composition of microbial communities in the following order: soil

type > time > specific farming operation (e.g. cover crop incorporation or sidedressing with mineral fertilizer) > management system > spatial variation in the field.

Conclusion

The increase in the number of microorganisms in rhizosphere of two different crops grown under organic management system confirm the positive effect of this agricultural practice on soil microbial population and biological health of soil compared to conventional management.

EFFECTS OF ORGANIC FARMING ON SOIL COMPACTION

Abstract

Soil compaction, an important dynamic and physical property of soil, is represented by the force needed for the compression of soil by the working components of an instrument, and can be quantitatively expressed as MPa. The use of heavy machinery and a large number of cultivation practices increase soil compaction. When soils are subjected to external pressure, soil compaction (increase in soil density) occurs, during which the liquid and gas phases of soil are partly or completely extracted. Anaerobic conditions and water stagnation in the active part of rhizosphere can also occur, resulting in the constrained development of the root system, unwanted chemical processes, anaerobic and slow organic matter decomposition. Soil compaction was tested on agricultural plots under certified organic and conventional farming systems, as part of the project supported by the Ministry of Agriculture of the Republic of Serbia. Regardless of their utilization, a high level of soil compaction was generally observed in soils examined at the territory of Central Serbia, caused by high content of clay fraction in the mechanical composition of soil. Identical values of soil compaction were found in the initial 10 cm layer (at the optimal level of 1,0 - 2,5 MPa) both in soils under organic and conventional farming, which can be explained by timely soil management. With the increase in soil depth, compaction of soils under organic farming was lower compared to soils under conventional farming. This result is attributed to higher content of organic matter which was determined in this research.

Keywords: *compaction, organic and conventional farming, soil*

Introduction

Organic farming is a system of ecological management which promotes and improves biodiversity, circulation of matter, biological activity and soil fertility. One of the prime principles of organic management is preservation and increase in soil fertility level (Republic of Serbia, 2010). Organic farming is one version of a sustainable management system, which uses crop rotation, intercropping, mulches, green manure, organic waste, and above all, integration of plant production and animal husbandry.

Considering the principles of organic production, this system of production is expected to ensure preservation and improvement of soil properties, and prevent soil degradation (Nešić et al., 2014).

Soil compaction is one of the main problems of modern agriculture. Increased soil compaction is caused by overuse of heavy machinery for tilling, harvesting, and transport on excessively wet soils, intensive management practices, improper crop rotation and unsuitable soil use. Compaction is defined by increased soil firmness and decreased fertility, caused by the deficiency in soil supplies and inaccessibility of water and plant nutrients. Tilling compacted soils results in increased energy costs, with decrease in yield and quality of crops grown on compacted soils. Furthermore, tilling compacted soils results in runoff and destruction of agricultural machinery, ultimately resulting in increased costs of production on these soils. Compacted soils are also unsuitable as habitats for soil flora and fauna. Since the soil compaction process and its effects on physical characteristics, plant growth, chemical and

ecological processes are still inadequately researched, this study focuses on causes and effects of compaction occurring on agricultural soils, and the possible solutions to this problem (Gajić, 2006).

The aim of the study is to review the effects of organic and conventional farming systems on soil compaction.

Materials and methods

The research was conducted on five locations in Central Serbia. Locations were chosen based on the concentration of plots under organic farming (data taken from the database of Serbia Organica). Area reconnaissance, field survey, and soil sampling were performed in the period from August to October 2013.

The tested soil plots under organic and conventional farming systems are nearby, and a after a review of field reports and through conducting a producers' survey, it was confirmed that the same tilling operations had been applied on the plots during a longer period of time.

Soil compaction was determined with the use of “Penetrologger – Eijkelkamp Agrisearch Equipment” supported by software “Eijkelkamp PenetroViwer Software” . The machine operates on the principle of measuring soil resistance to penetration of the working cone (expressed as MPa (1 MPa = 100 N/cm^2)). Penetration is performed through the opening on the reference metal board on the surface, whose function is to reflect the signal of the ultrasound sensor, precisely showing the depth of measurement. Reference board also serves to emit the signal which controls the speed of penetration. Soil compaction is determined up to 80 cm of soil depth. Total of 100 samples were collected at 14 localities, from the plots under both certified organic and conventional farming systems (Figure 1).

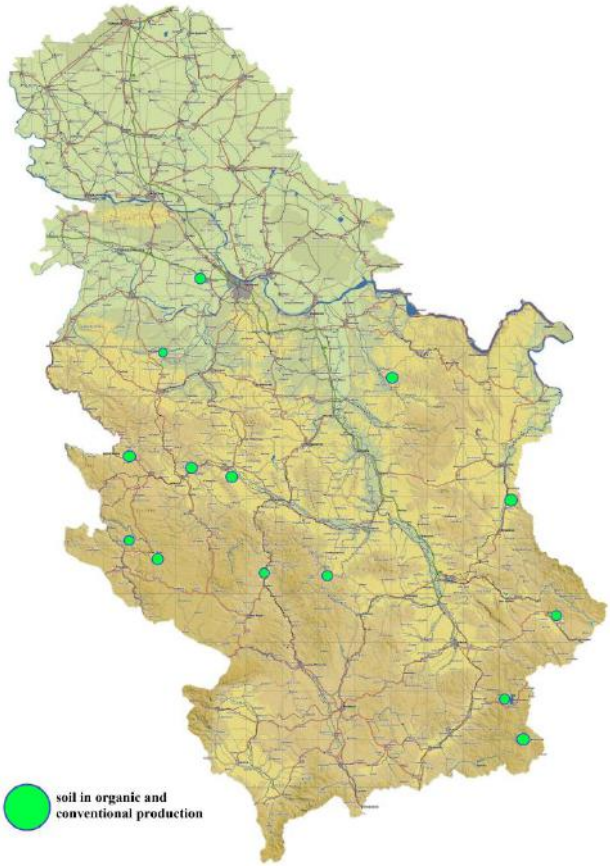

Figure 1 – Locations of plots under organic and conventional farming

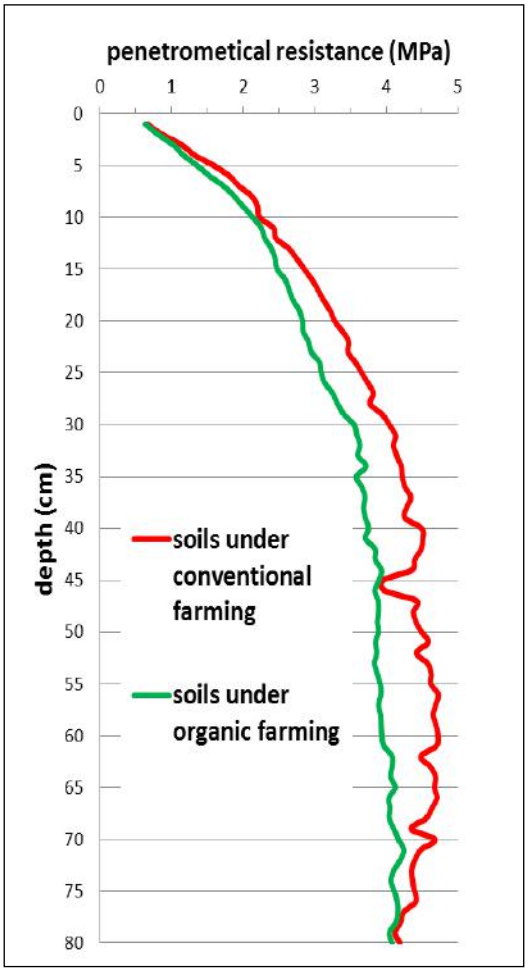
For the purpose of conducting analyses within this study, soils were sampled in disturbed condition using the agro-chemical probe at two soil depths (0-30 and 30-60 cm).
The collected samples were tested for soil mechanical composition (pipette method, sample preparation using Na-pyrophosphate according to Thun) and humus content (Turin method), at the Laboratory for Soil and Agroecology at the Institute of Field and Vegetable Crops. The research applied standard methods of the Laboratory accredited by the Serbian Accrediation Body Акредитационог according to the standard SRPS ISO/IEC 17025:2006.

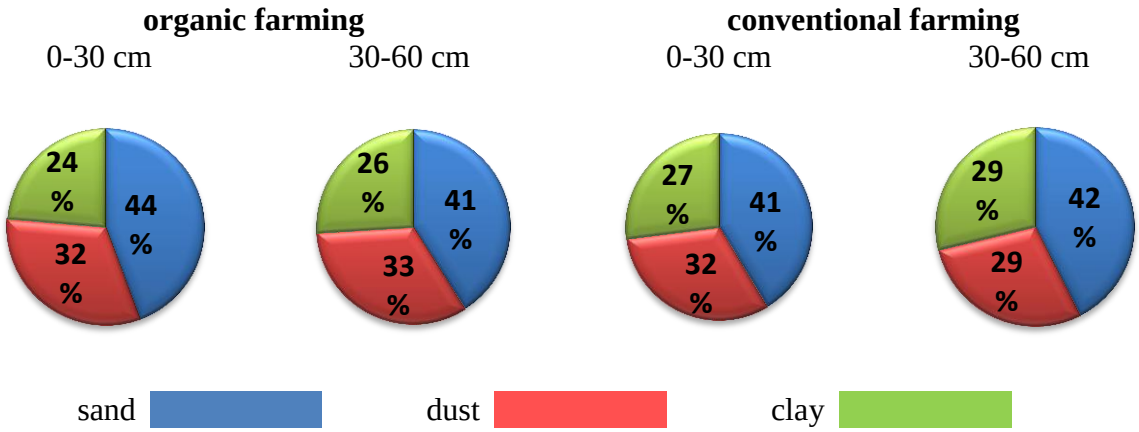
Results and discussion

Observed values of soil compaction (Graph 1) at the depth of 10 cm were classified as moderately or highly compacted soil (according to reference values used to estimate the relative compaction of a soil (Birkás, 2008).



Graph 1 – Compaction (penetrometric resistance) of soils

The obtained high values result from heavier mechanical composition of the tested soil (Graph 2), which is in accordance with the results of Baham (2005), Gajić et al. (2005), and Hettiaratchi (1987). These authors state that mechanical composition of soil is in direct proportion to the intensity of soil compaction, hence heavy soils (soils with a higher clay content) are more compacted.

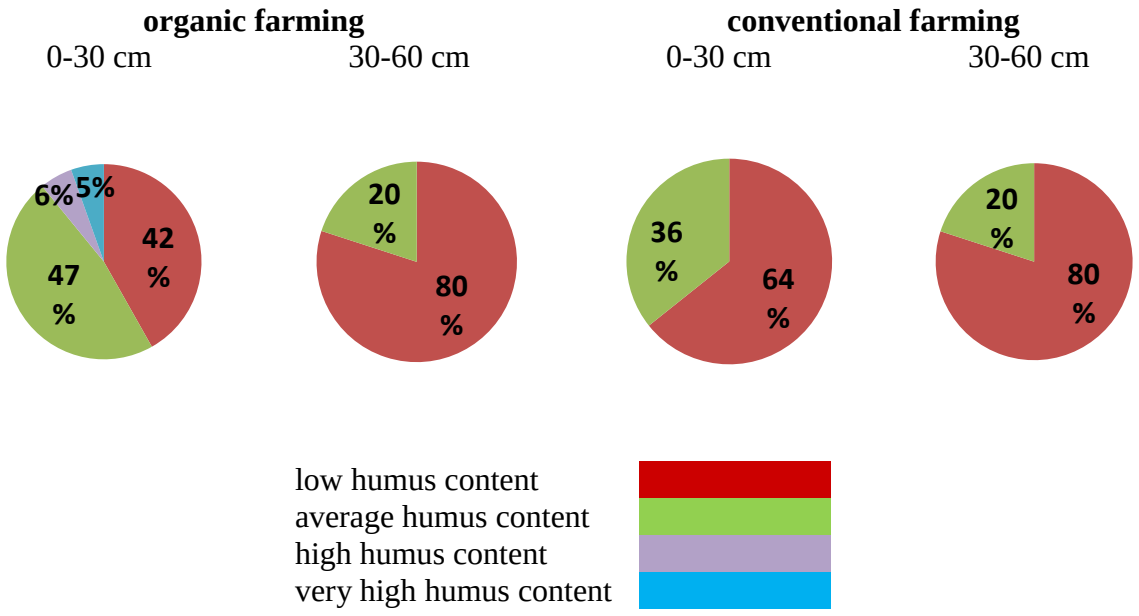


Graph 2 – Mechanical composition of the tested soil (percentage of sand, dust, and clay)

However, concerning that all sampled soils exhibited an equally heavy mechanical composition, it did not make any difference in soil compaction between soils under organic and conventional farming.

At the depth of 10-35 cm, which is the depth of organic manure application, there was a clear difference in soil compaction levels between soils under organic and conventional farming. The lower level of soil compaction in soils under organic farming is caused by application of organic fertilizers, and higher humus content in soils (Graph 3, Table 1).

Sample soils were divided into four groups according to their humus content: low 1-3 %, average 3-5 %, high 5-10 %, and >10 % very high humus content.



Graph 3 – Percentage of sample soils classified by the humus content

Table 1 – Humus content in sampled soils

Farming systems	Depth (cm)	Humus (%)	
		Mean ± SD	Range
Organic	0-30	4,09 ± 2,50	1,88 – 10,81
	30-60	2,23 ± 0,76	1,66 – 3,97
Conventional	0-30	2,92 ± 0,56	2,04 – 3,84
	30-60	2,00 ± 0,65	1,40 – 3,00

Gajić (2006) also reports that soils with higher humus content are more resistant to compaction, due to their elasticity and better structure.

The increase in soil depth by over 60 cm resulted in soils exhibiting similar values of penetrometric resistance (soil compaction) under both farming systems.

Conclusion

The results obtained from testing soil compaction and comparison of results between soils under organic and conventional farming indicate significant differences between these two concepts of farming.

Soils under organic farming exhibited lower values of soil compaction compared to soils under conventional farming, which should be attributed to the use of organic fertilizers (mainly manure). Higher content of humus (organic substances) was found in soils under organic farming. This claim is also supported by the differences observed between soil depth of 10 cm and the depth of organic fertilizer application (about 30-35 cm), while the same levels of soil compaction were observed in deeper soil layers within both farming systems.

Abstract

The scope of improving vegetable production through suitable intercrop combinations has not yet been exploited to its full potential. Research goals were to evaluate crop suitability for intercropping systems, to evaluate the effect of fertilization and sowing dates on productivity of green bean, lettuce and radish and to study the main factors responsible for crop performance when intercropped under field conditions in 2009–2010. A field trial was set up in a random block system with four repetitions on experimental field of the Institute for Vegetable Crops in Smederevska Palanka, Serbia. Green bean (*Phaseolus vulgaris* L.) as a main crop was intercropped with leaf lettuce (*Lactuca sativa* L.) and radish (*Raphanus sativus* var. *radicula* L.). Also, all crops were grown in pure stands. The intercrops were created according to the method of replacement series. The treatments of fertilization consisted of following variants: control treatment without fertilization, microbiological and mineral fertilizers and farm yard manure. All the treatments were examined for two sowing periods, spring and summer.Yield variation was significantly affected by the year of sowing, fertilization and interaction of these factors. LER values were always larger than 1 in intercropping systems. The mechanisms involved in the overyielding were the green bean canopy plasticity and its temporal deployment asynchrony when compared with lettuce and radish, allowing reduction of competition for light and production factors. The study showed that green bean based intercrops might provide the higher total yields.

Keywords*:* *intercropping, green bean, lettuce, radish, LER index*

Introduction

Intercropping is a traditional cultivation practice widely used all over the world (Carruthers et al., 2000; Ghosh et al., 2009). As a type of mixed cropping, it is defined as a cultivation of two or more crops in the same space at the same time (Vandermeer, 1989; Oljača et al., 2000 a).

Legume species are the most common members of intercrops, due to their ability to provide nitrogen through the sybiotic relationship with nitrogen-fixing bacteria. Comparing to corresponding sole crops, higher productivity was approved in many legume based intercrops, such as wheat and chickpea (Betencourt et al., 2012), barley and pea (Launay et al., 2009), maize and peanut (Xiong et al., 2013), maize and soybean (Dolijanović et al., 2013; Oljača et al., 2014) and especially maize and bean (Oljača et al., 2000 a; Mucheru-Muna et al., 2010; Worku 2014). The most of intercropping experiments were related to field crops. However there is lack of data for vegetable intercrops and only a few papers are strictly related to vegetable species (Yildirim and Guvenc 2005; Tosti and Thorup-Kristensen 2010).

Green bean (*Phaseolus vulgaris* L.) is very popular and widely grown vegetable species all over the world (Gepts 1998). As a member of *Fabaceae* family, green bean is in sybiotic relationship with nitrogen-fixing bacteria, and the majority of short green bean varieties mature after 50 to 60 days (Lešić et al., 2004). Lettuce and especially radish are also fast

ripening vegetable species (Lešić et al., 2004). During winter and spring, lettuce and radish are the first fresh vegetables on the market. Green bean, lettuce and radish are mentioned as good or bad neighbours in gardens (Lazić et al., 1991), but there is lack of data related to these intercrops analysed with contemporary scientific methods (Oljača et al., 2000b).
This study was conducted with a purpose to investigate the effects of intercropping green bean with lettuce and radish, different types of fertilizers and different sowing dates on green bean, lettuce and radish yields and productivity of intercrops evaluated using RY and LER indices.

Materials and methods

A two year (2009-2010) field experiment was conducted at the Institute for vegetable crops, Smederevska Palanka (44^o 22' N, 20^o 57'E, altitude 101 m above sea level), in order to evaluete vegetable intercropping systems based on green bean, lettuce and radish. Soil type was vertisol with pH 6.7, 3.13% of organic matter, 0.16% of nitrogen, 0.0% of calcium carbonate, 374.2 ppm of available phosphorus and 335.6 ppm available potasium (Egner et al. 1960).
The experiment was set up as a completely randomized block design with four replications. Lettuce (*Lactuca sativa* L. *cv.* "Neva") and radish (*Raphanus sativus* var. *radicula* L. *cv.* "Non plus ultra") were grown as a sole crops and intercropped with green bean (*Phaseolus vulgaris* L. *cv.* "Palanačka rana"). Green bean was also grown as a sole crop. Four fertilization treatments used were: a) control treatment without fertilization (C), b) microbiological fertilizer (MB), c) mineral fertilizer (NPK) and d) farm yard manure (FYM). All treatments were examined for two sowing periods, spring and summer.
The size of experimental plot was 12,5 m^2, with 0,5 m spacing between different experimental plots. Green bean sole crop experimental plots consisted of 12 rows (0.4 m inter-row spacing) and sowing density was 250 x 10^3 plants per hectare. Lettuce and radish sole crops experimental plots consisted of seedbeds, 1.0 m width, with 0.5 m spacing between seedbeds and sowing densities were 177x10^3 and 758x10^3 plants per hectar, respectively.
For intercropping treatments, the method of replacement series was used (de Wit 1960). Two rows of green bean (0.4) were associated with seedbed of lettuce or radish (0.8 m with). Plant spacing in mixtures was the same as in pure stands of examined crops. The number of plants per unit area in intercrops were 125 x 10^3, 114 x 10^3 and 525 x 10^3 plants per hectare of green bean, lettuce and radish, respectively.
Previous crop was wheat. The common tillage practices, such as plowing and disking were applied during the winter. Before additional tillage, certain experimental plots (fertilization treatments) were fertilized with mineral fertilizer (75 kg of nitrogen, phosphorus and potassium per hectare) or composted farmyard manure (40 t/hectare). Harrow with elastic spikes was used for presowing cultivation. Sowing (lettuce and radish: 13.04.2009. and 13.04.2010; green bean: 14.04.2009. and 16.04.2010.) and weeding were performed manualy.
Plots were watered several times during the growing season. With exception of certain plots mineral fertilizing, all cultivation measures were in accordance with organic production standards.
The microbial fertilizer Slavol (containing: *Bacillus megaterium, Bacillus licheniformis, Bacillus subtilis, Azotobacter chrocoocum, Azotobacter vinelandi, Derxia* sp.) was applied during the first true leaf stage of green beans. The application was performed using 1,5% microbial fertilizer aqueous solution in the amount of 6 l/ha. The treatment was repeated after 10 days.
At radish, lettuce and green bean maturity stage, iner rows were harvested and used to calculate yields per hectare, Relative yields (RY) and Land equivalent ratio (LER). LER is sum of the relative yields (RY) of intercrops (Vandermeer, 1989), green bean with lettuce

(LER = $RY_{green\ bean}$ + $RY_{lettuce}$) and green bean with radish (LER = $RY_{green\ bean}$ + RY_{radish}). The relative yields of green bean, lettuce and radish were calculated by following equation: RY = I / M (I is yield of some crop per hectare in intercrop and M is its yield per hectar in monoculture).

Results and discussion

Average monthly temperatures and rainfalls during the two experimental years, are shown in Figure 1. Comparing to long-term average, both experimental years were characterized by higher temperature values and rainfalls. In 2009 annual temperature mean (12,42°C), and average monthly temperatures (except november) were significantly higher than long term temperature means for Smederevska Palanka. Annual rainfall sum was 788 mm, but in april and may, extreme drought, uncommon for spring time, was noticed. Another drought period with less rainfalls occured in august and september. In 2010, similarly as the previos year of trial, annual temperature mean (12,6°C), and average monthly temperatures (except october and november) were significantly higher than long term temperature means. Despite the higher annual rainfall sum (730 mm), drought period appeared in august.

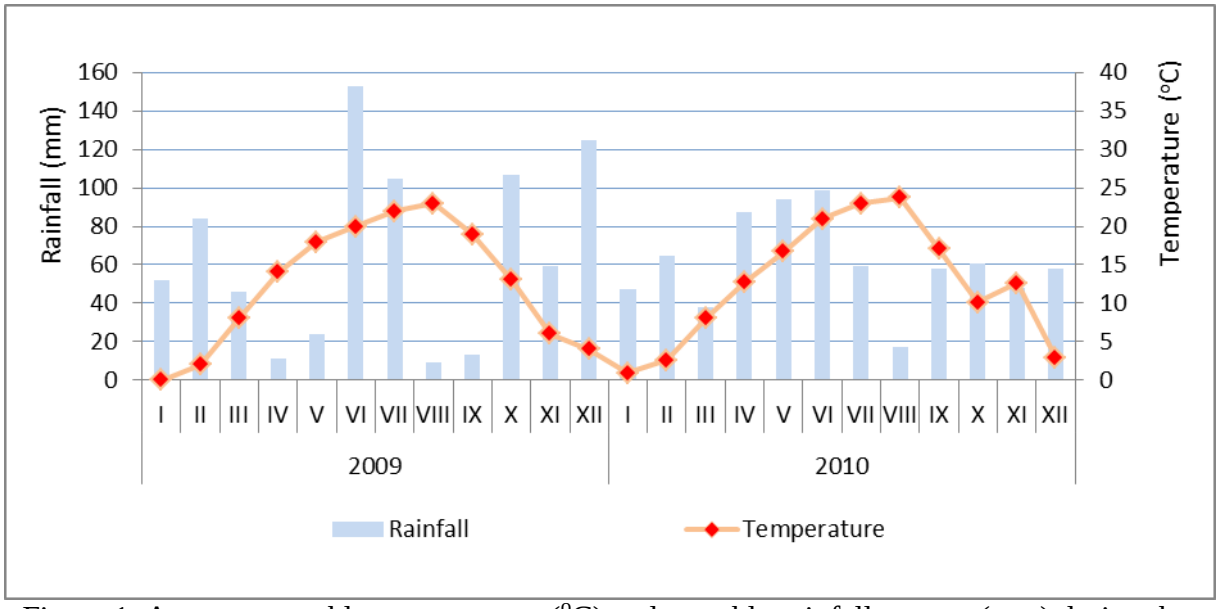

Figure 1. Average monthly temperatures (°C) and monthly rainfall summs (mm) during the two experimental years (2009-2010)

Green bean, lettuce and radish yields were affected by tested fertilizers, as shown in Table 1. Comparing to control treatment, higher green bean, lettuce and radish yields were recorded on the plots treated with microbiological fertilizer and farmyard manure. Similar results were already reported for green bean (Stone et al., 2003) and lettuce yields (Okur et al., 2008). Radish yield was also affected by tested fertilizers but, in this trial it was lower than yield reported by Miladinović et al. (1997). The highest green bean, lettuce and radish yields were recorded on treatments with the mineral fertilizer, probably due to a high availability of major nutrients.

Table 1. Yields of sole crops (SC), relative yields (RY), standard errors (SE) and land equivalent ratio (LER) of intercropped (IC) green bean with lettuce and radish, treated with different fertilizers, during the two growing seasons (two years average: 2009-2010)

IC	Treatment	SC yield	SE	RY	SE	LER	SE

First sowing date (spring)							
Green bean	Control	9,17	0,194	0,54	0,014	1,2	0,014

Radish		7,45*	0,231	0,72	0,006		

Control – without fertilizer; MB – microbiological fertilizer; NPK – mineral fertilizer (15:15:15); FYM – highly decomposed farmyard manure; * - blossom emergence;

Subjected to the sowing season, green bean and radish yields were higher in the second sowing date but lettuce yields were higher in the first sowing date. That was not in accordance with results of Ferreira et al. (2006) who reported lower green bean yields in later sowing periods. Also, in second sowing period, green bean treated with FYM, achieved higher yields than those treated with microbiological fertilizer. It was presumably caused by better soil properties and water accumulation, improved with high amounts of organic matter, contained in FYM. However, in second sowing period, in lettuce and radish sole crops and intercrops, regardless to fertilizing treatments, frequent blossom emergence was noticed. High temperatures and long day terms could promote blossom emergence (Miladinović et al. 1997), so the lettuce and radish yield quality was significantly reduced.

Green bean relative yields (RY) varied about 0,5 in both intercrops, i.e. relative yields of green bean were not significantly affected by intercropping, regardless of another intercropped species. Slightly higher green bean RY values were recorded in the first sowing

season but it is not definetly clear what caused these differences. Lettuce and radish RY were above 0,5 and influenced LER index values higher than one. LER is usually used for an intercrop efficacy evaluation. LER index higher than 1, sugests that the intercropping is much more efficient than sole crops and that the competition for light, water and soil resources among intercropped species is not significant (Vandermeer 1989).
Oppositly to first sowing period, in the second sowing period, LER index values of intercrops treated with FYM were higher than untreated or those treated with other fertilizers. It is probably corelated with soil water availability during the drought period. Hati et al. (2006) reported better rooting of soybean and improved physical properties of the soil after farmyard manure application.

Conclusion

Examined intercrops approved as a better choice, comparing to related sole crops. They could be useful in achieving higher total yields, regardless to applied fertilizer or sowing date. However different lettuce and radish genotypes should be used because the tested genotypes are not suitable for late season production. Application of microbiological fertilizers and highly decomposed farmyard manure are suitable for organic green bean/lettuce or green bean/radish intercropping production and also could lead to yield enhancing.

THE IMPACT OF BIOCHAR ON HYDRAULIC CONDUCTIVITY OF THE SOIL

Jana DOMANOVÁ*, Dušan IGAZ, Tomáš BORZA, Ján HORÁK

Department of Biometeorology and Hydrology, Slovak Agricultural University in Nitra, Hospodárska 7, 949 01 Nitra, Slovakia
*Coresponding author mail: domanova.jana@gmail.com

Abstract

Biochar as a highly porous material, thus its application to soil is thought to improve a range of soil hydro-physical properties. However, compared to these properties, little is known about the impact of biochar on soil hydraulic conductivity. The aim of this study was to evaluate the effect of biochar on soil hydraulic conductivity of sandy loam soil. Research study was undertaken at experimental site of Slovak University of Agriculture in Nitra (locality Malanta, near Nitra). Nine plots were set out on the experimental area. The field experiment consisted of 3 levels of biochar application 0, 10 and 20 tha^{-1}. Biochar was applied in March 2014 into the depth 0 – 10 cm of soil in 3 replications. Samples of soil were taken 53 days after applications of biochar. Saturated soil hydraulic conductivity was measured using Falling Head Method (FHM), based on measurement with variable hydraulic slop. After 53 days biochar amendment improved soil hydraulic properties. The rates of biochar significantly increased soil hydraulic conductivity.

Keywords: *biochar, saturated hydraulic conductivity,*

Introduction

Carbon plays very important role in soil. It has the potential to influence physical, hydro-physical and chemical processes in soil (DeLuca et al., 2006; Glaser et al., 2001). It has also been shown to affect soil productivity, quality and fertility and nutrient cycling, which all affect crop production (Skjemstad et al., 2002; Lal, 2004). The understanding how the addition of carbon may influence the soil is essential. The products produced from pyrolysis include a gaseous material referred to as ‘‘syngas’’ and a carbon (C) rich, charcoal material known as biochar (Lehmann, 2007).

Biochar is a stable, recalcitrant organic carbon material created by pyrolysis of biomass at temperatures between 300 and 1000°C under low or no oxygen conditions (Jeffery et al. 2011; Krull 2011; Verheijenet al.2010).

The application of biochar made to the soil has the potential to reduce the need for nitrogen fertilizer, as well as enhance soil chemical and physical properties (Krishnakumar et al, 2013). Biochar is highly porous, thus its application to soil is considered to improve arrange of soil physical properties including; total porosity, pore-size distribution, soil density, soil moisture content, water holding capacity or plantavabter content (PAWC) and hydraulic conductivity (Atkinson et al. 2010; Major et al. 2009; Sohi et al.2010; Sohi et al. 2009b; Zwieten et al. 2012). The possible mechanisms by which coal-derived humic acids improve soil physical properties are the formation of organic-mineral complexes by functional groups of the humic acids. The hydrophobic polyaromatic backbone reduces the entry of water into the aggregate pores leading to an increased aggregate stability and water availability.

Given the importance of hydraulic conductivity in determining the partitioning of precipitation between infiltration and overland flow (Mishera et al. 2003), which impacts water storage in the subsurface and thus plant available water, it is necessary to understand the effects of biochar on the hydraulic properties of different soil types.

Deveraux et al. (2012) estimate that biochar significantly decreased saturated hydraulic conductivity, on the other hand biochars produced from the pyrolysis of corn stover feedstock

at 350 and 550 °C temperatures significantly increased K of the Typical Fragiaqualf soil (Herath et al. 2013). Biochar amendment decreased saturated hydraulic conductivity by 92% in sand and 67% in organic soil, but increased K by 328% in clay-rich soil (Barnes et al. 2014).
This manuscript provides detailed assessment of the effects of applying 10 and 20 t/ha paper fiber sludge and grain husks biochar to a sandy loam soil in Nitra region of Slovakia.

Materials and methods

Experimental area

This field trial was conducted in March 2014 at the experimental site of SAU-Nitra (Nitra-Malanta) in Nitra region of Slovakia (lat. 48°19′00′′; lon. 18°09′00′′). The soil type is classified as OrthicLuvisol (FAO, 1998). The average annual air temperature was 10.3°C and annual precipitation was 640mm during the studied year (2014).

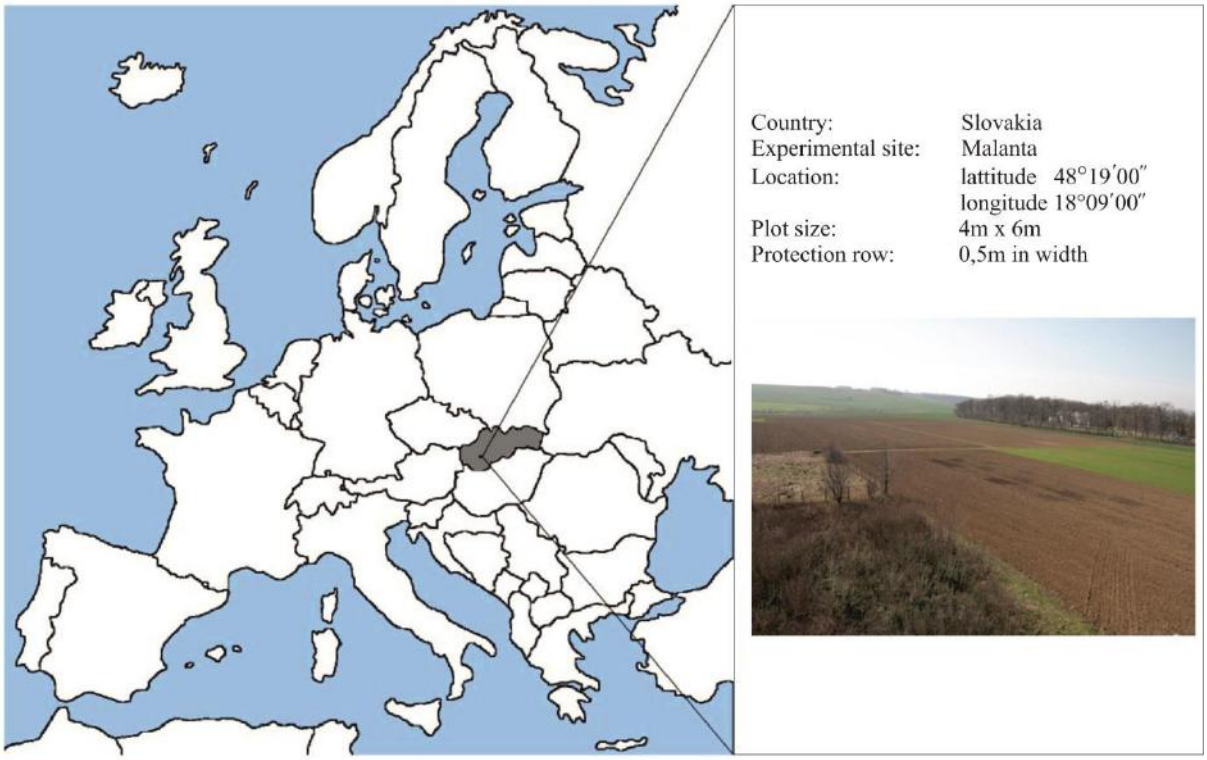

Fig. 1 Experimental site of SAU-Nitra (Nitra-Malanta) in Nitra region of Slovakia (lat. 48°19′00′′; lon. 18°09′00′′)

The field experiment consisted of treatments: Control (without adding biochar), B10 (soil+biochar in rate 10 t/ha) and B20 (soil+biochar in rate 10 t/ha). Every plot was in 3 replications. There were 9 plots (4m x 6m), separated by a protection row 0.5 m. Biochar was applying into the soil in March 2014 and 53 days after application there were taken the samples of soil for measuring of satured hydraulic conductivity.

Biochar characterization

Biochar used for the field experiment was produced from paper fiber sludge and grain husks (1:1 w/w) (company Sonnenerde, Austria) by pyrolysis at 550°C for 30 minutes in a Pyreg reactor (Pyreg GmbH, Dörth, Germany).

Tab. 1 Characteristics of biochar

	C / %	C / g kg^{-1}	N / %	N / g kg^{-1}	H / %	H / g kg^{-1}	O / %	O / g kg^{-1}
Biochar	53.1	531	1.4	14	1.84	18,4	5.3	53

Determination of hydraulic conductivity using falling head method

There was used device working on principle of measurement with variable hydraulic slope (i.e. above the measured soil sample changes the water level during time) to determine the hydraulic conductivity in laboratory condition.

Soil samples were taken into non-corrodible metal rollers with volume of 100 cm^3. It is necessary to have soil moisture at the value close to field capacity for taking undisturbed soil samples so therefore the sampling date was 2 days after intensive precipitations. Soil sample roller was lightly pressed into to soil using lever lifter. Soil sample was saturated by water before taking a measurement. The saturation lasted for 24 hours. The value of hydraulic conductivity coefficient was calculated according to equation:

$$K = \frac{L}{t}.\ln\frac{H_2}{H_1} \qquad (cm.s^{-1})$$

where:

L is the length of roller (cm), t is time of water drop from height H2 to H1(s), H_2 is an initial height of water in the extension piece, it is another roller whose flow surface is equal to flow surface of soil sample (cm), H_1 is the height of water in the extension piece after drop of water level (cm).

Statistical analysis

The statistical processing of the data included the determination of means and standard deviations. One-way analysis of variance (ANNOVA) at $p<0.05$ was performed to examine the effect of biochar at different application rates on satured hydraulic conductivity. Significant differences between means of three replications were identified using a least significant difference (LSD at $p<0.05$) test using STATGRAPHICS Centurion statistical software.

Results and discussion

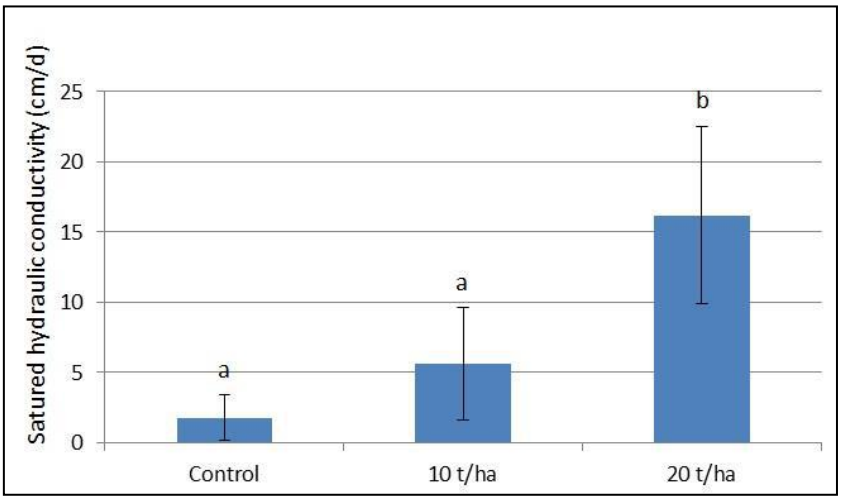

Fig. 2 Satured hydraulic conductivity 53 days after application of biochar into the soil in depth 0-5cm (± standard deviation, n=3). Different letters indicate significant difference between treatments means by the LSD test ($p < 0.05$).

Fig. 1 presents saturated hydraulic conductivity of loamy soil 53 days after application of biochar on field experiment at the experimental site of SAU-Nitra (Nitra-Malanta) in Nitra region of Slovakia. Biochar was applied in rates 10 and 20 t/ha. The average of control was 1,784 $cm.d^{-1}$. Figure shows that the boths rates of biochar increased soil hydraulic conductivity. However, there was not a statistically significant difference between the control and rate of biochar 10 t/ha ($p < 0.05$). The application 20 t/ha of biochar into the soil significantly increased satureded hydraulic conductivity by 906,22 % ($p < 0.05$). It was from 1,784 to 16,167 cm/d. The same situation was in publication of Barnes et al. (2014), there was increased satured hydraulic conductivity by 328% in clay-rich soil.

Conclusion

We used in the experiment 2 rates of biochar 10 and 20 t/ha, which were applicated into the soil. Saturated hydraulic conductivity was measured 53 days after application using falling head method . There was not a statistically significant difference between the control and rate of biochar 10 t/ha ($p < 0.05$). The application 20 t/ha of biochar into the soil significantly increased saturated hydraulic conductivity. Our study demonstrated that biochar has effect on satured hydraulic conductivity. It is very important the rate of biochar and biomass for produce bichar and also the type of soil. We demonstrated that 20 t/ha of biochar produced from paper fiber sludge and grain husks applicated to the loamy sand soil increased satured hydraulic conductivity.

Abstract

Rice is the staple food in Sri Lanka. Due to rapid growth of population, the production of rice also needs to be increased rapidly. The search of microbial inoculants that improve soil fertility and enhance plant nutrition has continued to increase, due to the negative health and environmental impacts of using synthetic fertilizers. A greenhouse experiment was established in Mihintale, dryzone of Sri Lanka, to evaluate the effects of inoculation of two traditional paddy varieties (Kaluheenati and Suwandel) and one improved paddy variety (Bg 300) with different *Rhizobium* spp. on the growth and yield. *Rhizobium* strains isolated from the nodules of *Glycine max*, *Mimosa pudica*, *Vigna radiata*, *Psophocarpus tetragonolobus*, *Vigna unguiculata*, *Vigna unguiculata* subsp. *sesquipedalis*, *Clitoria ternatea* and *Sesbania grandiflora* were tested for their potential to promote growth and yield of rice grown in potted soils with the un-inoculated control and had five replicates. Synthetic fertilizer was not added.

Some *Rhizobium* spp. inoculations increased relative growth rates and yield of paddy plants significantly ($p<0.05$) over un-inoculated controls in each of three paddy varieties. Further, significantly higher ($p<0.05$) performance was observed with the inoculation of *Rhizobium* spp. isolated from *Sesbania grandiflora*. Therefore, we conclude that *Rhizobium* spp. inoculants can be used to promote growth and yield even for the improved variety of paddy Bg 300. *Rhizobium* spp. inoculants can substitute the synthetic fertilizers even in improved paddy variety which earlier thought as highly synthetic fertilizer dependent. Therefore, the use of microbial inoculants should be maximized for enhance paddy crop production to meet the demands of an increasing human population and enables to supply healthy diet to human and increasing the number of healthy life years without any chronic disease.

Key words: *Rhizobium* spp., microbial inoculants, traditional paddy varieties, improved paddy varieties, synthetic fertilizer

Introduction

Rice (*Oryza sativa*) is the staple food of Asia and part of the Pacific. In ancient times, before the introduction of hybrid rice varieties, over 400 different varieties were grown all over the Sri Lanka. After the Green Revolution in the late 1960s, development of high-yielding varieties of cereal grains, expansion of irrigation infrastructure, modernization of management techniques, distribution of hybridized seeds, synthetic fertilizers and pesticides to farmers were introduced (Hazell and Peter, 2009).

It is estimated that there will be about 4.8 billion people will need to be fed with 760 million tons of rice in year 2020 (Hussain *et al*., 2009). Therefore, the production of rice needs to be increased by 2 percent per year to meet future demands (Hussain *et al*., 2009). Sri Lankan agricultural sector mainly base on paddy cultivation. However, most of the farmers in Sri Lanka still practicing conventional agriculture with using chemical fertilizers and pesticides. Hence there is severe need to develop agriculture practices, which can fulfill crop production and protection requirements economically on sustainable basis.

Use of sustainable or organic agriculture can reduce most of negative effects attributed from conventional agriculture and has potential benefits in enhancing soil quality (Maeder *et al*., 2002). Many types of microorganisms have ability to build strong interactions with the plants, being a member of plant rhizosphere. *Rhizobia* are soil bacteria that fix atmospheric nitrogen after becoming established inside root nodules of specific host legumes. Despite being unable to induce nodulation, rhizobia have been shown to be able to infect and colonize the roots of paddy forming root endophytic interactions which can act as plant growth promoting rhizobacteria (PGPR). They enhance PGP activities like mobilization and efficient uptake of nutrients (Biswas *et al*., 2000b), enhancement in stress resistance (Mayak *et al*., 2004), solubilization of insoluble phosphates (Hussain *et al*., 2009), produce plant growth hormones (Dakora, 2003) and siderophores (Hussain *et al*., 2009).
Few researches were conducted to see effect of *Rhizobium* spp. in growth of paddy (Yanni *et al*., 1997). But there is little or no evidence about traditional varieties with endophytic *Rhizobiu*m spp. Because most of the studies conducted to hybrid, fertilizer dependent rice varieties. As such this study was carried out with the objective of finding the rhizobial strains which promote growth and yield of some selected traditional and improved paddy varieties in Sri Lanka.

Materials and methods

A pot experiment was conducted on July to November, 2014 in the greenhouse at the Rajarata University, Mihinthale, Sri Lanka (8° 18′ 44N latitude and 80° 24′ 47E longitude).The temperature during the study period was 29.0-35.0 °C. Annual precipitation is between 1000-1500 mm and receives inter monsoon and the North-East monsoon rains mostly.

Paddy varieties

Seeds of two traditional paddy varieties of Sri Lanka called as “Kaluheenati” (KH), “Suwendel” (SD) and one improved rice variety as “Bg 300” (BG) were obtained from the Rice Research Center, Department of Agriculture in Batalagoda, Sri Lanka.

Isolation and inoculum preparation of *Rhizobium* and *Bradyrhizobium* strains

Different *Rhizobium* strains were isolated from the surface sterilized fresh nodules of *Glycine max* (T_1), *Mimosa pudica* (T_2), *Vigna radiata* (T_3), *Psophocarpus tetragonolobus* (T_4), *Vigna unguiculata* (T_5), *Vigna unguiculata* subsp. *sesquipedalis* (T_6), *Clitoria ternatea* (T_7) and *Sesbania grandiflora* (T_8) on yeast extract mannitol (YEM) agar. Pure cultures of the isolated strains were grown for 72 h to a density of 10^8- 10^9 CFU/ml in yeast extract mannitol (YEM) broth with shaking at 80 rpm and 30°C (Hussain *et al*., 2009) .

Pot experiment design and *Rhizobium* and *Bradyrhizobium* strains inoculation

The 3 kg of surface soils (0-15 cm in depth) of the field in Mihinthale, Sri Lanka was dispensed into each 108 pots. The soil was clay loam with 6.91 pH, 46 µS/m electrical conductivity and 67% moisture content. Water content was set to 3 cm high from the soil surface. There were eight treatments of *Rhizobium* or *Bradyrhizobium* were inoculated and one un-inoculated control. The experiment design was a Randomized Complete Block Design (RCBD) with three rice varieties and four replicates and one plant per pot.

Seedlings of three days age were gently uprooted from the seed bed and were treated with 2 ml of freshly prepared different rhizobial strains in YEM broth (10^8-10^9 CFU/ml) accordingly and were transplanted to the pots. Pots were kept under natural light conditions and watered regularly to maintain 3 cm high water level. Weeding was done manually and never used any

chemical pesticide or weedicide to manage pest and weed attacks. Ash was sprinkled over paddy plants as a repellent to pests and some of the insect repellent plants were grown inside the greenhouse.

Growth and yield parameters

Growth data such as plant height, number of tillers and number of leaves, length and width of the leaves were recorded in one month intervals. Yield data such as number of panicles, grains per panicle and un-filled (chaff) grains per panicle and dry weight of 100 grains were recorded.

Statistical analysis

Data were statistically analyzed using analysis of variance (ANOVA) to compare growth and yield of paddy with different rhizobial treatments and paddy varieties. Means were compared by using the Tukey's Studentized Range Test (SAS version 6.12) at a significance level of $p<0.05$ (SAS Institute, 1996).

Results and discussion

Growth and yield parameters

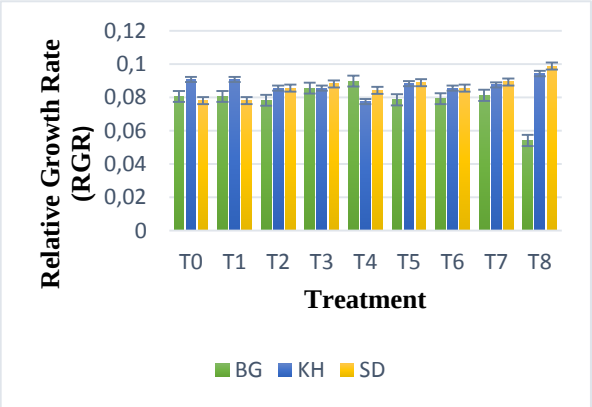

Fig.1. Effect of *Rhizobium* inoculation on relative growth rate (RGR) of selected three rice varieties under pot conditions. Error bars indicate 95%

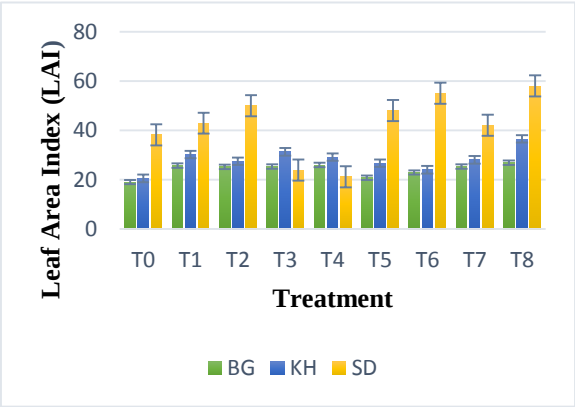

Fig.2. Effect of *Rhizobium* inoculation on leaf area index (LAI) of selected three rice varieties under pot conditions. Error bars indicate 95% confidence

The statistically significant increase ($p<0.05$) in relative growth rate (RGR) was shown *Rhizobium* strain isolated from *Sesbania grandiflora* (Fig.1). However, there was no significant increase shown with the other inoculated rhizobial species isolated from the other legume plants (T_1- T_7) over un-inoculated control (T_0). Also there was no significant increase ($p= 0.1088$) in RGR when considering the variety alone (Fig. 1). The increase in RGR might be the result of production of indole acetic acid and gibberellins when the effective endophytic association occurred (Singh *et al*., 2005).

There was statistically significant increase ($p= 0.0001$) shown in leaf area index of ‘Suwadel’ (SD) paddy variety with particular rhizobial strain inoculation compared to other two varieties (Fig. 2). Treatment comparison also showed significant difference ($p=.0015$) of LAI and the rhizobial strain isolated from *Sesbania grandiflora* (T_8) showed the highest response.

Significant variety and treatment effect ($p=0.0015$) was observed in number of leaves (Fig.3). Paddy varietal difference also significant ($p=0.0001$). Effect of T_8 treatment on SD variety was significantly prominent. Hussain *et al*., (2009) published results indicated that *Rhizobium* spp. isolated from green gram shown significantly high leaf numbers than those isolated from chick pea. Green gram has *Rhizobium phaseoli* and chick pea has *Mesorhizobium* sp. (Hussain

et al., 2009). These findings were also similar to the results of the present study which was observed that variation in relative efficiency of growth parameters of different paddy varieties with particular rhizobial strains can be explained by their ability to cope with specific paddy variety.

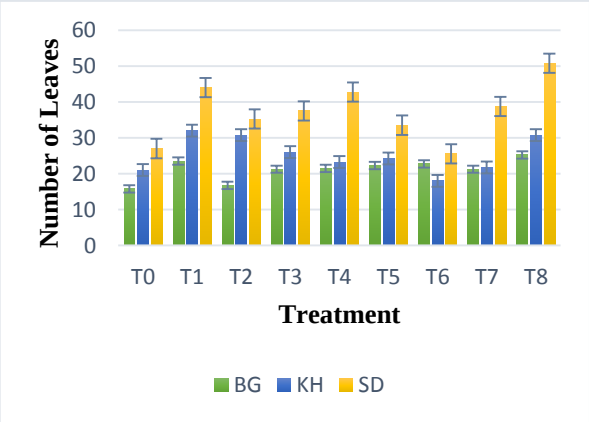

Fig.3. Effect of *Rhizobium* inoculation on number of leaves of selected three rice varieties under pot conditions. Error bars indicate 95% confidence

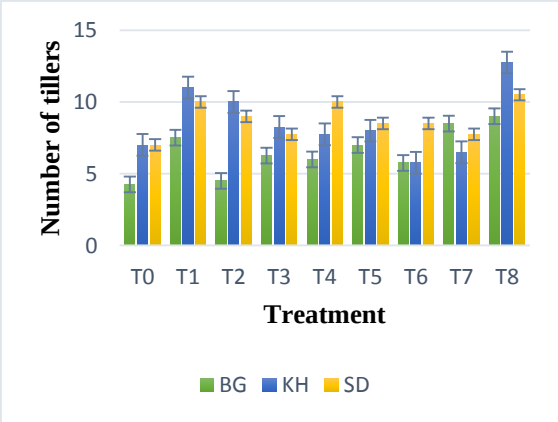

Fig.4. Effect of *Rhizobium* inoculation on number of tillers of selected three rice varieties under pot conditions. Error bars indicate 95%

Tiller numbers were shown significance difference (p=0.016) in variety and treatment interactions (Fig. 4). There was a significant difference in tiller numbers with the paddy variety (p=0.0001). Considering overall treatment effect the paddy variety Bg 300 showed lower number of tillers with the different rhizobial strains.

Panicle numbers were changed significantly when considering the variety and treatment interaction (p=0.016). Further it was shown that T_8 increase the number of panicles in all three varieties significantly over un-inoculated control (T_0) (Fig. 5). There were significant varietal difference also observed in panicle numbers and ‘Kaluheenati’ (KH) variety got the highest number of panicles despite the inoculated rhizobial strain (p= 0.0001). These results were in lined with Biswas *et al.*, (2000b) who have reported 16% increase in number of panicles in paddy plant and suggested that the improvement due to increased availability of nutrients and phyto-hormones such as indole acetic acid and ethylene. Similarly Peng *et al.*, (2002) concluded at increment of 27.11% in number of panicles per plant of rice due to *Rhizobium* inoculation over un-inoculated control. They were suggested efficient nutrient and water uptake as important mechanisms for that. Furthermore, differential behavior of different PGPR strains of rhizobia against common host has also been reported by Piesterse *et al.*, (2001).

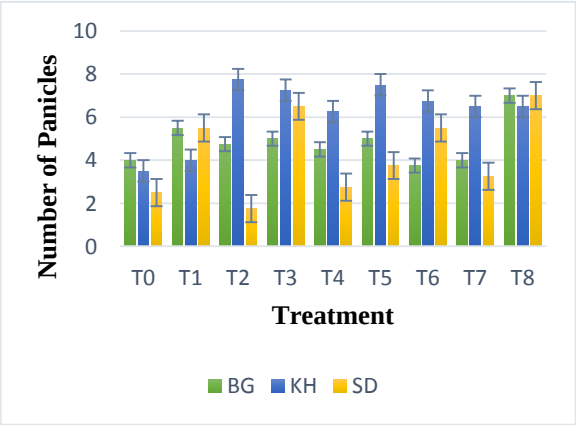

Fig.5. Effect of *Rhizobium* inoculation on number of panicles of selected three rice varieties under pot conditions. Error bars indicate 95%

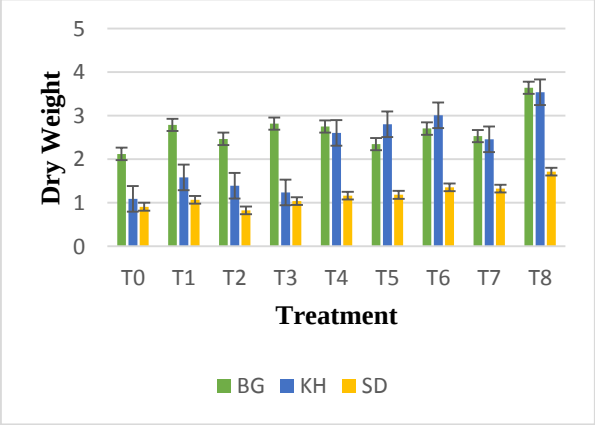

Fig.6. Effect of *Rhizobium* inoculation on dry weight of hundred grains of selected three rice varieties under pot conditions. Error bars indicate 95%

It was observed significantly different variety and treatment combination statistically on dry weights of 100 grains in all the rhizobial inoculation treatments (p=0.016). Again the specific rhizobial strain isolated from *Sesbania grandiflora* (T_8) showed highest dry weights of 100 grains in all three paddy varieties (Fig. 6). Similarly Hussain *et al.*, (2009) showed that maximum significant increase of 36.74% in the thousand grain weights of *Rhizobium* spp. inoculated paddy in comparison to un-inoculated control.

Conclusion

Specific *Rhizobium* spp. isolated from *Sesbania grandiflora* and *Glycine max* could improve paddy growth and yield. Growth and yield increase of two traditional and improved paddy varieties depend on the enhancing PGPR activity of the specific rhizobial strains. Even high inputs demanding, improved paddy variety also positively responds to the specific *Rhizobium* spp. inoculation. These results establish a strategy of using selected rhizobial strains to promote rice production capacity in sustainable agriculture practices.

Abstract

The agriculture sector is the foundation in Sri Lanka's economy. Most of the farmers in Sri Lanka tend to use chemical fertilizers for their cultivation processes. Synthetic fertilizers cause depletion of the nutritional content of foods and exposure to chemical fertilizers cause serious health problems. Therefore, the use of organic amendments can be a reliable solution to avoid many threats to the life caused by the application of chemical fertilizers. Biochar is a type of soil amendment helps in improving the quality of environment and human health. This research was conducted to find the effectiveness of biochar as an alternative to chemical fertilizer. For this purpose, soybean (*Glycine max* L.) was grown under tropical conditions in Mihintale, Sri Lanka, on red yellow podzolic soils in the greenhouse in ten-fold replication. Treatments were comprised control, wood biochar (15% by weight), saw dust biochar (15% by weight), compost (15% by weight),synthetic chemical fertilizer (111.5kg Urea ha^{-1}, 111.5kg P_2O_5 ha^{-1}, and 82.9kg K_2O ha^{-1}) and different combinations of above amendments together. The wood biochar treatment was found to significantly increase the plant height, number of leaves, number of nodules and number of pods in comparison to no biochar treatments. We conclude that biochar is promising to potentially improve growth and yield of soybean. The basic concept of biochar production is simple and therefore, it can be easily produced locally by farmers. Therefore, farmers can use wood biochar in the cultivation of soybean in sustainable agriculture practices to minimize the negative health effects caused by chemical fertilizers.

Keywords: *Wood biochar, saw dust biochar, organic supplement, compost, synthetic chemical fertilizer*

Introduction

Utilization of organic fertilizers can be a reliable solution to avoid soil pollution and many other threats to the environment and life caused by overuse of chemical fertilizers. The sustainable agricultural methods do not use synthetic fertilizers and pesticides. It attempts to close nutrient cycle on the farms, protect the environment quality and enhance beneficial biological interactions and processes. Many researchers found that comparing to conventional agriculture, organic crops yielded 95 – 100 % percent (Major *et al*., 2005),along with 50% lower expenditure on fertilizer and energy as well as 97% less pesticides (Mader, 2002).

Biochar is a kind of soil amendment. It is a type of charcoal prepared from the pyrolysis of a range of biomass feedstock like wood, crop, yard wastes and manures (Novak *et al*., 2009). The primary function for biocharis as a soil enhancement to facilitate retention of water and nutrients and a habitat for soil microbes (Baldock and Smernik, 2002). Biochar usage has been revealed to promote soil nutrient quality and stabilize soil than other organic amendments (Lehmann and Joseph, 2009). Laboratory studies estimated that biochar has a residence time in soils on the order of 1300–4000 years (Cheng *et al*., 2008). Research reveals that beneficial mycorrhizal relationships and biological nitrogen fixation together are improved by biochar applications in common beans (*Phaseolus vulgaris*) (Rondon*et al*., 2006). Researches have also shown that the biochar characteristics important to plant growth can be improved with time after its incorporation into soil (Major *et al*., 2010).

Soybean (*Glycine max*) which is one of the major and widely cultivated legume crops in dryzone of Sri Lanka. Application of innovative agricultural method to improve the growth and yield of this crop against the continuing depletion of soil organic nutrients will help in improving the livelihood of this rural population. It was therefore, the aim of this research to investigate the effect of biochar on the growth and yield of soybean in dry zone of Sri Lanka.

Materials and Methods

Study site

The study was conducted under greenhouse conditions and natural light at the Rajarata University of Sri Lanka in Anuradapura district, dry zone of Sri Lanka(8° 21' 0" North, 80° 30' 0" East) on red yellow podzolic soils from July 2014 to December 2014. The environmental temperature during the trial was 29.0-35.0 °C. Annual precipitation is between 1000-1500 mm and receives inter monsoon and the North- East monsoon rains mostly.

Biochar production

The biochar use in this study was produced from wood chips and saw dust. Dried wood chips of *Cinnamomumzeylanicum, Mangiferaindica, Micheliachampaca, Heveabrasiliensis, Anacardiumoccidentale*used for the production of wood biochar. Fresh woods of *Artocarpusheterophyllus, Meliadubia, Tectonagrandis, Swieteniamahagoni* used for the production of saw dust biochar. Biochar was produced at a 450 -550 °C pyrolysis temperature using the two-barrel nested design. Organic matter used to produce biochar was filled in to the small barrel and the lid was closed. The small barrel was placed in the inverted position inside the large barrel. The organic matter in the inner barrel was heated to about 450 – 550 ° C by burning wood scraps stuffed into the space between the inner and outer barrels. The produced biochar was ground by passing through a 2 mm sieve.

Experimental design and data collection

A randomized complete block design (RCBD) was used with ten replicates in this experiment. The experiment included control and six treatments as, control without amendments (T_1), field soil + wood biochar (15% by weight) (T_2), field soil + saw dust biochar (15% by weight) (T_3), field soil + compost (15% by weight) (T_4), field soil + synthetic chemical fertilizer (111.5 kg N ha^{-1}, 111.5 kg P ha^{-1}, and 82.9 kg K ha^{-1}) (T_5), field soil +wood biochar (15% by weight) + compost (15% by weight) (T_6), field soil + saw dust biochar (15% by weight) + compost (15 % by weight) (T_7). Soils were sampled in the field in Anuradhapura, Sri Lanka, at depth 0- 15 cm, air dried and then ground to pass a 2 mm sieve and prepared for a total weight of 3 kg pot^{-1} and mixed with various amendments accordingly. *Gliricediasepium*leaves were air dried and 100 g of ground leaves were added to each pot. Data were subjected to analysis of variance (ANOVA) and mean separation using the Tukey'sStudentized Range Test (SAS version 6.12) at a significance level of $p<0.05$ (SAS Institute, 1996).

Results and discussion

Potential growth and yield of soybean

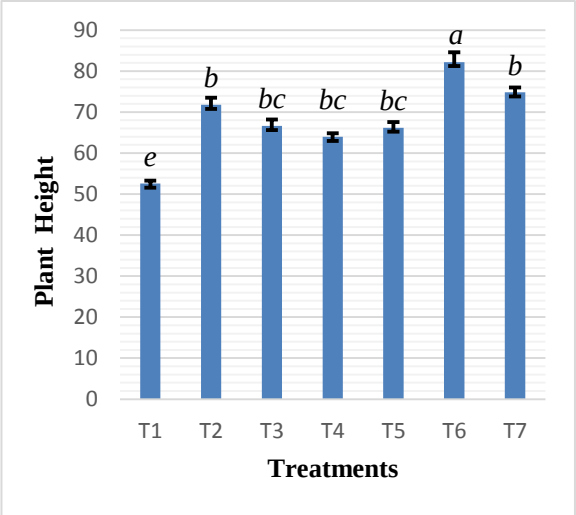

Fig.1.Plant height of soybean plant at different biochar,organic and fertilizer amendments. Means denoted with different letters are significantly different at p< 0.05.

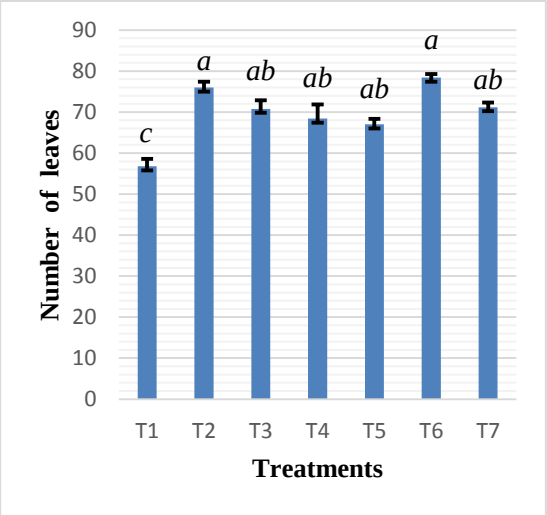

Fig. 2.Number of leaves of soybean plant at different biochar, organic and fertilizer amendments. Means denoted with different letters are significantly different at p< 0.05.

Plant height was significantly higher ($p<0.05$) in the pots with wood biochar and compost together (T_6) (Fig.1). This growth improvement could be explained that compost and biochar together increase retention of water and nutrients specially nitrogen in the soil and thereby uptake of water and nutrients by the plants (Steiner *et al*., 2010). Wood biochar and compost has improved soybean plant height than saw dust biochar and compost addition treatment (T_7). Plant responses to biochar additions might dependent on the feedstock which was used in the production (Major *et al*., 2010).

Leaf numbers were significantly different ($p<0.05$) in the treatments and control, field soil without amendments (T_1) shown the least (Fig. 2). Again wood biochar addition was improved the leaf numbers (T_2 and T_6). The relative ratio of surface area to weight of the particles in biochar is thought to be one of the major determinants of its efficacy as a soil amendment, as this criterion would be reflected directly in the adsorption characteristics of biochar (Zimmerman, 2010).

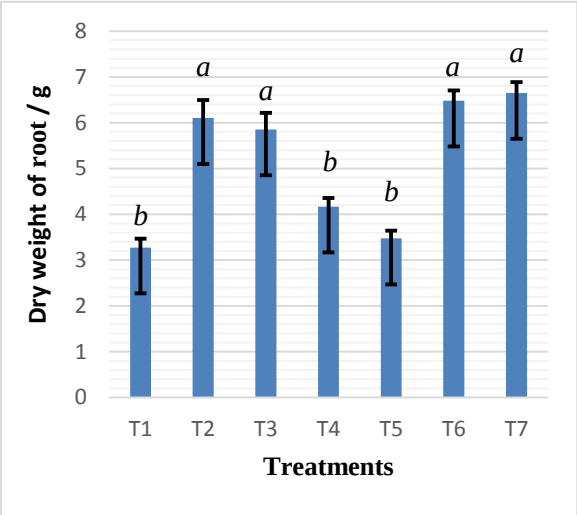

Fig.3. Root dry weight of soybean plant at different biochar, organic and fertilizer amendments. Means denoted with different letters are significantly different at p< 0.05.

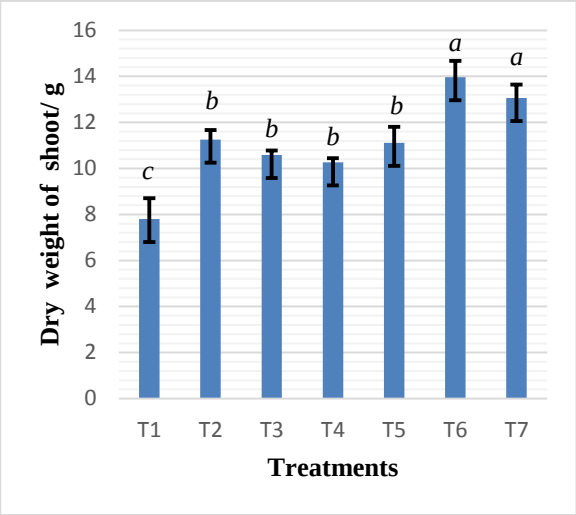

Fig.4. Shoot dry weight of soybean plant at differentbiochar, organic and fertilizeramendments. Means denoted with different letters are significantly different at p< 0.05.

Both biochar types (T_2, T_3, T_6 and T_7) were significantly increased (p< 0.05) root dry weight of soybean (Fig. 3). Similar responses of stimulating root growth with biochar were also published (Noguera*et al*., 2010). Biochar and compost together increased shoot dry weight of soybean plant significantly (p<0.05) (Fig. 4). Responses to biochar addition may be influenced shoot and root growth through a direct and interactions between biochar particles and roots. Fine roots and root hairs may take up nutrients and water from surfaces or from internal biochar pores (Lehmann and Joseph, 2009). Biochar, compost and root interactions positively influenced on structure and activity of surrounding microbial community and release or sorption of chemical signals affecting root growth (Schmidt and Noack, 2000). These biochar–root interactions could initiate a range of responses in root growth and affect shoot growth and plant performance.

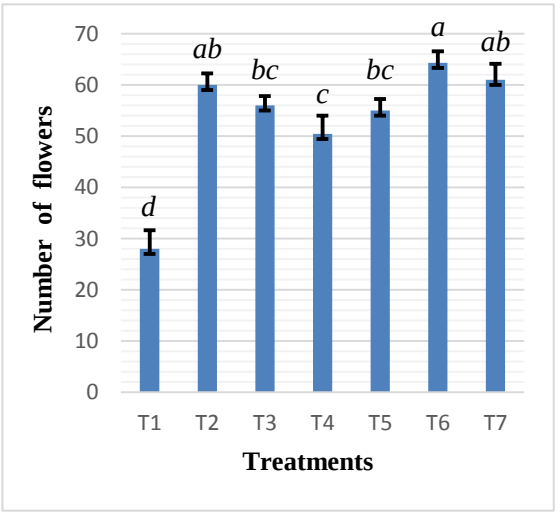

Fig. 5.Number of flowers of soybean plant at different biochar, organic and fertilizer amendments. Means denoted with different letters are significantly different at p< 0.05.

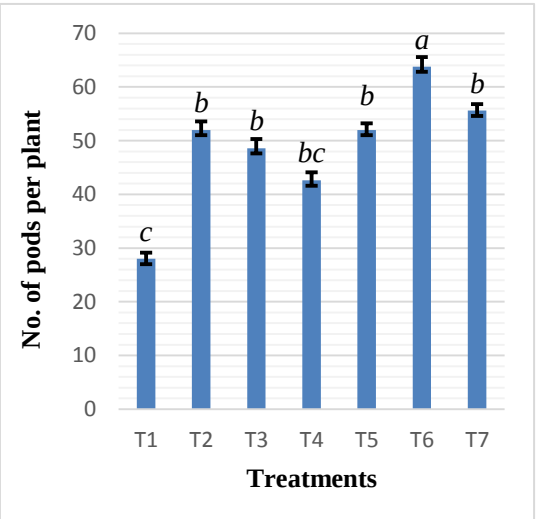

Fig.6. Number of pods of soybean plant at differentbiochar, organic and fertilizeramendments. Means denoted with different letters are significantly different at p< 0.05.

Adding biochar and compost into soybean growing soil (T_6) increased the number of flowers (Fig.5 and Fig. 6) and the number of pods of the plant significantly ($p<0.05$). It has proven that biochar and compost together synergistically improved plant yield. This result agrees with other previous studies, indicating that biochar and compost added into the soil ameliorated the growth of plant significantly and increased yield compared to non- treated soil (Sohi*et al*., 2010).

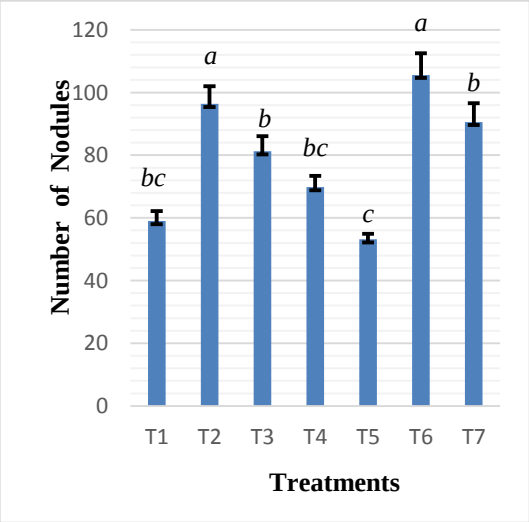

Fig. 7.Number of nodules of soybean plant at different biochar, organic and fertilizer amendments. Means denoted with different letters are significantly different at p< 0.05.

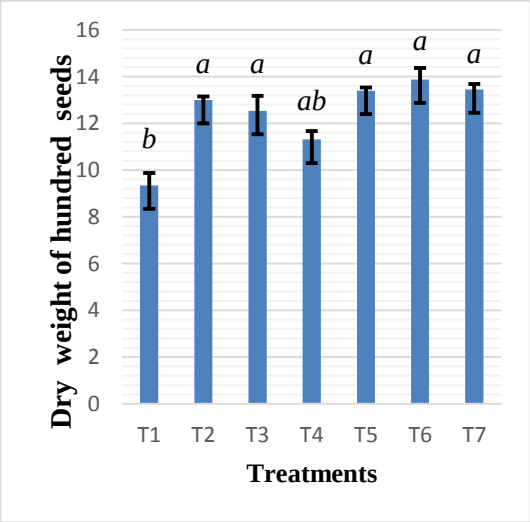

Fig. 8.Dry weight of 100 seeds of soybean plant at differentbiochar, organic and fertilizeramendments. Means denoted with different letters are significantly different at p<

Treatments of wood biochar (T_2) and wood biochar with compost (T_6) significantly increased ($p<0.05$) the nodule number of soybean (Fig.7). The treatment synthetic fertilizer (T_5) showed the least number of nodules. It has proven that availability of inorganic nitrogen negatively affect on soybean nodulation (Fig.7). Ammonium ion exchange between the biochar surface and soil solution likely to modify nitrogen availability to plant roots and may stimulate the nodulation (Liang *et al*., 2006). Dry weight of 100 seeds of soybean was significantly increased ($p<0.05$) with biochar and synthetic fertilizer treatments. (Fig.8).

Conclusion

Adding biochar into soil of soybean enhance its growth and yield and is an important alternative to chemical synthetic fertilizer. Wood biochar is promising to increase growth and yield of soybean compared to saw dust biochar. The impacts of biochar on growth and yield of soybean depend on the type of biochar. Biochar and compost together synergistically improve soybean growth and yield. Therefore, we conclude that soybean farmers can use wood biochar and compost together in the cultivation of soybean in sustainable agriculture practices.

Abstract

Spider mites are important pests in agricultural practices. They cannot be seen and many species are polyphag and live together. Through sucking plant juice, they can cause pale or bright dots on leaves and with intensive invasion they may cause leaf drops. Spider mites have several hosts and generally chemical pesticides are used to control *Tetranychus urticae* Koch (Tetranycidae: Acarina). However, chemicals may have severe impacts on both nature and their predators. Chemical control may also emerge pesticide resistant species. Organic control may be considered as an alternative environment-friendly tool to control *Tetranychus urticae.* Some practices like removing infested plants, proper pruning, avoiding dusty conditions, using natural insecticides and plant extracts can be considered as organic control agents.Contact impact of myrtle (*Myrtus communis* L.(Mytraceae)) extracts on *T. urticae* were tested in this study. About 3 cm diameter leaf discs from unsprayed *Phaseulus vulgaris* (L.) (beans) were used as the nutriment for the mite. Dipping method into these disks was used and experiments were conducted in 4 replications. In experiments, 2, 4, 8 and 12% doses of myrtle plants were used and counts were performed at 2^{nd}, 24^{th} and 48^{th} hours. While high rate contact was observed with 2% dose at the end of 48^{th} hour, 100% impact was observed at the highest dose.

KeyWords: *Organic control, spider mites, natural insecticides*

Introduction

Pesticides have been used against the pests for years both in the world and Turkey. These chemicals have already created serious risks on environment and human health. *Tetranchus urticae* Koch (Acarina; Tetranychidae) is a significant proliferous polyphag pest and chemicals (synthetic) are commonly used to control the pest. Negative impacts of pesticides on environmental and human health, residues left over the plants and resistance-development of the pests against the chemicals are considered as the disadvantages of pesticides. Previous researches indicated resistance development of *T. urticae* against chemicals in time (Hoyt et al. 1985; Sawickiand Denholm 1987; Keenaand Granet 1987; Herron and Rophail 1998; Van Leeuwenet al. 2004). Especially in studies carried out upto 2004, it was indicated that Tetranychidae developed resistance against 80 different acaricides (Darp, 2004).

Researchers have focused on alternative methods to overcome the negative impacts of insecticides and acaricides like resistance to these chemicals. Plant extracts and essential oils are among such alternative methods used against pests. Therefore, various plant extracts are used against pests in previous studies (Kim et al., 2003; Gökçe et al., 2007; Mahdavi Arab et al., 2008; Al-Mazra'awi and Ateyyat, 2009; Zoubiri and Baaliouamer, 2011, Çetin and Elma, 2011). Among the plant extracts, *Azadirachtin indica* A. Juss is a significant one used against pests. It was reported in previous researches that the extracts obtained from this tree were effective on more than 200 pests and insects (Kısmalı andMadanlar, 1988; Ascher, 1993; Lowery and Isman, 1993; Spollen and Isman, 1996; Bankenand Stark, 1997).

Plant essential oils containing terpenoid, alkaloid and flavonoids are also effective in pest control (Grodnitzkyand Coats, 2002; Kim et al. 2003). In a study carried out with mites,

thyme essential oil was found to be toxic for *Tetrancyhus cinnabarinus* adults and prevented egg-laying (El-Gengaihi et al. 1996).
In previous studies, together with plant extracts obtained from some weeds, essential oils of 53 different plants were also used against *T. urticae* (Tomczyk and Szymanska 1995; Kawkaand Tomczyk 2002).
In this study, leaf extract effects of *M. communis* of Mytracea family were used against Tetranychidae.

Material and Methods

The present experiments were conducted in 2015 in a climate chamber with 26 ± 1 ^{o}C temperature and 16:8 light:dark photoperiod at GOP University Agricultural Faculty. *Myrtus communis* L. (Myrtle plants) and *Tetranychus urticae* Koch individuals constituted the material of the study.
Tetranychidae individuals were obtained from stock culture over beans at GOP?? University. In experiments, 3 cm *P. vulgaris* (bean) disks were used as nutriment.
Experiments were conducted in randomized blocks design with 4 replications including a control treatment for each dose.

Extracts

Myrtle plants were supplied from Plant Protection Department of GOP University. The plants were dried at dark under room temperature and ground in a hand mill. Ground plants were supplied with methanol, shaken for 24 hours and extracted in a Soxhlet device. Then, Rotary Evaporatorwas used to evaporate methanol (Brauer and Devkota 1990).
Contact impact was investigated in extraction study and dipping method was employed. 3 cm leaf disks were dipped into extracts at different doses (2, 4, 8 and 12%) and left to dry for 30 minutes. Leaf discs were dipped into distilled water in control treatments. Dried leaf disks were then placed into petri dishes supplemented with wet cotton. Over these leaf disks, 6 mites were placed. Experiments with 4 replications were repeated 2 times. Ultimately, mites were counted at 2nd, 24th, 48thand 72nd hours.

Results and discussion

Contact impact experiments

Dipping method was used in contact impact experiments. 3 cm leaf disks were dipped into plant extracts prepared at 2%, 4% 8%and 12% doses and left to dry for 30 minutes. Leaf disks were dipped into distilled water in control treatments. Dried leaf disks were then placed into petri dishes supplemented with wet cotton. Over these leaf disks, six mites were placed on each.
Results on contact impact of *M. communis* extracts prepared in methanol are provided in Table 1.The impact rates at 2% dose were observed as 16.67% at 2nd hour, 30% at 24th and 48th hour and 53.36% at 72nd hour. The impact rates at 4% dose were observed as 26.67% at 2nd hour, 83.34% at 4th hour and 100% at 48th and 72nd hour. at8% and12% doses, 100% mortality was observed at the end of 24th hour.

Table 1.Contact impact of *Myrtus communis* L. extract on *Tetranychus urticae*

Counting time	Doses (%)			
	2	4	8	12
	Mortality Rates			
2nd Hour	16.67	26.67	26.67	40
24th Hour	30	83.34	100	100
48th Hour	30	100	100	100
72th Hour	53.56	100	100	100

Pests, mites and especially *Tetranychus urticae* are polyphag creatures causing significant damages on cultural crops, ornamental plants, recreation and forest plants and today plant extracts and essential oils are commonly used against these pests. Such extracts and essential oils usually terminate feeding, reproduction and egg-laying, they serve as a repellent and acaricide. Lee et al. (1997) reported significant fumigant impact and prevention of egg-laying of *Mentha* spp. etheric oil components. In another study, 100% mortality was reported with etheric oils including1.8-cineole, α-terpineol, verbenol and geraniol at the end of second day (Lee et al., 1997, El Gengaihiet al., 1996). Çetinand Elma (2011) investigated the contact impact of *Laurus nobilis* L plant extracts against *Callosobruchus maculatus* F. adults and assessed the impacts on prevention of egg-laying. Researchers reported LC50 value as 2.02% and LC90 value as 33.73%.

In the present study, 12% dose of *M. communis* had the greatest acaricide impact and yielded 100% mortality at the end of 24 hours.

It was concluded in this study that plants extracts and essential oils could reliably be used against spider mites as an alternative to pesticide and as a residue-free environment-friendly organic product.

Abstract

Thymus vulgaris L. essential oil with high thymol content and *Origanum onites* L. essential oil with high carvacrol content and their equal mixture were tested for controlling of common purslane, (*Portulaca oleracea* L.), redroot pigweed, (*Amaranthus retroflexus* L.) black nightshade (*Solanum nigrum* L.) and ground cherry (*Physalis angustifolia* L.). Each essential oil was applied at the rate of 0, 40, 80, 160 and 320 L/ha in the micro-plots. The experimental design was 3 x 5 factorial with 3 replications in the micro-plots. *O.* essential oil was found more effective on the germination inhibition of redroot pigweed, black nightshade and ground cherry than those of *T. vulgaris* and equal mixture of both essential oils. However, *O. onites* and *T. vulgaris* essential oils had similar effects on the germination inhibition of common purslane. Germination inhibition of weed seeds seriously decreased with the application of essential oils higher than 80 L/ha. The results of the current study showed that oregano essential oil could be used against weeds of the cultivated areas especially in the high value organic crop growing areas**.**

Keywords: *Weed control, essential oil, germination inhibition, organic farming*

Introduction

Essential oils, composed of complex mixtures of monoterpenes, biogenetically related phenols, and sesquiterpenes, are volatile natural complex secondary metabolites characterized by a strong odor (Azcan et al., 2000; Hudaib et al., 2002). Essential oils have a broad spectrum of activity against pest insects, plant pathogenic fungi, weeds and plant pathogenic bacteria. Some forms of essential oils are used as a soil drench to control weed seed germination, root pests like wireworms, while others serve as foliar pesticides applied directly to the plant itself with a range of effects from lethal toxicity to repellence.

Thymus vulgaris and *Origanum vulgare*, pleasant smelling perennial medicinal and aromatic herbaceous plants belonging to the Lamiaceae family, widely used in the Western Mediterranean countries. As a mixture of monoterpenes, major essential oil components of *T. vulgaris* are thymol, p-cymene, γ-terpinene and carvacrol (Azcan et al., 2000; Thompson et al., 2003; Giweli et al., 2013). In addition to monoterpenes, terpenoids, flavonoid aglycones, flavonoids glycosides, and phenolic acids were also found in *Thymus* spp. (Vila, 2002). *T. vulgaris* and *Origanum onites* essential oils exhibit multiple biological activities including anti-inflammatory (Braga et al., 2006), immunomodulatory (Albu, 2012) antispasmodic (Babaei et al., 2008), antioxidant (Aeschbach et al., 1994), antibacterial (Copur et al., 2010; Lakis et al., 2012), antifungal (Arslan and Dervis; 2010), antiviral (Bukovska et al. 2007), antihelminthic (Rasooli et al., 2006), carminative (Dapkevicius et al., 2002), and free radical scavenging properties (Fujisawa and Kadoma, 1992). Traditionally, the leaves of *T. vulgaris*, *Origanum vulgare* and their essential oils have been used in food industry for the flavour, aroma and preservation. Presently, an increasing interest has been expressed for *T. vulgaris* and *Origanum vulgare* because of their relatively broad biological activities. The latest researches in medicine and pharmacy have focused on developing new drugs and biomaterials based on essential oils or plant extracts, this field being a new future direction for treating

different pathologies (Bouchra et al., 2003; Baydar et al., 2004; Uremis et al., 2009; Arslan, and Dervis, 2010; Padmavathi, 2013; Haider et al., 2014).

In the organic farming systems, weeds cannot be controlled by synthetic herbicides. Hence, hand hoeing, inter-row tillage, mulching and ground covering are the major approaches to control weeds. Nevertheless, these techniques are costly and may not adequately control weeds. Consequently, naturally occurring biologically active compounds from biological origins receive more attention as a rich source of potential weed-control agents. Essential oils have a rich potential source of an alternative and environmentally safe and acceptable weed control compounds.

The purpose of the current study was to investigate the herbicdal effects of essential oils of Thymus vulgaris and *Origanum vulgare* on the germination and seedling and root growth of common purslane, redroot pigweed, black nightshade and ground cherry.

Materials and Methods

The fruits of common purslane, redroot pigweed, black nightshade and ground cherry were collected from infested areas in the experimental farm of Mustafa Kemal University in September 2013. The fruits were shade dried in the laboratory at ambient temperature (20-25 ºC) for 30 d. To break dormancy, imbibed seeds were stored for 21 d at 4 ºC in the dark.

Dry leaves of *Origanum vulgare* and *Thymus vulgaris*, grown in the Research Farm of Mustafa Kemal University Hatay-Turkey, were subjected to steam distillation for 3 h using a Clevenger type apparatus. Essential oils obtained were dried over anhydrous sodium sulphate and stored at –20ºC until gas chromatography-mass spectrometry (GC-MS) analysis.

Analysis of the essential oil was carried out by using Thermo Scientific Focus Gas Choromatograph equipped with MS, auto sampler and TR-5MS (5% Phenyl Polysilphenylene-siloxane, 0.25 mm x 60 m i.d, film thickness 0.25). The carrier gas was helium (99.9%) at a flow rate of 1 mL/min; ionization energy was 70 eV. Mass range m/z 50-650 amu. Data acquisition was scan mode. MS transfer line temperature was 250 ^{o}C, MS Ionization source temperature was 220 ^{o}C, the injection port temperature was 220 ^{o}C. The samples were injected with 250 split ratio. The injection volume was 1µL. Oven temperature was programmed to 50 ^{o}C to 220 ^{o}C at 3 ^{o}C/min. The structure of each compound was identified by comparison of their mass spectrum (Wiley) using the Xcalibur software program. The retention indices (RIs) were calculated for all volatile constituents using a homologous series of *n*-alkane standard solutions C8-C20 (Fluka, product no. 04070) and C21-C40 (Fluka, product no. 04071).

Bio-herbicide containing oregano and thyme essentials were prepared by dissolving 0, 40, 80, 160, and 320 ml oregano and thyme essential oils separately in 60 ml ethanol and 3 ml Tween 80 and sterile distilled water was added to have until 1 L volume. The commercial chemical Dasomet, (3, 5-dimethyl-1, 3, 5-thiadiazinane-2-thion), acts as fungicide, insecticide and nematicide, was used as control. Oregano and thyme essential oils were tested at 0, 40, 80, 160, and 320 l/ha concentrations, while the commercial Dasomet (Tetrahydro-3,5,dimethyl-2H-1,3,5-thiadiazine-2-thione) was used for positive control. Equal amount of oregano and thyme essential oils were mixed to have 0, 40, 80, 160, and 320 L/ha oregano + thyme essential oil. Equally mixed oregano and thyme essential oils dissolved in the sterile water as described above.

Two hundreds of common purslane, redroot pigweed, black nightshade and ground cherry seeds were mixed evenly in the sterilized soil in 0.5 x 0.5 m micro-plots. Essential oils were applied at the concentrations of 0, 20, 40, 80, 160 and 320 L/ha in the micro-plots. No essential oil was added in the negative control plots. After bio-herbicide treatment, the micro-plots were covered with polyethylene film for 7 days.

Soils of common purslane, redroot pigweed, black nightshade and ground cherry containing plots were placed in a growth chamber at 28/32 ºC for 12/12 h and dark/light period for 16/8 h. Treatments were arranged in a completely randomized design with 4 replications. After 2 weeks, number of germinated seeds were counted. Percent germination inhibition was calculated as:

$GI = [(CG-TG)/.CG] \times 100$ (1)

where, GI is the per cent germination inhibition (%); CG, germination rate in check treatment; TG, germination rate in extract treatment. Analysis of variance was performed for all data using a general linear model procedure. Data from 2 experiments were pooled and mean values were separated on the basis of least significant difference (LSD) at the 0.05 probability level.

All experiments were conducted in a completely randomized plot design with three replicates. The statistical analysis of experimental data was determined using a general linear model procedure of SAS for Windows (Version 8.02, SAS Institute, Cary, NC, USA), applying the one way analysis of variance (ANOVA). Mean separation was calculated according to Tukey's test ($P \leq 0.05$).

Results and Discussion

More than 28 and 27 components were identified in thyme and oregano essential oils, respectively (Table 1). However, most of the essential oil components constituted less than 1 %. Only 4 components detected in the essential oil of thyme in concentrations more than 2 % were thymol, carvacrol, caryophyllene and *p*-Cymene (Table-1). Three components in concentrations more than 2 % i.e., carvacrol, *p*-Cymene, and γ-Terpinene were detected for oregano essential oil (Table-1). The active ingredient for herbicidal activity in thyme and oregano essential oils were thymol (69.97%) and carvacrol (73.64), respectively.

Compared to negative control, germination inhibition of Redroot pigweed varied between 98.45 % and 60.30%. The highest was obtained from Dasomet and the lowest was obtained from thyme and oregano oil equal mix of 20 L/ha dose (Table 2). The inhibition rate for both thyme and oregano essential oil increased with the increased essential oil rate. When ground cherry was in consideration, the highest inhibition was obtained from Dasomet with 98.33% and the lowest was obtained from 20 L/da equal mix of both essential oil with 57.22%. Similar inhibition rates were obtained for black nightshade. The inhibition rate for *black nightshade* varied between 98.45 and 60.31%. The lowest and the highest inhibition rates were obtained from Dasomet and equal mix of both essential oil with the lowest application dose (20 L/ha), respectively. The germination inhibition of common purslane had the similar inhibition rate for both tested essential oil and their equal mix (Table 2). Inhibition rate of two essential oils on the germination of redroot pigweed, ground cherry, black nightshade and common purslane seeds were much more different at the lower concentrations, while the effects on the germination was much more less at the higher concentrations. Differences in herbicidal activity of essential oils have been attributed to differences in major active essential components (carvacrol, thymol, caryophyllene and *p*-cymene). The current study confirms the findings of Onen et al. (2002), Angelini et al. (2003), Tworkoski (2002), Kordali et al. (2008) and Uremis et al. (2009) that essential oil had great potential to inhibit seed germination and seedling growth.

Development of natural herbicides would help to combat with problem weeds without threating human health and environment. In this respect, thyme and oregano essential oils may be effective, biodegradable and less toxic to the environment. Based on the present results, thyme and oregano essential oils could be suggested as alternative herbicides for organic farming to control weed seedling emergence.

Conclusion

Herbicidal potential of *Thymus vulgaris* and *Origanum vulgare* essential oils were investigated on the germination inhibition of common purslane, redroot pigweed, black nightshade and ground cherry. The major active components of both essential oil had great herbicidal potential on the germination inhibition of the tested weed seeds either alone or equal mix. The germination inhibition of the tested essential oil increased with the increased concentration.

Abstract

In the small-plot field experiment (2012) we identified efficiency of biological preparations based on agronomically beneficial microorganisms under organic farming conditions. We studied the application of presowing treatment of sunflower’s, maize’s, buckwheat’s seeds by the biological preparation Polymyxobacterine based on phosphate-solubilizing bacteria *Paenibacillus polymyxa*, and suspension of bacteria genus *Bacillus* which has useful properties, such as nitrogen-fixing ability and plant growth-promoting properties, and also the antagonistic properties to some phytopathogenic fungi. In the soil samples taken from a plants’ rhizosphere the number of microorganisms belonging to main ecological and trophic groups, the activity of invertase, dehydrogenase, and phenol oxidase was identified. We have found out a positive effect of inoculation on the state of microbial cenosis of podzolized chernozem in the rhizosphere of plants and on the crop yields. The number of soil microflora in root zone of plants was increased by 10 – 55 %, including the increase in number of phosphate-solubilizing bacteria by 35 – 54 % or more. Enzymatic activity of soil has increased also. The extent of the positive effect of every biopreparations on the biological properties of soil and on the yield depended on the type of agricultural crops that were grown. Sunflower yields increased by 1.4 – 1.9 times, buckwheat yields increased by 1.4 – 1.6 times, maize yields increased by 1.1 – 1.2 times. In addition, in the long-term stationary field experiment (2014) we studied the efficacy of microbial preparation Polymyxobacterine at sunflower cultivation in the condition of organic farming. The number of rhizosphere microflora enhanced by 21 %, the enzyme activity increased by 10 – 20 %, the yield increased by 29 %. Our results show a prospect of application of microbial preparation Polymyxobacterine and preparation based on bacteria of genus *Bacillus* in organic farming.

Keywords: *organic farming, biological preparation Polymyxobacterine, soil microbial communities, soil enzymatic activity.*

Introduction

A shortage of high quality fertilizer based on manure of cattle and poultry in Ukraine lead to the acquiring of relevance of applicative development projects aimed at improving of soil fertility and plant yields through the application of biological preparations based on agronomically useful microorganisms that contribute to the activation of native microflora and positive soil-biological processes, optimization of plant root nutrition. The use of microbial preparations is extremely important under conditions of organic farming. These enable increase in productivity and improve the quality of crop production and provide energy and raw materials saving. A topical issue is not only the development of measures in order to improve the biological activity of the soil, but also determine the effectiveness of their application in various technologies of cultivation of crops under conditions of organic farming on different types of soils.

Our previous studies (Naydyonova et al., 2013) found that in the soil where organic farming system was used during a long term, provided only straw of different crops was used as organic fertilizers, the number of microorganisms and biological activity was reduced. In the

condition of limited resources, it is appropriate to use microbial preparations based on agronomically useful microorganisms for activation of the soil microflora.

The preparation Polymyxobacterine was created at the Institute of Agricultural Microbiology and Agroindustrial Production NAAS of Ukraine on the basis of phosphate-solubilizing bacteria *Paenibacillus polymyxa* for increasing the yield of many crops, in particular, sunflower and maize (Volkogon et al., 2006, Melnyk et al., 2007).

Miroshnichenko, Dotsenko et al. (2013) have established in a field experiments on typical chernozem that the application of presowing treatment of spring barley seeds by the biological preparation Polymyxobacterine (2004 – 2005) ensured increase of grain harvest at 18.8 %, which is equivalent to the fertilizing of phosphate fertilizers in a dose of 20 kg of active substance per hectare in the background without bacterization. Under favorable agrometeorological conditions application of Polymyxobacterine ensured of the growth harvest of green mass of corn 55 centners (5500 kg) per ha or 19.2 % compared to control. In the background without fertilizers growth of harvest of sunflower seeds as a result of application of Polymyxobacterine was 2.8 centners per ha or 12.3 % (2010).

Earlier in the small-plot field experiment (2012) we identified efficacy of various microbiological measures, including Polymyxobacterine and bacteria of the genus *Bacillus* in growing sunflowers, buckwheat and maize in organic agriculture (Naydyonova, 2014).

Bacteria of the genus *Bacillus* from collection of Soil Microbiology Laboratory of NSC ISSAR have nitrogen-fixing and plant growth-promoting properties and the antagonistic to some pathogenic fungi properties.

According to the results of the small-plot field experiment, one of the most effective measures in the cultivation of sunflower in organic farming was presowing treatment of seed by the Polymyxobacterine. But, before recommending this biological preparation for wide introduction of organic production enterprises, it needs to be tested in terms of experiments on larger areas.

The purpose of our research in 2012 was to establish the efficacy of presowing treatment of sunflower’s, maize’s, buckwheat’s seeds by microbial preparation Polymyxobacterine and suspension of bacteria of the genus *Bacillus* in their cultivation in organic farming systems. We studied the effect of preparations on the microbiological and biochemical parameters of soil, crop yield and quality of plant products and identified the most effective measures for each of the studied crops for inclusion in the technology of organic production. The purpose of research in 2014 was to identify the efficacy of Polymyxobacterine at sunflower cultivation in organic agriculture by its effect on soil microbial communities in the root zone of plants and yield.

Materials and methods

Efficiency of application of biological preparation Polymyxobacterine and bacteria of the genus *Bacillus* was studied in 2012 in the small-plot field experiment, which was laid in the long-term stationary field experiment, conducted from 1989 on podzolized chernozem in Suburb experimental field of NSC ISSAR (Korotych village Kharkiv district of Kharkiv region). Area of experimental plots was 1 m^2. Presowing treatment of seeds was performed with an aqueous solution of preparation Polymyxobacterine in compliance with the dose recommended for certain weight of every culture seeds.

Pure culture of bacteria of the genus *Bacillus* from collection of Soil Microbiology Laboratory (strain № 531) was accumulated at an appropriate nutrient medium, and then an aqueous suspension was produced and used to spray seeds of crops.

Efficiency of Polymyxobacterine in growing sunflower cultivar Jason was studied in 2014 in the long-term stationary field experiment of Agrochemistry Department of NSC ISSAR on podzolized chernozem in Suburb experimental field of NSC ISSAR (Korotych village, Kharkiv district Kharkiv region). Area of experimental plots was 168 m^2, 3-time

repetition. Organic farming system in experiment provides for the use only organic fertilizers (straw of different crops) and without herbicides means weed control.
In soil samples we identified following biological indicators: a number of microorganisms of main ecological and trophic groups by method of microbiological seeding on dense nutrient media (Zvyagintzev et al., 1980): organotrophic bacteria on the meat-peptone agar (MPA), microorganisms assimilating mineral nitrogen compounds and actinomycetes on a starch-ammonium agar (KAA), fungi on a Richter's medium, oligotrophic microorganisms on a starvation agar (SA), microorganisms, solubilizing mineral phosphates on a Muromtsev's medium, microorganisms, solubilizing organic phosphates on a Menkina's medium. Calculated indices, such as mineralization index (Mishustin, 1975), oligotrophicity index (Aristovskaya and Chudyakova, 1977) and the microbial transformation of soil organic matter (MTSOM) index (Muha, 1980), describing the tension mineralization processes and trophic regime of soil, were determined by the ratio of some groups of microorganisms, the summary biological index (SBI) by the method of relative values according to Azzi (1959).
Analyses to determine the quality of maize grains were carried out in the Instrumental Soil Research Methods Laboratory of NSC ISSAR.
Biochemical activity of soil was determined by soil enzymatic activity by photocolorimetric method: invertase activity by method set out Zvyagintzev et al. (1980), dehydrogenase by Galstyan (Haziev, 1976) and phenol oxidase according to Karyagina and Michaylovskaya (1986).
The reliability of the experimental data was assessed by means of variance analysis using the standard software package «Statistica 6.0».

Results and discussion

Results of small-plot field experiment (2012)

The use of biological preparations had a positive effect on the state of microbial communities of podzolized chernozem in the root zone of plants, both in their structure and in function. The number of most studied groups of microorganisms in soil samples from experimental plots where the preparations were used was higher than on the control plots (table 1). Thus, number of microorganisms assimilating organic nitrogen statistically significantly increased under presowing treatment of sunflower seeds by Polymyxobacterine and by suspension bacteria of the genus *Bacillus.* Also, the number of microorganisms of this group increased under the presowing treatment of maize seeds by Polymyxobacterine. Both preparations used in the experiment positively influenced on the number of microorganisms utilizing mineral nitrogen both soil under sunflower and maize. Significant effects on soil microflora under buckwheat were not found.

Oligotrophicity index which characterizing soil nutrient regime, in variants with preparations usually had lower values compared to the control that indicated the improvement of trophic regime of soil. The mineralization-immobilization of nitrogen index for soil in variants, where the biological preparations were applied, was in most cases slightly higher, that indicating a more intensive course of mineralization processes in soil. Higher values had a MTSOM index that indicated higher biochemical activity of microorganisms.

Effect of investigated preparations on the state of soil microbial communities under each crop was evaluated using SBI, which was determined taking into account number of microorganisms of main ecological and functional groups. According to values of SBI, presowing treatment of seeds by Polymyxobacterine had the greatest positive effect on the number of microorganisms in the soil root zone of maize and sunflower. Application of bacteria genus *Bacillus* had a slightly less positive effect.
Both used preparations positively effected on the number of phosphate-solubilizing bacteria, which dissolve mineral phosphates. Their number increased in comparison with control at the

beginning of the growing season by 35 – 52 % 37 – 54 % 43 – 166 % depending on the crops grown (sunflower, buckwheat, maize respectively).

LSD – least significant difference.

The important index of biological activity of soil is its enzymatic activity. Under the action of preparations activity of some enzymes increased at some extent in soil of plants rhizosphere. In the soil root zone of sunflower dehidrogenase activity increased by 21 – 27 % under the influence of application of bacterial suspension and Polymyxobacterine. In soil under buckwheat activity of this enzyme has increased by 38 – 41 % respectively. In the soil under maize dehidrogenase activity intensified under conditions of application of *Bacillus* sp. by 29 %. Invertase and phenol oxidase activity increased with using both preparations by 49 – 80 % and 12 – 28 % only in the soil under sunflower.

Increase in a number of microorganisms of basic groups in soil and increase of its biochemical activity under condition of application of microbial preparations in organic farming positively influenced harvests of agricultural plants. A harvest of dry mass of sunflower plants with treatment by Polymyxobacterine was higher than control by 71 %, anthodium by 93 %, with treatment by bacteria by 23 and 45 % respectively. Plants grown from treated seeds were higher than untreated. The harvests of buckwheat grain increased due to the treatment by Polymyxobacterine by 36 %, and due to the treatment of seed by bacteria it increased by 57 %. The harvest of raw green mass of maize increased by 4 %, raw ear maize by 16 % due to application of Polymyxobacterine, due to the treatment of seed by *Bacillus sp*. st. № 531 – by 10 and 13 % respectively.

Moreover, the use of preparations significantly improved the quality of maize grain (table 2). The most significant positive impact on the yield of sunflower and maize cobs was caused by Polymyxobacterine.

Results of long-term stationary field experiment (2014)

Application of Polymyxobacterine had positive impact on microflora and biological activity of the soil in root zone of sunflower. Under action of the preparation a number of bacteria utilizing organic nitrogen was increased by 22 – 36 %, a number of microorganisms assimilating mineral nitrogen was increased by 9 – 24 % a number of oligotrophs was increased by 5 – 34 %, the total number eutrophs was increased by 12 – 27 % (table 3).

CFU – colony forming units;
MTSOM – coefficient of microbial transformation of soil organic matter;
SBI – summary biological index;
LSD – least significant difference.

According to SBI values, on average the number of bacteria in the soil of root zone increased by 21 % due to application of Polymyxobacterine.

Due to increasing in the number of eutrophic microorganisms when applying Polymyxobacterine, at the beginning of the growing season oligotrophicity index decreased that indicating improvement of soil trophic regime and was essential for plant growth at the initial stages of their development. A positive aspect is the reducing of the mineralization index that causes preservation of soil organic matter reserves. Noticeable growth of coefficient MTOSM indicates intensification microbiological activity in the root zone.

Given the fact that the active bio-agent of microbial preparation is strain of phosphate-solubilizing bacteria, in the soil root zone of sunflower plants three times during the growing season number of bacteria that dissolve mineral and organic phosphates was defined. Under conditions of Polymyxobacterine application significant increase in bacteria mobilizing soil organic phosphates was observed (Fig. 1).

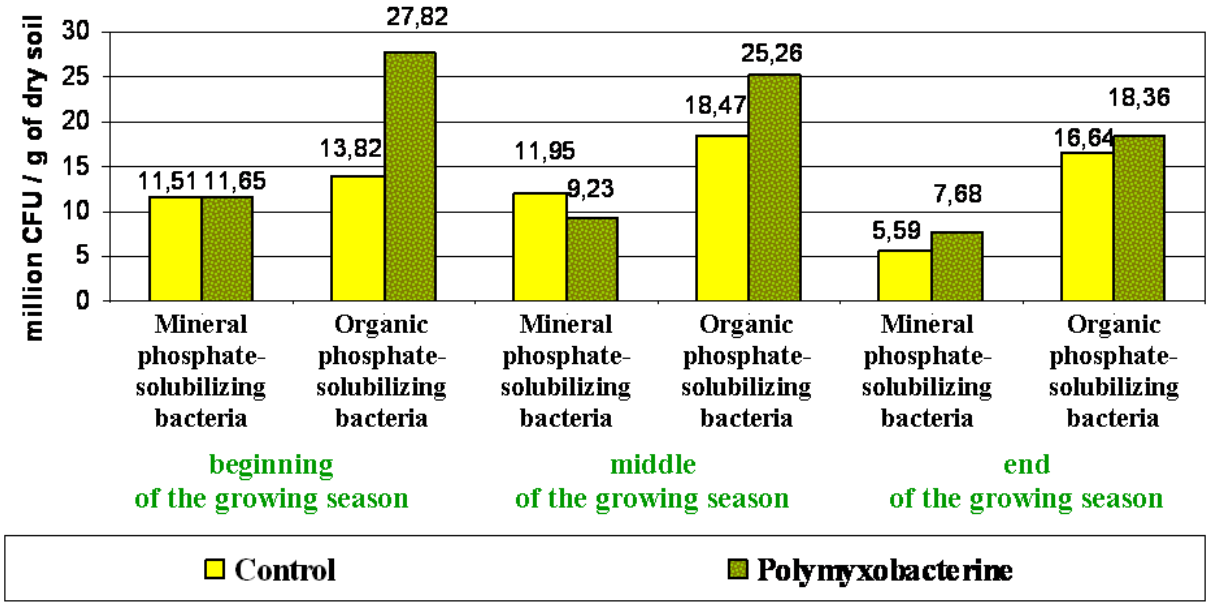

Fig. 1 – Impact of Polymyxobacterine on the number of phosphate-solubilizing bacteria in the soil root zone of sunflower plants

It is known that in addition to the direct action of microorganisms, which are part of biopreparations, their positive impact on soil root zone of plants is to enhance native soil microflora, resulting in increase of its biochemical activity (Volkogon et al., 2006).

Positive effect of Polymyxobacterine on the enzymatic activity of the soil in the root zone of plants was noted (table 4).

Invertase activity was increased at the beginning of the growing season by 11.6 %, at the end of the growing season it increased by 83.6 %. The most noticeable phenol oxidase activity was increased due to the use of Polymyxobacterine. It was greater than control in all periods of observations: at the beginning of the growing season by 10 %, in the middle of the growing season by 15.7 %, at the end of the growing season by 19.6 %. Increase in phenol oxidase activity is particularly important for organic farming, given that phenol oxidase is involved in the synthesis of humus components, so increase in its activity determines the orientation of biochemical processes in the direction of preservation and stockpiling of its reserves in the soil.

Table 4 – Effect of Polymyxobacterine on enzymatic activity of soil root zone of sunflower plants (2014)

Variant of experiment	Dehydrogenase, mg TPF / 100 g per 24 hours			Invertase, mg glucose / 1 g per 24 hours			Phenol oxidase, mg 1,4-n-benzoquinone / 10 g per 1 hours		
	1	2	3	1	2	3	1	2	3
Control	157.50	41.83	133.50	2.41	9.45	2.14	600.00	547.23	612.00
Polymyxobacterine	145.50	46.27	127.50	2.69	9.00	3.93	660.00	633.16	732.00
$LSD_{0,05}$	14.86	4.02	9.68	0.19	0.52	0.34	29.20	26.14	34.97

Notes to Table 4:
1 – at the beginning of the growing season; **2** – in the middle of the growing season; **3** – at the end of the growing season;
TPF – triphenylformazan;
LSD – least significant difference.

Activation of native microflora and positive soil-biological processes was effected on the yield of sunflower (table 5). Application of Polymyxobacterine ensured sunflower yield increase by 29 %.

Table 5 – Effect Polymyxobacterine on the yield of sunflower, centner · ha^{-1} (2014)

Without biological preparation	Application of Polymyxobacterine	LSD $_{0,05}$	Increase of yield	
			centner · ha^{-1}	%
32.38	41.67	4.82	9.29	28.69

Conclusion

In small-plot field experiment (2012) positive impact of seeds inoculation by Polymyxobacterine and by bacteria of the genus *Bacillus* on the number of soil microflora and soil enzymatic activity in root zone of sunflower, buckwheat, maize plants was established. The degree of positive influence of each type of treatment on the biological properties of soil and crop yield depended on the grown crop. Strain № 531 of bacteria genus *Bacillus* from collection of Soil Microbiology Laboratory of NSC ISSAR has potential as bio-agent for the developing of a biological preparation based on it.

According to the results obtained in the long-term stationary field experiment (2014), a significant positive effect of biological preparation Polymyxobacterine for the number of microorganisms in the root zone of sunflower plants under organic farming condition was identified. On average, number of investigated microorganisms increased by 21 %. Also soil enzymatic activities significantly increased: invertase by 12 – 84 %, dehidrogenase by 11 % phenol oxidase by 10 – 20 %. Sunflower yield was increased with use of Polymyxobacterine for 9.29 centner · ha^{-1}. The number of agronomically valuable phosphate-solubilizing bacteria significantly increased too.

The economic effect of the use Polymyxobacterine in sunflower growing under conditions of organic farming is in increasing harvest by 28.69 %. However, environmental effect is also valuable for the organic farming that means environmental cleanliness maintenance and preventing soil pollution.

Abstract

Studies on microorganisms have in recent years to develop the concept of "organic fertilizers" based primarily on properties known as "beneficial" in some organizations. Apart from these nitrogen-fixing bacteria widely used for making organic fertilizers are capable of some dissolved minerals in rhizosphère. These bacteria find a land application in agriculture in structuring the soil rhizosphere species *Vicia faba* beans or kidney beans (v v equina and the minor), presents an excellent host rotation enriches the soil with nitrogen by root excretion of nitrogenous products by detachments nodule or remaining roots.

Before culturing the eleven floors of this rough textures, and heavy, after chemical and physical fronts v f crop Vicia faba equina and minor crops were put in the two species separately and has made the same physico -chemical, it was noted that the rate of carbon and nitrogen falling on almost all soils after cultivation.

The resulting C / N ratios vary, but the rate of phosphorus are significant and increase in both types of cultures nodulation tests were positive with a slight difference noted in favor of the minor variety, it rots due to be rhizoidal diversity of flora which is at the origin of nodulation and that would be specific to this variety has rather to the overall charge of this flora latter finding at least partly explain the difference in nitrogen levels between the two types cultures, which could be related to deficiencies flora associated symbiotic.

the decrease was less pronounced in the variety minor compared to the variety equina by against the latter seems more preferment viewpoint nitrogen fixation.

Keywords: rhizobia, symbiosis, nodule, fixing

Introduction

Soil is a real habitat, natural environment where plant roots dominate in bacterial and fungal microflora (Raoul, 2003). In soil and root soil interface, trace elements undergo various transformations related to their property and under the control of physical, chemical and biological parameters and often influenced or controlled by the action of microbial soil community and more particularly in the rhizosphere of plants (Deneux- Muslin et al, 2003). Among the species found in legumes Vicia faba or fava beans (V. equina L. and V. minor L.) that perfectly illustrates the symbiotic interaction with rhizobia agronomically. In view of the paucity of studies targeting two varieties mentioned, this study is a contribution to the knowledge of existing biological and soil interactions before and after culture of faba beans. Legumes have an important plant family in the world since agriculture include all protein and are involved in the improvement and enrichment of soil nitrogen (Nour, 1995).

Materials and methods

1 Soil Analysis

1.1. Soil collection N Sampling sites

Soils used in this study were obtained from eleven (11) locations in the *Province of Bejaia (Algeria) (Fig..1) *

Fig.1: Location map of soil sampling sites

1.2. Preparation of fine soil

The amounts collected are dried in the open air before undergoing manual crumbling.

1.3. The culture of faba

I carried out the seedlings Both varieties of faba bean (equina and minor). Culture lasted two months during which we kept watering and regular monitoring.

1.4.Physical analyzes

1.4.1. Grit

This is to determine the statistical distribution in a sample of fine soil (Φ <2mm) size fractions of five data according to diameter classes according to the scale of Atteberg defining classes following different diameters (Baize, 1997; Mc Sweeney, 1999)::

1.4.2. pH measurement

The pH is measured by electrometer (pH monitoring) on a soil solution which pondéro-volume report soil / water is 1 / 2.5.

1.5. Chemical analysis

1.5.1. Determination of Organic Carbon

The organic carbon content is determined by the Walkley-Black method; further modified method called Anne (Dugain et al, 1961;. Baize et al, 1995.) ..

Then, an excess dichromate ion is titrated with a solution of ferrous salts to 8% (Mohr salt). The rate of OM is derived by multiplying the percentage of organic carbon by u

n factor of 1.72 (MO = 1.72 * ROD).

1.5.2. Determination of Total Nitrogen

The assay is performed on a sample of 1 g of fine earth by the Kjeldahl method, the protocol is as follows (Kaouritchev, 1980):

- Mineralization (Norrg ammoniacal N2) in the presence of hot concentrated H2SO4, and a mixture of catalysts (Se, K2 SO4 and CuSO4).
- Distillation in the presence of NaOH (40%) and H3BO4 (4%).

Titration with a cold solution of H2SO4 (N / 50). (Appendix 5).

1.6. Expression of Results:

All results except pH, are usually expressed per 100 g of fine earth: Different size fractions (A, LF, LG, SG and SF) and organic carbon (C ANNE), comparable in% = g / 100g TF

- Total nitrogen (NKJELD.) = ‰ in g / kg of m.p.

1.7. Bioassays:

a-Counting nodules

having dug up the plants in each pot until the total removal of the soil. We counted the number of nodules in both varieties equina (E) and minor (M) grown in 11 soils.

The location and shape of nodules on the root system are photographed to be described hereafter

3.1. Shape and location of nodules

Racines – *minor*

Racines – *equina*

Nodules – *minor*

Nodules – *equina*

3-2. Observation and result

Our watches these images that there is a variety diferences between both minor and equina roots of minor and more than nodulate therefore equina symbiosis and very strong in minor than equina

3.3. Plants soil microorganisms Interactions:

/	N	C	C/N	P	number nodules
Variety equina	+	-	variable	++	++
variety minor	++	+	variable	++	+++
before Culture	+	++	+	-	/

T4 . Variations of the main parameters depending on the cultivar

Conclusion

These results offer us two perspectives, first from a purely agronomic by enriching the soil with nitrogen and the other on that of basic research and should note any time that these variations do not follow the same rate on all the parameters covered in this study; it appears that the soil is a complex and dynamic environment, integrating all living beings in its own operations and in all interactions with wildlife

DIRECT SEEDING EMERGENCE IN THE AGRICULTURAL FARMS OF THE SETIF PLAIN (ALGERIA)

Ryma LABAD[1]*, Tarik HARTANI[1,2]

[1]National High School of Agronomy, Agricultural water management laboratory, Algeria
[2]Tipaza University Center, Algeria
*Corresponding author: ryma_loulou308@hotmail.fr

Abstract

The conservation agriculture concept enables to define different production systems. Its selection and application depends on soil properties, climate and socio-economic considerations. Direct seeding was firstly introduced in Algeria to improve the wheat production in the high plains of Setif and by the “Large Crops Technical Institute” which is a state agency provided assistance and technical support to farmers in this purpose.

Surveys were conducted through a representative set of ten cereal farms in the Setif agricultural plains during the 2014/2015 season. The objective was to describe the agricultural practices associated to the direct seeding and analyze their possible effects on the environment.

Our first results show that the agronomic yield has been improved compared to the traditional technique of seeding in addition to some improvements in organic matter, water retention, biological activity and especially limiting erosion. However, we observed that the use of chemical herbicides (glyphosate) has adverse effects on soils, crops and even humans.

Keywords: *Conservation agriculture, direct seeding, efficiency, glyphosate, Setif.*

Introduction

The cereal sector is one of the main sectors of agricultural production in Algeria. The Setif plains were considered since a long time as the leading for cereal production in Algeria. They have large areas of agricultural lands and receiving amounts of rainfall enabling wheat production. However, yields are generally low due to declining soil’s fertility. The main factors that predisposed to this degradation are: water deficit, overexploitation of agricultural lands and actual farmer’s practices. To increase the production, the “Large Crops Technical Institute” of Setif (L.C.T.I) which is the Algerian pioneer development agricultural institution introduced in 2002 direct seeding to spread the conservation agriculture in public and private agricultural farms. In this framework, several studies were conducted particularly the characterization of some parameters of soil fertility and crops behavior (Ziza, 2007). The author described the direct seeding introduction and diffusion in the Setif plains and presented the expected are the effects of this new agricultural technique. To carry out our work, we implemented a comprehensive approach based on farmer’s survey and physical measurements.

Material and methods

The Setif agricultural plains are located north eastern of Algeria (figure 1). The climate is continental and semi arid with cold rainy winters and hot summers and rainfall is the unique irrigation resource. This context is responsible of high evaporation, soil erosion and soils fertility decrease. Field surveys were conducted over the study area of 1011 ha during the agricultural season 2014/2015.

Our investigations focused on 10 agricultural farms covering 381 ha which are practicing with direct seeding and one aim of this study was to assess the possible impacts of these practices on soil properties. Semi open questions were asked face to face to a sample of 10 farmers involved with durum wheat cultivation by direct seeding.

The agricultural farms were selected to include all the sub areas of the study site according to precipitation magnitude: northern farms receiving an average rainfall varying between 500 and 400 mm, high plain farms receiving an average rainfall between 400 and 300 mm, southern farms which were subdivided into two groups, farms receiving between 300 and 200 mm and farms receiving less than 200 mm.
According to Lahmar et al. (1993) in Karkour (2012), “the whole soils of the studied region are carbonated. The northern part is covered by calcareous soils whereas in the region of high plains soils are calcic type, rich in clay and poor in humus in their northern part and turn into stony in their southern part”. Farmers were asked about their actual and past practices, their farm’s characteristics like soils properties before the emergence of direct seeding. The main observations about the introduction of direct seeding and the dominant weeds and treatment used were recorded and finally others problems dealing with durum wheat development in the region. In consistency with the literature review, organic matter lost, biological activity and water retention level were assessed.

Figure 1: Location of Setif plains and the study area

Results and discussion

During the survey, we noticed that 60% of the farmers have secondary level of education and 40% have a high level of education. This factor may probably impact the farmer’s adoption capacity of direct seeding. They generally came to the agriculture by heritage (family links) and they seem enthusiastic to use direct seeding. When the question “why did you introduce direct seeding?” many answers were provided among which the following are listed:
- "The direct seeding which was introduced in Large Crops Technical Institute of Setif in the framework of a collaboration with the International Center for Agricultural Research in the Dry Areas gives good results. This institution is strongly involved in developing durum wheat production in the Middle East and North Africa. Its local staff provided a technical support in relation with this technique".
- "The direct seeding is not perceived as a new technique. It is an amelioration of the old technique, because before apparition of the plough our grandfathers had used plow to cut soil and make seeds, after that they lock soil by their foot, so they had not till soil deeply".
The other information kept from field is related to the herbicide applied to the soils when seeding. Most of farmers use roundup and/or glyphose depending on its availability in the national market. The active matter is glyphosate with chemical formula is C3H8NO5P with a concentration of 360 g/l. The herbicides are used with different amounts from a farmer to another.The determination of an amount depends of the rate of weeds before seeding and the farmer's purchasing power.
The pioneer farmers started with an amount of 6l/ha and currently all farmers apply an amount that ranges from 3to 1.5 l/ ha. The concentration of the active matter due to the herbicide which depends on the amount applied and the duration of the application was

calculated (table 1). According to the results, there are 03 groups of agricultural farms: low active matter group (< 1 kg/ha), medium group (between 1 and 6 kg/ha) and high active matter group (> 6 kg/ha). This result should affect the agronomic performance in terms of yield and the environmental one in terms of impacts on soils sustainability.

60% of the surveyed farmers who introduced direct seeding in 2005 found that direct seeding increase the content of organic matter in the soil in agreement with the conclusion of Belagrouz (2013). Boudiar (2013) calculated the total carbon in similar conditions of direct seeding use and found an amount of 39.60%. Zetal (2011) assessed the cumulative of organic matter in a sub humid climate due to direct seeding and found it ranging from1.99% to 1.60% respectively from the surface horizon to the deep. The surveyed farmers have unanimously listed the water deficit -and consequently its conservation in the soil- as the top issue for a good production. In fact, Mrabet (2001) stated that the direct seeding improves the storage of water of rainfall from 10% to 30% when compared with conventional technique. The Water retention capacity of the soil is linked to its structure and rate of organic matter. This point has been studied in many researches and confirms the amelioration of retention capacity of water with direct seeding in the region of Setif. Moreover, 70% of the surveyed farmers noticed an amelioration of soil especially in dry season. In 2011, Zetal (2011) has evaluated water retention capacity with a comparative study between direct seeding and conventional technique, the results are that "The direct seeding preserves water in the soil compared with conventional technique with a gap to 3%, during the development cycle of wheat, humidity varied between 22% and 15% and water retention capacity is very significant in direct seeding, it varied respectively from 9.8%-20.7% and 8.6% respectively from the surface horizon until deep horizon".

The second indicator of soil fertility is the biological activity. A few results about the development of a biological activity in the region of Setif are available particularly in the case of the direct seeding (Ziza, 2007). However, farmers claim that some soils lombiriciens are regularly observed.

More over farms located between isohyets of 300 and 200 mm i.e the dry part of the study area, suffer from soil erosion. Farmers state that direct seeding has limited this phenomenon. They confirmed that direct seeding was mainly introduced in Setif in 2002 to limit erosion. Belagrouz (2011) said that "the direct seeding system is a promising technique to protect the soil against erosion”. Another question has been asked regarding the weeding operation in post seeding. "What do you think about the weeding operation in post seedling and the herbicide than you have used?" According to the farmers, the treatment of weeds by glyphosate before seeding preserves the land during the whole of the cycle development of wheat and reduces costs of weeding. However, this may be responsible of no germination of weeds before seeding particularly when rainfall is irregular. In these conditions, the farmers apply the herbicide just after seeding, but before apparition of the wheat seeds.

Table 1: Active matter of glyphosate in the study farms of Setif 2014

Glyphosate application duration (in years)	Amount of glyphosate per area	Concentration of active matter (kg/ha)
1	10,5 kg/12 ha	0,875
2	17.15 kg/25 ha	0,660
7	73.5 kg/10 ha	7,350
8	728 kg/130 ha	5,600
8	369,6 kg/66 ha	5,600
8	16.8 kg/3 ha	5,600
9	1176 kg/120 ha	9,800

Conclusion

The present research enabled to explore the context of the emergence and diffusion of the direct seeding in Algeria. Agricultural farms were classified in three groups according to the amount of herbicide, agronomic yield and soils properties.

Field observations shows that direct seeding is a good solution for some parameters of the soil in particular erosion, water retention, organic matter and biological activity.

Although, natural and human constraints listed by farmers surveyed like the lack of water resources, the lack of permanent vegetation in soil and the poor weed management plays a negative role for the direct seeding management.

Abstract

The aim of our study is to isolate, purify and characterize two entomopathogenic bacterial strains of the genus Bacillus from the soil of Adrar in the Algerian Sahara. The molecular characterization of the isolated strains was carried out by DNA isolation, PCR and sequencing of 16S rRNA gene, followed by a phylogenetic analysis. After that, the study of the bacteria toxicity on the fifth larvae stage of Locusta migratoria was conducted by assessing rates of mortality, LT_{50} and $LC_{50.}$ The phylogenetic analysis showed that the two strains (Strain-B1 and Strain -B2) were identified as Bacillus sp. (HE799656) and Bacillus sp. (HE805963), respectively, with a very high similarity (99%) with the strains Bacillus thuringiensis (NR_043403) and Bacillus weihenstephanensis (NR_024697). Besides, the results of toxicity tests showed that larvae of L. migratoria are influenced by the two isolated bacterial strains. This action is more pronounced with the Bacillus sp. strain-B1 (HE799656) compared to Bacillus sp. strain-B2 (HE805963). Examination of TL_{50} shows that these times vary depending on the bacteria and concentrations applied. Similarly, the LC_{50} are closely related with time and they also vary depending on the bacterial strain tested.

Keywords: *Locusta migratoria, Bacillus sp*., larva-mortality.

Introduction

Among the locusts' enemies of Sahelian cultures, the migratory locust *Locusta migratoria* (Linnaeus, 1758) (*Orthoptera, Acrididae*) is the major pest invasion period. The damage is mainly limited to grass, increasing the risk of social erosion and poverty (Zakaria *et al.,* 2003). The migratory locust occupies a very large geographical extension. Many subspecies have been described mainly in Africa, Madagascar, Oriental Asia, Australia and Mediterranean regions (Duranton *et al.,* 1982). Locust remains a major concern in the strategies of crop protection (Zakaria *et al.,* 2003). However, current methods of control using insecticides are very effective in the desert but also harmful to many other animal species biotope and the environment. In this context, the use of insect microorganisms with insecticidal effects offers some potential (Joung & Cote , 2000).

It is in this concept that this work falls. It aims to isolate bacterial strains belonging to *Bacillaceae* group, of the same biotope as the locust's, to assess their biological impacts on the later by determining the rate of mortality and calculating LC_{50} and LT_{50}.

Material and methods

Soil sampling

Sampling was achieved from soil cultivated in the region of Adrar in the Algerian Sahara soil in September 2013. Samples were taken at the rhizosphere layer.

Isolation, identification and characterization of bacterial strains

Different soil samples are separately dried, screened and finely ground. Of each sample was weighed 10 g to suspend in 90 ml of sterile physiological saline water, whilst stirring. Thereafter every suspension undergoes a series of decimal dilutions (10-1 to 10-5) (Guiraud, 2003). The purity is checked after each passage by microscopic examination of a smear stained with blue methylene and having undergone a Gram. The identification of purified isolates has been subject of a multiphase study, comprising a macroscopic, macroscopic, physiological, biochemical and molecular study of characters.

Molecular identification

DNA extraction, PCR and sequencing of 16S RNA

Extraction of DNA was performed as described by Ausubel *et al*. (1988). The extracted DNA is electrophoresed on agarose gel at 1% for 30 minutes under an electric current of 100V. The DNA was subsequently recovered from the agarose gel and purified using the Jetsorb extraction gel kit (Genomic DNA purification system-PROM, EGA).
The purified DNA is amplified by a Hot Start PCR (94 ° C) using specific primers eubacterial 16S rDNA primers (forward primer 5'AGAGTTTGATCCTGGCTCAG3' (*Escherichia coli* positions 8-27) and reverse primer 5'ACGGCTACCTTGTTACGACTT3' (*E. coli* positions 1494-1513) (Weisburg *et al* 1991). Each 50 µl reaction volume is composed of 2µl of PCR buffer, 0.5 mM of each primer, 1.5 mM MgCl2, 50 mM of each deoxynucleoside triphosphate and 1 µl of Taq polymerase.
The samples analyzed are deposited into the wells of 50 µl PCR plates, installed in a thermocycler type Mastercycler Personal (Eppendorf, Germany). The following program was used: 95 °C for 1 min, followed by 40 cycles of denaturation (1 min at 95 °C), annealing (1 min at 55 °C) and polymerization (2 minutes at 72 °C) for 5 min.
The amplification products are purified using the PCR DNA GFXTM Kit and Gel B and Purification Kit (Amersham Biosciences) then cloned into a vector based on the instructions of manufacturer's instruction (INST / AcloneTM PCR Product Cloning Kit, MBI Fermentas). Transformed clones were selected on LB medium containing ampicillin (100 mcg / ml) and X-gal (80 mcg / ml).

Phylogenetic analysis

The 16S rRNA gene sequences obtained after sequencing were subjected to a similarity search of sequences deposited in the Genbank database (on the NCBI National Center for Biotechnology Information website) using the BLAST program. The multiple sequence alignment was performed by CLUSTALW 1.8 (Thompson et *al*., 1994). The sequence homology was then evaluated and the phylogenetic tree was created by neighbor joining method (Saitou & Nei, 1987) using the MEGA 5 software (Tamura *et al*., 2011). The confidence levels of the topology of the phylogenetic tree obtained were estimated by the analysis of data resampling methods (bootstrap) with 1000 replications.

Evaluation of the toxicity of the bacteria on larvae L5 of *Locusta migratoria*

Source of locusts

The study is performed on L5 larva of the species *Locusta migratoria*. These are captured in the desert of Algeria and put into mass breeding in the laboratory.

Preparation of bacterial suspensions and application of biological treatments

To highlight their entomopathogenic power towards the migratory locust, we have initially conducted the preparation of the mother-solutions. Successive dilutions are then prepared to

10^{-4} dilution. For the application of biological tests, 48 hours old larvae are treated after fasting for 24 hours orally (Oulebsir-MohandKaci, 2012).

Calculation of mortality percentages

The percentage of mortality observed in the control and treated larvae is calculated using the following formula:

Observed mortality = (Number of dead individuals / Total number of individuals) X 100

Calculation of LC_{50} and LT_{50}

Before calculating the TL_{50}, the percentage of observed mortality is corrected relative to the control in the form of ABBOT (1925).

To calculate the LC_{50} (concentration needed to kill half of a population) for each bacterium, we have transformed the concentrations used in logarithms and mortality percentages for corrected probits by using the table probit. The LC_{50} is determined from the equation of the regression line.

Statistical analysis

To confirm the effectiveness of the biological treatment performed, the results are subject to the test analysis of variance. We have applied the Tuckey. The software used is the XLSTAT.

Results and discussion

Physiological and biochemical characterization of bacterial isolates

The multiphase study, being initiated by exploring the macroscopic appearance of bacterial cultures grown on nutrient agar, has shown that isolates carrying the B1 and B2 codes provide well-isolated colonies, broad, smooth, flat, circulars, cream color with irregular edges. Observation under the light microscope of fresh cells and after simple staining with methylene blue and Gram stain, has shown that the two strains are Gram positive and are long stick shaped with square end. Alongside the microscopic study, malachite green staining revealed that both isolates have a spore form. The spore has an oval shape nondeforming center position. Moreover, isolates B1 and B2 have shown positive results for the test of catalase, nitrate reductase and mannitol-mobility. The results of the pyruvic acid derivatives appeared positive for the Voges Proskauer reaction and the two isolates show a positive response for the hydrolysis of starch, gelatin and casein. In contrast, strains B1 and B2 expressed negative hydrolysis test against the indole and the Simmons citrate, and strain-B2 had not hydrolyzed urea. Both strains showed growth after culture and incubation at 45 °C, contrary to the incubation at 55°C and 65 °C which showed negative results.

Isolates have all the cultural characteristics of the genus *Bacillus* already described by Brossard & Terry (1984) and Euzeby (2007). The specific classification has helped join the two bacterial strains isolated from the ground of the Algerian Sahara to the genus *Bacillus* (Guiraud, 2003). Partial sequencing confirms this affiliation with a very high similarity to *Bacillus thuringiensis* (NR_0434030). Indeed, the majority of bacteria of the genus *Bacillus* live in the soil or they persist with their spores. These are bacteria from land who derive their nutritional needs from an organic matter, nitrogen and minerals present in the soil (Brossard & Terry, 1984; Ashnaei *et al*., 2009).

Phylogenetic analysis

The phylogenetic position of the two strains (Strain and Strain-B1-B2) is represented in a phylogenetic tree drawn by the neighbor joining method (Figure 1). The bar represents one substitution per 100 nucleotides. Level nodes of the values indicate the probabilities calculated by bootstrap. The 16S rDNA sequences of the two strains were obtained with 760 and 1504 nucleotides and stored in the database EMBL / EBI under reference numbers HE799656 accessions and HE805963 for the strain B1 and B2, respectively. Sequence analysis of these two strains has shown they are related to organisms belonging to the family

Bacillaceae. They are affiliated to the genus *Bacillus* showing very high sequence identity (99%) with the strains *Bacillus thuringiensis* (NR_043403), *Bacillus cereus* AM7 (JQ435684), *Bacillus weihenstephanensis* (NR_024697.1) and *Bacillus mycoides* (NR_036880). The two strains are in the same cluster as that of *Bacillus thuringiensis* (NR_043403) and *Bacillus cereus* AM7 (JQ435684).

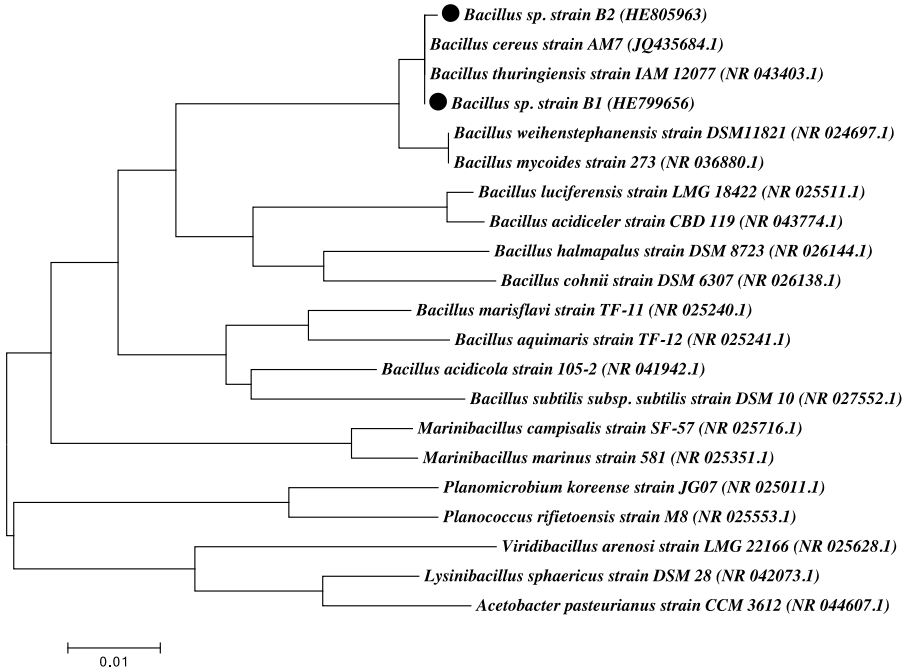

Figure 1: Phylogenetic tree drawn by Neighbor-Joining method of showing the phylogenetic position of strain-B1, strain-B2 and representatives of some other related taxa based on 16S rDNA sequences.

Evaluation of the toxicity of the bacteria on the larvae of *L. migratoria*

Effect on Mortality

Within L5 larvae treated with *Bacillus sp*. strain-B1 (HE799656) (Figure 2), mortality reached 100% after 12 days after treatment at the high dose D1 and at 21 days after treatment at the intermediate dose D2 and finally 90% mortality obtained the same day after treatment with low doses D3. Similarly, mortality rates ranging from 86.67% after treatment with high dose to 70% after treatment medium and low dose of *Bacillus sp*. strain-B2 (HE805963) are achieved after 22 days (Figure 3). Analysis of variance revealed a very highly significant difference at 5% level ($P < 0.0001$) between the control batch and the treated batch by both tested bacteria. Similarly, the Tukey test revealed significant differences for all combinations.

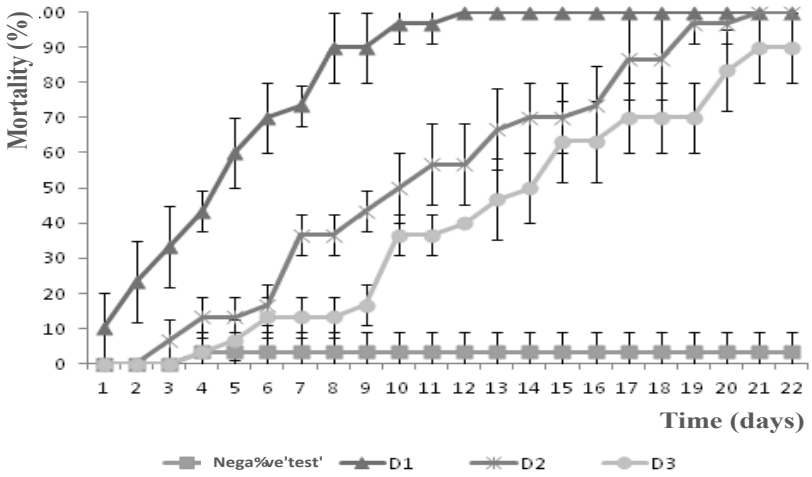

Figure 2: Cumulative daily mortality rate L5 larvae of *L. migratoria* treated with *Bacillus sp.* strain-B1 (HE799656) at doses D1 =1.6 mg/ml, D2 = 0.59mg/ml, D3=0.33 mg/ml.

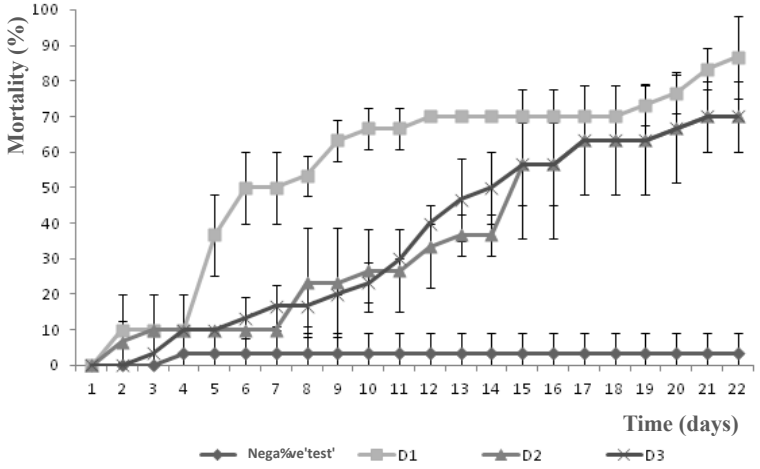

Figure 3: Cumulative daily mortality rate of L5 larvae of *L. migratoria*t reated with *Bacillus sp.* strain-B2 (HE805963) at doses D1= 1,67 mg/ml, D2=0,62 mg/ml, D3=0,35 mg/ml.

In the light of results, and for this parameter, it appears that larvae are influenced by our two bacterial strains. This action is faster with the strain *Bacillus sp*. strain-B1 (HE799656) compared with *Bacillus sp.* strain-B2 (HE805963). The terms of mortality vary between 12 and 22 days. This can be attributed to the mode of action of the majority of the genus *Bacillus* bacteria which act by releasing toxins that demand special conditions or by the conditions of the intestinal environment of crickets that do not fit the growth and bacterial multiplication which requires a relatively long time adaptation (Greathead *et al.,* 1994; Lacey *et al.,* 2001). Indeed, the use of *B. subtilis, B. thuringiensis* and *B. larvae* against larvae *Schistocerca gregaria,* showed 90% mortality, 80% and 70% achieved after 16 days in L4. However, *Pseudomonas aeruginosa* has caused total mortality after 4 days (Mohand-Kaci & Doumandji-Mitiche, 2006).

Finally, in a recent study, the effects of acute toxicity from topical application of growth regulators on three *Locusta migratoria var. manilensis* were evaluated in laboratory conditions with a recorded mortality rate of 97% for flufenoxuron, 100% for azadirachtin and 48% for pyriproxyfen (Bi Zhen et *al*., 2012).

Calculation of TL50 and LC50

Thus, the lethal time for 50% of individuals varies on the bacteria and the bacterial concentrations administered (Figure 4). The L5 larvae of *L. migratoria* processed by *Bacillus sp.* strain-B1 (HE799656) presented the lowest LT50 with a value of 3.32 days recorded at the high dose, 9.12 days for the middle dose and 13.37 days for the low dose. They are followed by L5 larvae treated by *Bacillus sp*. Strain-B2 (HE805963) with 9.19 days for the high dose, 12.94 days for the intermediate dose and13.87 days for the low dose.

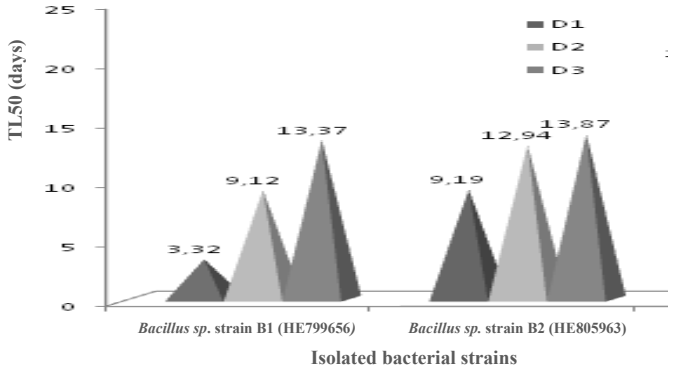

Figure 4: TL50 obtained for L5 larvae of *L. migratoria* treated with 3 concentrations of *Bacillus sp. Strain-B1* (HE799656) and *Bacillus sp. Strain-B2* (HE805963).

The comparison of LC50 obtained for mortality observation time for 5, 7 and 14 days after treatment shows that the LC50 is closely related with time; it varies depending on the tested bacterial strain (Figure 5). Indeed, the lowest LC50 are obtained at the 14th day with 0,37mg/ ml and0.62 mg/ ml for the strains *Bacillus sp.* strain-B1 (HE799656) and *Bacillus sp.* strain-B2 (HE805963). The higher LC50 are recorded on the 5th day with values of 1.37 and 2.87 mg/ml.

Furthermore, if one compares the lethal dose by ingestion of the different tested strains, we can see that the strain *Bacillus sp*. Strain-B1 (HE799656) shows considerably more effective and fast reaction than others. It presents the LC50, the lowest in all tested times (5, 7and 14 days after treatment).

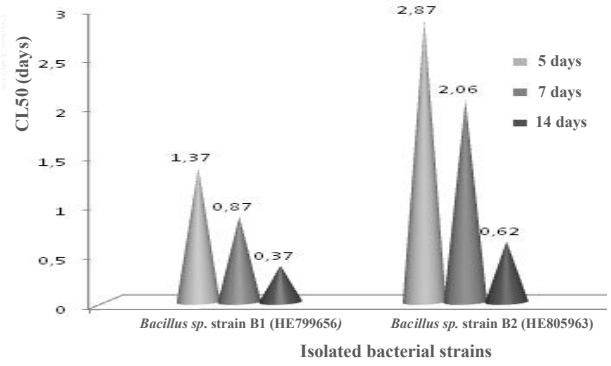

Figure 5: CL_{50} obtained for L5 larvae of *L. migratoria* treated with 3 concentrations of *Bacillus sp.* strain-B1 (HE799656) and *Bacillus sp.* strain-B2 (HE805963).

Our results agree with those of Ould El Hadj et *al*. (2006) which recorded a 7,5 days TL50 for L5 larvae *Schistocerca gregaria treated* with Neem, 8.2 days to 10.4 days for *Melia* and *Eucalyptus*. In addition, comparison of the sensitivity of *Locusta migratoria* to a commercial product and a local strain of *Metarhizium* showed that the latter has a higher activity with a pathogenic TL50 of 7.1 days (Niassy et *al*., 2011).

Gry *et al. (*1966) notes that the calculation of lethal doses determines the dose of the insecticide to be applied to the insect to obtain the desired percentage of mortality, allowing to judge accurately the insecticide product's power. The mortality rate in adult females of the mite *Tetranychus urticae* increased with increasing the concentration of conidia of two strains of entomopathogenic fungi and the most virulent against the mite was *Paecilomycis fumosoroseus,* having the lowest value of LC50 (9.1×10^4 conidia/ml) and LT50 (4.58 days to 1×10^8 conidia/ml) followed by *Verticillium lecanii* with an LC50 (1.7×10^6 conidia / ml) and LT50 5.45 days 1×10^8 conidia / ml (Amjad et *al*., 2012).

Conclusion

In conclusion, despite the proven value of these biological control agents, it appears that they are not much used. Yet they seem to offer the best prospects for biological controls, especially those that can be formulated to be multiplied and spread like biopesticides, particularly during locust control campaigns where they help reducing the outbreak mass.

EVALUATION OF METAL AND METALLOID CONTAMINATION IN SOIL FROM MINING WASTE FOR REHABILITATION AND FUTURE LAND USE

Barry NOLLER

The University of Queensland, Centre For Mined Land Rehabilitation, Brisbane, 4072, Australia
*Corresponding author: b.noller@uq.edu.au

Abstract

Following mining of ore, extraction or separation of the economic item is required. Mine site wastes comprising waste rock and tailings are held in separately constructed structures to minimise erosion and contaminant transport. Key contaminants present in waste from base metal mining and other sulfidic deposits are metals (e.g. cadmium, copper, lead and zinc) and metalloids (antimony, arsenic, bismuth and selenium). Because processed mine minerals are finely divided, there is potential risk from such materials entering the environment and food chain and to be transferred to animals/humans such as via cattle grazing. Principle 4 of the International Council on Mining and Minerals ten principles for sustainable development of mining identifies quantitative indicators of rehabilitation success to: ‘implement risk management strategies based on valid data and sound science’. To avoid health risks to communities from mining activities, good prediction and planning is required, together with well-designed monitoring to detect adverse trends of contaminants. A risk assessment process underlies the risk management strategies adopted. The bioavailability of contaminants is a key component but data is generally lacking to provide a realistic health risk assessment of arsenic and metals from mine wastes. This paper provides an overview of the rationale and application of using metal and metalloid bioavailability data for risk assessment of rehabilitated mined land and its application to develop site specific guidelines for protection of human health and the environment and potential of metal uptake by grazing animals.

Keywords: *Metals/metalloids; mining; contaminants; risk management; bioavailability.*

Introduction

In mineral rich countries such as Australia, mine sites are potential sources of metals and metalloids. If not properly managed, mining activities and dispersion of such contaminants may cause adverse effects on the environment and human health. Limiting the effects of mineral processing activities on nearby communities is vital for sustainable development in mining and mineral processing to avoid environmental and human health impacts from associated contaminants (ICMM, 2007). The International Council on Mining and Minerals (ICMM, 2003) developed ten principles for sustainable development in the mining and minerals industry. These principles have been adopted in Australia and elsewhere to promote rigorous mine closure programs before mining completion and identify quantitative indicators of rehabilitation success. In particular, Principle 4 of the ICMM’s ten principles describes ‘implementing risk management strategies based on valid data and sound science’(MCA, 2005). Often, high costs are incurred during the mine rehabilitation process in an effort to return the land to its former state and/or an accepted future land use. A common option in Australia is the utilisation of mined land for future pastoral activity. Criteria may also be developed to assess the risk to grazing animals, from arsenic and lead liberated from rehabilitated mine wastes (Bruce, 2004; Ng et al., 2014).

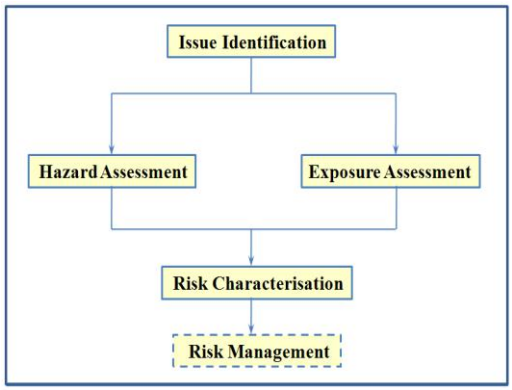

Figure 1. Framework for human health risk assessment (enHealth, 2012)

The Australian National Environmental Protection Council (NEPC, 2013) (Figure1) set Health Investigation Levels (HILs) for site contaminants in soil including some metals and arsenic (Table 1) based on guiding principles for health risk assessment (enHealth, 2012). Although no specific HILs exist for mine sites in the current Australian National Environmental Protection Measure (NEPM) (NEPC, 2013), the enHealth risk assessment framework is universally applicable to mine site health risk assessment. Bioavailability data is generally lacking for realistic health risk assessment of metals and metalloids from mine tailings in Australian conditions (Diacomanolis et al., 2007). If the health-based investigation level (HIL) is exceeded (Table 1), a further Tier II risk assessment of the site is required. In the absence of site specific data, the HILs may not provide accurate close out criteria for mined land (Ng et al., 2003). Significantly, the revised Australian NEPM (NEPC, 2013) adopted the concept of bioavailability and this can be considered in a “Tier-two” risk assessment step. Bioavailability (in-vivo) is defined as the fraction of a compound that is absorbed and reaches the circulatory system after ingestion, inhalation or dermal contact (Ng et al., 2015). Bioaccessibility (in-vitro) is the proportion of metal and metalloid that can be absorbed by an organism and is generally a more conservative approach to predict bioavailability of contaminated wastes such as from mining.

Table 1. Soil contamination health investigation levels in Australia (NEPC, 2013)

Metal or metalloid (mg/kg)	Australian soil contamination Health Investigation Levels (NEPC, 2013)			
	Residential A (Low-density with garden)	Residential B (High-density minor garden)	Residential C (Open-space recreational)	Residential D (Commercial/industrial)
Arsenic	100	500	300	3,000
Cadmium	20	150	90	900
Copper	6,000	30,000	17,000	240,000
Lead	300-	1,200	600	1,500
Zinc	7,400	60,000	30,000	400,000

The bioavailability of a contaminant is a key component of a risk assessment and is conservatively assumed to be 100% when no specific data exists. Research to generate bioavailability data for various metals and metalloids of mine tailings has been undertaken in order to provide a more accurate risk assessment of rehabilitated mine facilities under Australian conditions and to develop quantitative indicators for mine closure (Bruce et al., 2002; Diacomanolis et al., 2010). In-vivo bioavailability of arsenic from contaminated land has been assessed using small mammals including rodents, meadow voles, dogs, pigs, monkeys and more typically guinea pigs or rabbits (NRC, 2003). The rat model was utilised

to estimate arsenic and lead bioavailability to provide a risk assessment in calculating the potential exposure route via soil ingestion (Diacomanolis et al., 2007). Absolute bioavailability is measured via animal uptake but is expensive and time consuming. A more practical approach uses in-vitro PBET (physiologically based extraction test) to determine the bioaccessibility of metals and metalloids in soils (Bruce et al., 2007; Ruby et al., 1996).
When mined land is utilised for pastoral activity the key component of risk assessment is the ability to estimate a realistic and safe exposure, or dose rate, of the mine tailings to the grazing cattle over a set period of time. Grazing trials conducted directly on rehabilitated tailings facilities have provided valuable in-situ information on arsenic and heavy metal dose rates and associated accumulations (Bruce et al., 2002).
A review of current bioaccessibility methods and their limitations gives guidance in the Australian NEPM for determining their use and application in contaminant site assessment specifically of arsenic and heavy metals to give prediction of bioavailability (Ng et al., 2015). Comparison of in-vivo bioavailability measurement using animal (rat) uptake provides a means to validate the in-vitro bioaccessibility measurement (Bruce et al., 2007; Ruby et al., 1996).
This paper reviews the significance of speciation and bioavailability of arsenic and metals in managing health risks for mine site rehabilitation and shows how mine site rehabilitation can be better managed by mapping contamination with bioaccessibility-adjusted concentration data. Site specific guidelines can then be established based on the bioaccessibility and bioavailability assessments undertaken for arsenic and lead.

Materials and methods

Two different approaches were employed as risk assessment tools: (i) the in-vitro PBET (physiologically based extraction test) determination of bioaccessibility of individual soils (Bruce et al., 2007; Ruby et al., 2006); and (ii) in-vivo bioavailability measurement of composite wastes using rats (Diacomanolis et al., 2007). All mine waste samples were tested for bioaccessibility (PBET) in a synthetic gastric fluid system under increasing pH values of 1.3, 2.5 and 4.0 simulating fasting, partially fed and fed stomach conditions respectively, and at pH 7.0 simulating the small intestinal pH condition for the extraction tests (Bruce et al., 2007; Ruby et al., 1996). The case study of the Woodcutters lead zinc mine in northern Australia was used to illustrate site specific guideline development for arsenic and metals in soil (Diacomanolis et al., 2010) from on-site contamination. Woodcutters ore production commenced as an open pit in 1985 and became an underground operation in 1986. Mining ceased in March 1999; the mine closure program for the site has continued since then.
A metal and metalloid survey of 60 surface soils was conducted at Woodcutters mine in September 2005; the soil samples were representative of 4 different categories of mine waste materials (Table 3). Finely ground soils (<70 μm) were digested in aqua regia and total arsenic and metal concentrations determined by ICP-AES.
In-vivo bioavailability testing on composite samples of mine wastes from Categories 1-4 was undertaken using animals. Rats weighted at approximately 180 g each were divided into groups of 4. For positive controls, rats were injected intravenously using the salt solution and the other groups were given slurries of mine material by oral gavage. The mine materials were weighted for each rat separately according to the dose rate and body weight. The rats were kept in individual metabolic cages and were fasted over the night before dosing. The dose rates were: arsenic 0.5 mg As/kg b.w. (in the form of sodium arsenate or sodium arsenite, the latter being most conservative) given intravenously via the tail vein for the positive control and lead at 1mg Pb/kg b.w. as lead acetate solution; other metals were not considered for this bioavailability assessment. Rat treatment groups were dosed by oral gavage with 1g of mine waste in a slurry per 200 g body weight. Urine samples were collected 24 h prior to dosing

and then daily over 10 days post dosing; arsenic and lead were determined in urine by ICP-MS. Bioavailability was calculated from the area under the urinary excretion curve of a treatment group compared to that of the positive control group. The complete data analysis is given elsewhere (Diacomanolis, 2013).

Results and discussion

Mean arsenic and metal concentrations in mine wastes are summarised in Table 2.

Table 2. Total concentrations (mean ± s.e.) of arsenic and metals in Woodcutters mine wastes

Element (mg/kg)	Category 1 Creek sediment	Category 2 Material processing	Category 3 Waste rock	Category 4 Tailings
Arsenic	180±50	1340±720	330±40	450±50
Cadmium	120±70	70±40	9±3	5±1
Copper	105±10	130±30	120±30	110±8
Lead	840±280	5450±2700	870±230	550±80
Zinc	7800±2400	7700±4400	1200±470	820±120

A desk top risk assessment on total arsenic and metal concentrations (Table 2) showed that many samples exceeded the HILs for Residential C-open space recreational use (Table 1). In the absence of site specific bioavailability and exposure data, a worst case scenario was necessary to identify potential “hot spots” based on the accepted risk assessment framework (enHealth, 2012). All mine waste samples were then tested for bioaccessibility using PBET. Mean percentages of bioaccessibility for arsenic, cadmium, copper, lead and zinc from the 4 categories of waste materials are shown in Table 3.

Historical investigations into the distribution and concentrations of metals at the Woodcutters mine site indicate that there was an elevated natural background of various minerals. Accordingly, site specific remediation guidelines were developed for Woodcutters mine site following the bioaccessibility studies. The approach adopted now follows the procedure established by the NEPC (2013) and led to the further refinement of the proposed remediation guidelines (Table 3). The measurement of % BAc using PBET was confirmed by rat bioavailability (%BA) of arsenic and lead in key soil types and enabled the development of the site specific remediation guidelines. Application of the site specific guidelines from the risk-based approach indicated that the extent of contamination was limited to a small number of discrete locations at the mine site. Arsenic showed good agreement between BA and BAc, while BAc for lead was approximately 10 times higher than for BA and indicated that BAc was a conservative measurement for lead (Table 3).

Table 3. Summary of bioavailability (BA) and bioaccessibility (BAc) data obtained in 2005 and proposed remediation guidelines for Woodcutters mine site rehabilitation

Metal/metalloid	% BAc 2005	% BA 2005	NEPM Residential C (mg/kg)	Proposed Remediation Guideline (mg/kg)
Arsenic	3-10	1.6-8.9	300	1000
Cadmium	17-30	-	90	80
Copper	5-13	-	17,000	10,000
Lead	10-18	0.6-1.4	600	1,500
Zinc	23-27	-	30,000	40,000

Although the 2005 soil survey results for total arsenic and lead concentrations were relatively high in the mine site rehabilitated areas, adjustment of the results using % BAc from PBET indicated that the contamination was not a significant health risk (Table 2). Only cadmium at

one site and lead at 4 sites in soil were considered to be contaminated and significant when compared against the site specific remediation criteria.

A second key component of arsenic and metal risk assessment is the estimation of realistic exposure, or dose rate, of the mine waste to the grazing cattle over a set period of time (not described here in detail). Hence, grazing trials can be conducted directly on rehabilitated tailings facilities and have provided valuable in situ information on arsenic and heavy metal dose rates and associated accumulation at other mine sites (Ng et al., 2014).

Conclusion

The investigation and development of site specific thresholds demonstrates that careful examination of specific source characteristics and receiving context can greatly improve the focusing and application of resources in closure processes. This had a significant bearing on the focus and extent of remediation activities and success of the Woodcutters mine closure process in enabling local people to access the site for recreational purposes.

Abstract

Extensive herbicide and pesticide application is undertaken for a diverse range of agro-based activities of the Namphong River sub catchment of the Mekong River in Northeast Thailand. The Namphong River has extensive in-river cage aquaculture for Tilapia production in addition to rice and mixed vegetable cultivation, pulp and paper manufacturing utilising local eucalyptus tree cultivation and sugar cane for molasses and ethanol production. The agro-based activities potentially add herbicides and pesticides to river flow and affect the aquatic ecosystem and food chain. Passive samplers were deployed at 5 sites along the Namphong River and used to accumulate herbicides and pesticides on polydimethyl siloxane (PDMS) strip during 29 days deployment in January-February 2012 (analysed at the Queensland Health Laboratories, Brisbane, Australia). Measured herbicides and pesticides except chlorpyrifos were present at exceedingly low concentrations in Namphong river water. However chlorpyrifos was <20 times lower than an Australian aquatic guideline (10 ng/L; 95% protection aquatic freshwater species for protection of aquatic species and was identified as the highest volume of insecticide importation in Thailand. Comparison with an earlier 2005 study of the paddy field ecosystem 50 km N from Khon Kaen shows a shift from organochlorine use to low persistence pesticides, particularly chlorpyrifos. Increased application rate of chlorpyrifos in the Namphong River may increase and exceed the threshold of toxicity for fish and other species and be a threat to cage aquaculture.

Keywords: *Herbicides; pesticide; passive sampling; land use practice; environmental risk management.*

Introduction

The Namphong River in the Northeast (NE) part of Thailand is within a sub-catchment of the Mekong River (Fig. 1). The Namphong River flows to the Chi River via the Mun River to the Mekong River. Below Ubolratana Dam, extensive agro-industry and farming activities along the Namphong River use irrigation from dam storage and some supplementary groundwater supply. Pesticides and herbicides from agro-industry activities are identified as potential risks to human health and the environment and as significant pollutants (Somparn et al., 2014). Chlorpyrifos was identified as the highest volume of pesticide importation in Thailand (Department of Agriculture, 2012). The aquatic ecosystem of the Namphong River is a critical aspect for evaluation of pesticides dispersed in the environment. Ecotoxicological effects from pesticides on aquatic organisms may be observed via biomonitoring with both individual organisms and ecosystem function and structure. The Namphong River also supports

extensive cage aquaculture which may be affected by pesticides. In 2010, 209 cages produced 1536 tonnes of Nile tilapia in Khon Kaen province (Department of Fisheries, 2010).
This study aims to identify if pesticides and herbicides from multiple agro-based activities comprising agro-industry and small-scale farming activities along the Namphong River, are environmental and health risks, causing any impact to the Namphong River water body at different sample locations, and compare with existing data from the 2012 dry season.

Materials and methods

Pesticides and herbicides were accumulated on polydimethylsiloxane (PDMS) strip passive samplers during 19 January-23 February 2012 at 5 sites at the Namphong River from below the Ubonratana Dam, the tributary downstream of the paper mill and vegetable and paddy fields down to the Chi River above the junction of Namphong River (Fig.1).

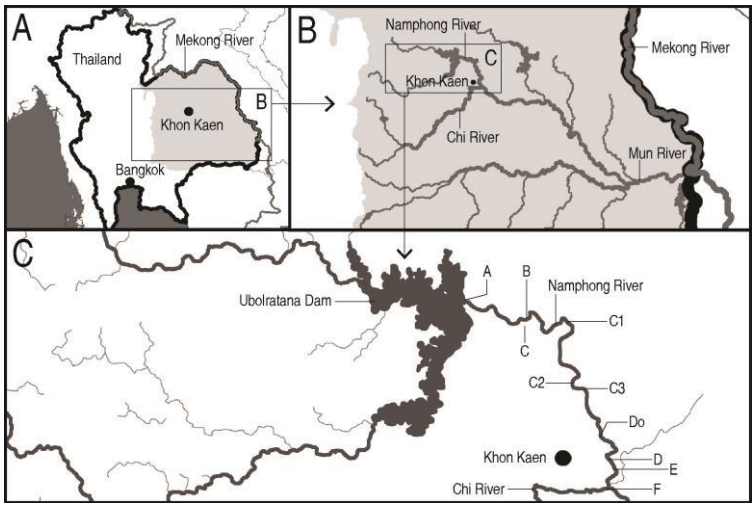

Fig. 1 Location of study site in the Mekong River basin NE Thailand (Maps A and B) and sampling sites along the Namphong River (Map C) *[Sites A – Ubolratana Dam; B – fish cage (in-river cage aquaculture for Tilapia production); C – pulp/paper industrial plant (discharge via small tributary to main river); sugar industrial plant; C2 cucumber culture; C3 corn culture; Do vegetables culture; D vegetable culture and paddy fields; E vegetables culture; and F – vegetables culture, residential discharge to Chi River just upstream from confluence with Namphong River]*

Site C is on a small tributary less than a few km to the Namphong River from the pulp and paper mill (Fig. 1.C). Prior to application each PDMS sampler (strips 2.5 cm x 92 cm and thickness about 400 μm) was cleaned on a horizontal shaker in fresh redistilled hexane for three consecutive 24 h periods followed by drying under high purity nitrogen gas steam, wrapping in acetone rinsed aluminium foil and stored in the refrigerator until dispatched to Khon Kaen. The PDMS samplers were placed under water at 0.50 m depth and left for 29 days. Following collection, the PDMS samplers were placed in pre-cleaned acetone rinsed aluminium foil envelopes and refrigerated until dispatched with quarantine clearance details from Khon Kaen to Australia for sample processing and analysis using the routine procedures of Queensland Health Organic Chemistry Laboratory. Prior to PDMS extraction in hexane and following instrumental analysis each of them was cleaned by scrubbing with water, dipping in redistilled hexane for 30 seconds and 0.5M HCL for 20 seconds followed by rinsing with acetone and isopropanol. Water quality measured using standard techniques described (Komarova et al., 2012, 2013).
Passive samplers using polydimethylsiloxane are low cost and have an improved affinity for polar compounds relative to other samplers (Rusina et al., 2007). Comparative studies (Shaw et al., 2010) showed that PDMS samplers accumulated many compounds with log Kow 2.9 to

6.4 dissolved in water. The mass captured was 6 times higher in PDMS compared with other samplers with the same surface area at log Kow of 4.7 (chlorpyrifos) and 4.27 (trifluralin).
Well developed and validated procedures are used at all steps of PDMS passive sampler application (Shaw, 2005). The mass of contaminants accumulated in a PDMS sampler are converted to their concentrations in water (Cw, ng/L) using a sampling rate (Rs in Ld^{-1}) that is estimated for different pesticides at different environmental conditions in laboratory calibration study (Huckins et al., 2002) by Eq.1:

$$Cw = M_{PDMS} / Rs\ t \quad (1)$$

where M_{PDMS} is the mass of a pesticide found in the PDMS sampler after deployment (ng) and t is the deployment time in days. Method detection limits are calculated from the lowest mass per sampler detected on analytical equipment (LCMS, GCMS) and respective compound sampling rate (e.g. <50 ng/mL for the extracted volume in the laboratory and 0.001 ng/L for chlorpyrifos in PDMS samplers for 29 day deployment). The detection limits are an order of magnitude lower than for pesticide concentrations using grab sampling techniques (Shaw, 2005). The linearity of the relationship between log Kow and sampler to water partition coefficients covers a wide range of compounds for PDMS (Yates et al., 2007).
After extraction and extensive clean-up procedures using size exclusion chromatography, pesticide and herbicide are analysed by different instrumental analytical methods: these are gas chromatography (GC), high performance liquid chromatography (HPLC), GC/MS and LC/MS-MS undertaken in the Queensland Health NATA accredited laboratory (according to ISO 17025) and based on USEPA Method EPA 503/6-90-004. All standards (3 external standards) and samples are spiked with an internal standard just prior to analysis.

Results and discussion

Table 1 gives the pesticide and herbicide concentrations with highest inputs for effluent at Site C (Paper Mill) when compared with Table 2. Galaxolide, terbuthylazine, phosphate tri-n-butyl, tonalid and terbutryn are added in paper mill effluent (Table 1) but only galaxolide remains detectable at much lower concentration (1:35) showing dilution down to Site F at the Chi River; tonalid is diluted 1:10 at Site C3 (Fig. 1.C) but is then undetectable downstream.
Table 2 gives the pesticide and herbicide concentrations for all sites upstream or lower downstream; i.e. below Site C2. Ametryn, oxadiazon, chlorpyrifos, prometryn and atrazine are all found at measureable concentrations at Site A below Ubonratana Dam (Fig. 1.C) indicating that application of these pesticides and herbicides has occurred in the upper Namphong River catchment above Ubonratana dam and contribute to the downstream river load. Fig. 1 shows that about 60% of the Namphong River catchment is associated with the two branches above Ubonratana dam. The input of ametryn, oxadiazon, chlorpyrifos, prometryn and atrazine increased from Site 3 downstream (Fig. 1.C, Table 2). The comparison of measured concentrations of pesticides and herbicides for all sites in Tables 1 and 2 with compiled details of guidelines and LC50 values for fish and other freshwater species shows that all compounds are well below concentrations that will induce a toxic response. While all compounds excepting chlorpyrifos are present at exceedingly low concentrations, chlorpyrifos is only 10-20 times lower than the validated Australian aquatic guideline ANZECC/ARMCANZ (2000) (Table 2 – note no Thai guideline available).
The application of chlorpyrifos is associated with insect control of vegetable and paddy field areas in line with the highest volume of insecticide importation in Thailand cited above (Department of Agriculture, 2012). The pesticides and herbicides that were detected at the sampling sites of the Namphong River in January 2012 are all low persistent compounds and indicate recent applications. Comparison of the observed pesticides and herbicides identified in this study with an earlier 2005 study of paddy fields, horticulture and vegetable farming in the Namphong River basin sediment, water samples and PDMS samplers (Boonthai-Iwai et

al., 2007) showed that the pesticides and herbicides in use at that time included atrazine, oxadiazon and the organochlorines dicofol and endosulfan. Tables 1 and 2 now show there was no detection of organochlorines in 2012 but that chlorpyrifos is used extensively together with a range of herbicides. If the application rate of chlorpyrifos increases, the level in Namphong River may increase and exceed the threshold of toxicity for fish and be a threat to cage aquaculture. Thus there needs to be a more systematic and complex assessment of chlorpyrifos in the Namphong River basin to develop a tool for its control and environmental risk management.

Table 1. Pesticide and herbicide concentrations for 19-23 January 2012 showing Site C (Paper Mill) effluent with highest input (average of 2 PDMSs per site)

Sampling site	Galaxolide[a]	Terbuthylazine	Terbuphos	Phosphate Tri-n-Butyl	Tonalid	Terbutryn

Conclusion

This paper identified that the Namphong River basin can absorb current inputs of pesticides and herbicides that arise from the agro-based activities and is not causing any impact to the water quality in the Namphong River itself. Measured pesticides and herbicides except chlorpyrifos were present at exceedingly low concentrations in Namphong river water. However chlorpyrifos is only 10-20 times lower than the Australian aquatic guideline (noting no Thai guideline) for protection of aquatic species and was identified as the highest volume of insecticide importation in Thailand. If the application rate of chlorpyrifos is increased, the level in Namphong River may increase and exceed the threshold of toxicity for fish and other species and be a threat to cage aquaculture. Although there is no current contamination problem there is a potential issue with chlorpyrifos in water which has higher risk and requiring further data and information. Thus more detailed assessment of chlorpyrifos in the Namphong River basin is required to improve control and environmental risk management.

SEASONAL DYNAMIC ANALYSIS OF AEROALERGENIC POLEN OF BIRCH, ALDER AND HAZEL IN BANJA LUKA (B&H) DURING 2008-2014

Gordana BABIĆ*, Bojana ĆURKOVIĆ, Vojislav TRKULJA

PI Agricultural institute of Republic of Srpska, Banja Luka, Bosnia and Herzegovina
*Corresponding author: brkljacg@hotmail.com

Abstract

Members of the subclasses *Hamamelidae* are characterized by the production of huge quantities of pollen grains transmitted by air. Among them an important source of allergens represents pollen of birch, alder and hazel, as the most frequent causes of pollen allergies in the spring. Considering that the mentioned species are characterized by moderate to strong, or very strong allergenic capacity in the case of birch, the main objective of this study was to monitor the seasonal dynamics and analyze 7-year monitoring of mentioned allergenic species in Banja Luka.

Systematic measurements are carried out using the method defined by the International Association for Aerobiology (IAA).

During the 7-year period, for pollen representatives of the family *Betulaceae,* it is determined birch pollen domination and considerably lower proportion of total alder and hazel pollen count in Banja Luka (Bosnia and Herzegovina). On annually level maximum total number of p/m^3 for *Alnus glutinosa* was registered in 2014 (426 p/m^3). Same year, the maximum total number of 311 p/m^3 was registered for hazel, while for birch the maximum total number of 1223 p/m^3 was registered in 2011.

Keywords: *seasonal dynamics, pollen aeroallergens, Betulaceae, Banja Luka*

Introduction

Members of the subclasses *Hamamelidae* (Cronquist, 1988) are characterized by small and often unisexual flowers without leaves, as well as the production of huge quantities of pollen grains transmitted by air (so-called anemophiles species). Such case is with the species of order Fagales (family *Betulaceae: Alnus* spp., *Betula* spp. and *Corylus* spp.) which presents a significant source of allergens in northern, central and eastern Europe (Łukasz *et al*., 2014). Alder, hazel and birch are actually among the earliest flowering plants and in which beginning of pollen release depends on the atmospheric conditions, especially from the cumulative air temperature (above zero) (Scamoni, 1955). The intensity of pollen release and total count of pollen grains are also affected by the meteorological conditions in the previous year (August), when the sporogennous tissue begins to develop (Rodkiewicz *et al*., 1996). *Corylus* and *Alnus* reacting as primers of allergic sensitisation to *Betulaceae* pollen allergens, resulting in greater clinical symptoms during the *Betula* pollen season (Ianovici *et al*., 2009). It has been pointed out that *Betula* pollen concentrations greater than 30 pollen grains/m^3/day trigger severe symptoms, and values greater than 80 pollen grains/m^3/day produce symptoms in 90% of patients (Corsico, 1993). As well according to Vik *et al*. (1991) *Corylus* pollen gives allergic reaction at concentrations of 20:30 pollen grains/m^3 and *Alnus* pollen at concentrations of 50 pollen grains/m^3.

Considering the above and that the species in the family *Betulaceae Corylus avellana* - hazel and *Alnus glutinosa* - alder are characterized by moderate to strong allergenic properties and *Betula pendula* - birch are characterized by very strong allergenic properties main objective of this study was to monitor the seasonal dynamics of allergenic species, or determined the beginning, duration and end of the period of pollination. The obtained data are presented

through the media of public information in the form of daily aeropalinology reports and forecasts of the seven-day period.

Material and method

Monitoring the concentration of aeroallergenic species of alder pollen (*Alnus glutinosa*), hazel pollen *(Corylus avellana*) and birch pollen *(Betula pendula*) during the period of pollination (febraury – may from 2008 to 2014) was conducted at the Public institution Agricultural Institute of Republic of Srpska, Banja Luka (PI AIRS, Banja Luka) (N 44º47`41.0``, E 017º12`22.6``), by Hirst's type pollenometar (Hirst, 1952) using the method defined by the International Association for Aerobiology (IAA). The device Burkard (Burkard Manufacturing Co., Uxbridge, Middlesex, UK) is calibrated for sampling 10 liters of air/min through a hole 14 x 2 mm diamtear, which always faces in the direction of the wind and it is protected from direct rainfall. By passing, air through the hole, it comes to the fixation of pollen grains on glass coated with silicone gel, which is moving at a speed of 2 mm/h.

Visual identification, or qualitative and quntitative assessment, of sampled pollen grains was carried out on a daily basis after 24 hours, based on the morphological characteristics of species in the family *Betulaceae* under a light microscope Olympus BX51 at magnification x400, according the International Association for Aerobiology and converting the obtained results in the concentration of pollen grains per m^3 of air. Immediately prior to screening, microscopic slide with 24-hour segment, is prepared by placing polyvinyl alcohol substrate (Gelvatol), phenol, and glycerol, which allows color fuchsin staining of pollen grains and easy separation of the same from dust particles and fungy spores. After preparation and drying microscopic slide determining the number of pollen grains is carried out by the method of longitudinal lines in two-hour intervals and reviewing the 3 horizontal lines. At the end of the analysis, the obtained values are converted to daily concentrations determined by multiplying the number of pollen grains by a factor F, depending on the characteristics of the device for sampling air, surface of 24 hour segment, characteristics of the microscope and the surface of the inspected sub-sample. Concentration of the pollen grains per m^3 of air is important for symptoms occurence of allergic reactions, because the number of pollen grains in 1 m^3 of air, which causes interference in most patients is not the same for all types of pollen. In case of alder pollen it is enough > 50 pollen grains per m^3 of air, the birch pollen > 30 pollen grains per m^3 of air while in acse the of hazel pollen it is enough > 12 pollen grains per m^3 of air to cause an allergic reaction.

In addition to daily concentrations during the sampling of *Betulaceae* aeroallergenic pollen it was determined seasonal dynamics of pollination species *Betula, Alnus* and *Corylus*, or beginning and end of the season with the maximum concentration values present aeroallergens in the area of Banja Luka.

Obtained data are presented to the public media in the form of aeropalynological reports or so called pollen semephore (tab. 1).

Tab. 1. *Number of trees pollen grains in the air with the corresponding percentage of people with a possible symptoms occurence of allergic reactions (Forsyth County Environmental Affairs Department Pollen Rating Scale, PRS)*

Pollen value	**No of pollen grains/m^3 air**	**Symptoms occurence of allergic reactions**
	trees	
Not present	0	No simptoms
Low	1-15	Only in extremely sensitive individuals
Medium	16-90	In 50% sensitive individuals
High	91-1500	Almost all allergic individuals
Very high	>1500	All allergic individuals

Results and discussion

Beginning of season pollination of aeroalergenic species of family *Betulaceae* (*Alnus glutinosa, Betula pendula and Corylus avellana*) in Banja Luka, during the seven years of monitoring, has been recorded since the second week of March for the period 2008 - 2011 and from the third decade of February for the period 2012 - 2014. According to the literature in Italy (Tedeschini *et al*., 2003), the beginning of pollination in plants that bloom in winter, like *Corylus* may occur later, which is exactly the case in the area of Banja Luka during 2008 - 2011, while earlier pollination of hazel was recorded during the three-year period 2012 - 2014. On the other hand for the species *Alnus glutinosa* and *Betula pendula* in the area of Banja Luka during the seven-year monitoring was recorded early pollination, from the end of the first decade and the beginning of the second decade of March, which also states in areas of northern Europe (Van Vliet *et al*., 2002). However occurence of alder and birch pollen grains is characterized by the appearance of actually low concentrations or absence of pollen grains from the beginning of pollination, which means that the allergic reaction could occur only in extremely sensitive individuals (Photo 1-7).

According to the monitoring more than 70% of pollen species in the family *Betulaceae* were sampled during March and April. However pollination season through seven years monitoring lasted until the third decade of May, which is actually longer pollination season for *Betulaceae* aeroallergen, and in such circumstances, or during long periods of pollination the risk of cross reactions between *Betulaceae* pollen and pollen of fruit species could increase (Radisic *et al*., 2003).

On anually level total recorded *Alnus glutinosa* pollen number/m^3 was 315 p/m^3 (2008), 294 p/m^3 (2009), 261 p/m^3 (2010), 252 p/m^3 (2011), 208 p/m^3 (2012), 359 p/m^3 (2013) and 426 p/m^3 (2014). Total recorded *Betula pendula* pollen number /m^3 was 1006 p/m^3 (2008), 957 p/m^3 (2009), 951 p/m^3 (2010), 1223 p/m^3 (2011), 703 p/m^3 (2012), 982 p/m^3 (2013) and 457 p/m^3 (2014). In cas of *Corylus avelana* total recorded pollen number /m^3 was 126 p/m^3 (2008), 118 p/m^3 (2009), 108 p/m^3 (2010), 100 p/m^3 (2011), 168 p/m^3 (2012), 130 p/m^3 (2013) and 311 p/m^3 (2014) (Photo 8).

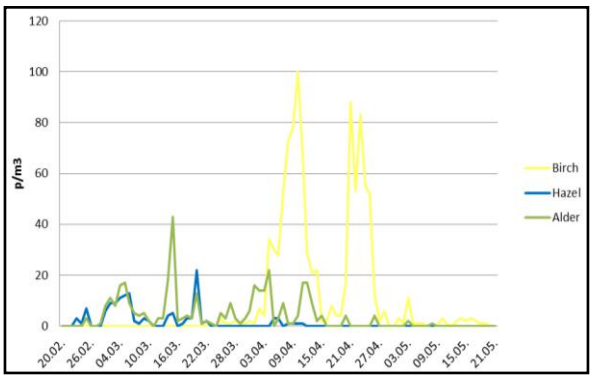

Photo. 6. *Seasonal dynamic of Betulaceae species pollination in 2013*

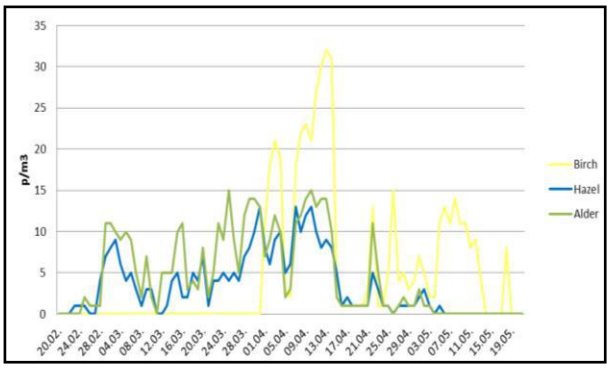

Photo. 7. *Seasonal dynamic of Betulaceae species pollination in 2014*

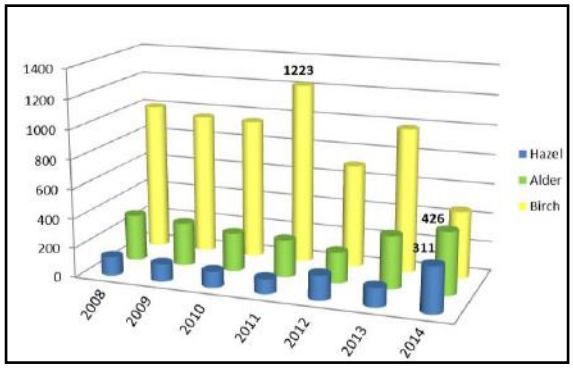

Photo. 8. *Concentration of Betulaceae pollen species in Banja Luka during 2008 - 2014*

Conclusion

During seven year monitoring (2008 - 2014) pollen of three species in the family *Betulaceae*, it was established dominance of birch pollen and proportionally significantly lower total recorded hazel and alder pollen value in the Banja Luka city. On the dominance of birch pollen indicates the number of days with a concentration of pollen that exceeds the level of occurrence of allergic reactions because the birch pollen ranged between 5-12 days, 2-4 days for the hazel pollen, while in case of alder pollen in seven monitoring was not determined a concentration of pollen that exceeds the level of allergic reactions occurrence.

In addition to birch pollen dominance among species in the family *Betulaceae*, according to results of monitoring the birch pollen season has shown significant variation in terms of the total amount of pollen on annualy level and the dynamics during the period of pollination, which is why monitoring is still necessary, especially for people with high sensitivity to *Betulaceae* species.

OCCURENCE AND DISTRIBUTION MAPPING OF INVASIVE WEED SPECIES HELIANTHUS TUBEROSUS L. IN NORTH WESTERN AREA OF REPUBLIC OF SRPSKA

Gordana BABIĆ*, Vojislav TRKULJA

PI Agricultural Institute of Republic of Srpska, Banja Luka, Bosnia and Herzegovina
*Corresponding author: brkljacg@hotmail.com

Abstract

Species *Helianthus tuberosus* L., as many belonging to the *Helianthus* genus, are caracterised by their successful vegetative propagation, allelopathy or shading, aggressive spreading, elimination of other species of the natural habitats, changing the structure of plant communities, and even behave as dangerous weeds. Considering species habitat requirements, Republic of Srpska is definitely one of the area for potential distribution of Jerusalem artichoke as invasive weed species. In this sense main goal of this study was to investigate the occurence and carry out distribution mapping of Jerusalem artichoke in north western part of Republic of Srpska (RS).

Distribution and abundance parameters were done for 40 Helianthus stands based on Blanque Braun (1964) method and GIS software. A wide-spread distribituion reveal a high spreading and renewal potential of the species which turns it into a real threat to native flora and wildlife habitats, watercourses etc.

By current research in the north western part of RS Jerusalem artichoke is in significant expansion, resulting in negative ecological, economic and social impact. Regarding to those research priorization process for mentonied area on local level is of a great importance.

Key words: *Jerusalem artichoke, occurence, distribution, mapping, Republic of Srpska*

Introduction

The Jerusalem artichoke (*Helianthus tuberosus* L.), native to temperate regions of North America, has been grown in Europe since the 17th century (Slimestad *et al*., 2010) mainly for tubers. In the mid-18th century it was widely replaced by the potato as a staple food in central Europe (Hartmann *et al*., 1995). But this species, as many belonging to the *Helianthus* genus, are caracterised by their successful vegetative propagation, allelopathy or shading, they spread aggressively, eliminate other species of the natural habitats, change the structure of plant communities, and even behave as dangerous weeds. Another major issue related to the invasive taxa of this genus is that by their getting wild, they earn phenologic plasticity, probably hybridize, so their taxonomic position is uncertain and largely debated (Balogh, 2006). The first escaped plants were found in the mid 19th century in some countries, the invasive spread began mostly around 1900 and became more rapid in central Europe in the 1930s (Hartmann *et al*., 1995). Thus in many European countries *H. tuberosus* allready have invasive status or it was placed on watch-list wich comprises invasive alien species that have potential to cause damage and therefore their spread should be monitored (photo 1, http://www.cabi.org/isc/datasheet/26716).

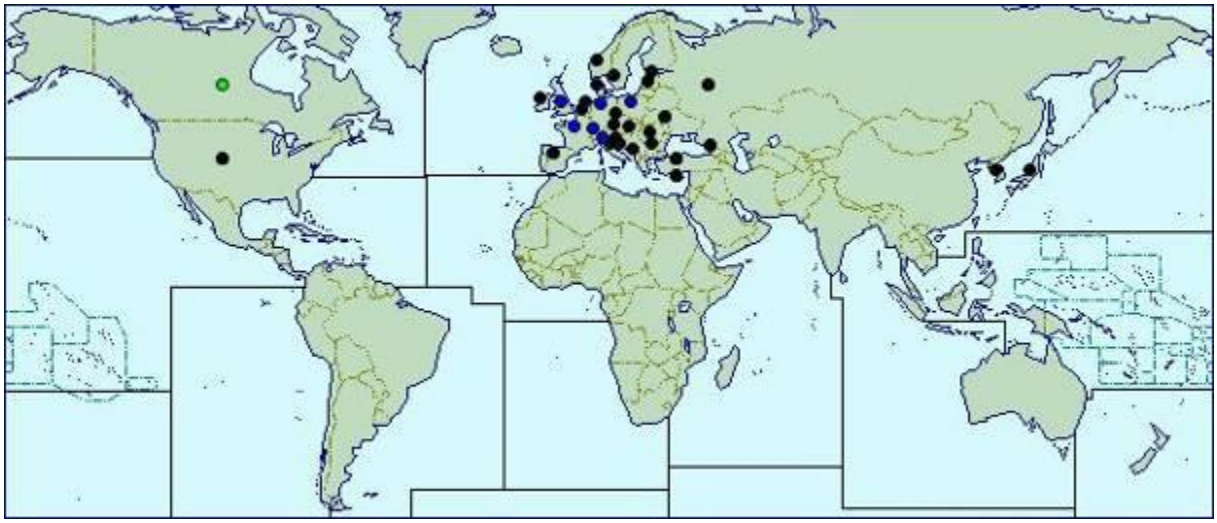

Photo 1. Naturalised distribution of Jerusalem artichoke: ●= Present, no further details; ●= Widespread; ●= Localised; ●=Confined and subject to quarantine; ●= Occasional or few reports; ● = Evidence of pathogen; ●= Last reported; ●= Presence unconfirmed; ●= See regional map for distribution within the country (source http://www.cabi.org/isc/datasheet/26716)

According to EPPO (European and Mediterranean Plant Protection Organization) the Jerusalem artichoke (*H. tuberosus* L.) is one of the 34 invasive taxa (source www.eppo.org/QUARANTINE/ias_plants.htm). The species is invasive even in its native country, disturbing natural forest communities (Balogh, 2006). It is considered an invasive species in Poland, Austria, Italy, Germany, France and Hungary (Wittenberg, 2005). According to Nature protection and biodiversity - State and impacts (Bosnia and Herzegovina) (Eropean Enviroment Agency) from 2010 the same status Jerusalem artichoke has in BiH. Among the invasive weed species *Helianthus tuberosus,* is one the most common in our area. This species also have a negative effect on the habitats of hygrophilous woods of willow, alder and poplar, which are particularly common in the Posavina area of Bosnia and Herzegovina (source www.eea.europa.eu/soer/countries/ba/nature-protection-and-biodiversity-state).

In spreading of invasive species one of the aggravating circumstances are floods. According to Fehér (2001), the floods also distort riparian vegetation and thus creating new opportunities for colonization by invasive species and forming a source population for spreading invasive species into the surrounding landscape. As an invasive species on river banks, *H. tuberosus* can result in increased flood erosion, as it has fewer fine roots than native river bank vegetation and leaves the soil bare and unprotected after it dies back in autumn. In addition, its tubers are dug after by rodents resulting in further damage to river banks and flood protection dams (Hartmann *et al.*, 1995; Kowarik, 2003). Regarding to those research in Rebublic of Srpska, with already conolized area by invasive Jerusalem artichoke, flooding waves recorded during 2010 and 2014 are aditional threath for further spreading.

Spreading potential, aggressiveness and invasiveness of Jerusalem artichoke as invasive weed species, as well as all facts mentonied above were the background to the main goal of this study which was to evaluate the occurrence, as well as to carry out distribution mapping of invasive species *Helianthus tuberosus* in north western part of RS.

Material and method

The current research mainly focuses on the north western part of RS in relation to species habitat requirements and main environmental features. Field survey was conducted during the vegetation period 2014 in the area of a large number of municipalities of the Republic of Srpska, with emphasis on the territory of the municipalities of Banja Luka, Čelinac, Kotor Varoš, Gradiška, Srbac, Prnjavor and Derventa. Assessment of the occurrence and distribution of Jerusalem artichoke were taken along the roads in the urban areas, between the settlements in ruderal and less arable land, and on the edges of farmland, on arable land, along the river Sava and Vrbanja, as well as along the fish pond, in ditches and on the edges of forests. Quantitative distribution, study species density measure was assessed based on Blanque Braun (1964) method. During fieldwork Helianthus stands were mapped and recorded with GPS, while polygons were digitized using GIS software. All stands have been assigned to size classes (0-10m^2; 10-100m^2; 100-1000m^2; >1000).

Species habitat requirements

H. tuberosus prefers certain habitat types (Fehér and Končeková, 2001). It is best adapted to rich, moist soil that can be found along roadways, in wasteland areas and gardens (Wyse *et al*., 1986). According to Hartmann *et al*. (1995) *H. tuberosus* is completely naturalized on moist, nutrient-rich, sandy or loamy soils, especially along rivers. The most substantial site of occurrence includes riparian nitrophilic vegetation along watercourses, but also a variety of anthropogenic sites. In the landscape, it spreads very aggressively and settles more and more areas. It is contributed not only by spreading through generative diaspores, but also by vegetative propagation of broken-off parts of corms washed away by water to new sites along the watercourse (Cvachová *et al*., 2002).

Results and discussion

A wide-spread distribution of invasive weed species *H. tuberosus* was observed in the number of municipality of Republic of Srpska, specialy near the water sources in Banja Luka, Prnjavor, Vrbanja, Čelinac, Kotor Varoš and Derventa but as well between the above mentioned municipalities along the roads in populated areas, between settlements in ruderal and less arable land, on the edges of farmland and arable land, along the river Sava and Vrbanja, as well as along the fish pond, in ditches or even in the urban aerias (photo 2-7).

Photo 2. *H. tuberosus* between Banja Luka and Vrbanja

Photo 3. *H. tuberosus* in urban area of Derventa

Photo 4. *H. tuberosus* along the fish pond

Photo 5. *H. tuberosus* in corn crop

Photo 6. *H. tuberosus* on river bank of Vrbanja in Čelinac

Photo 7. *H. tuberosus* on the edges of farmland near Banja Luka

Regarding to other regions of Europe, *H. tuberosus* behaves as an invasive weed species in the studied region. Frequent expansion of the species into the surrounding sites inner town, near agricultural lands and the cultivated field is also noticed, beside the expansion on the river bank of Vrbanja and Sava. The abundance of Jerusalem artichoke points to a high density of individuals e.g. up to 70/m^2 along the fish pond between Prnjavor and Derventa, as well on river bank of Vrbanja and Sava (up to 30-40/m^2). *Helianthus tuberosus* can invide a resident plant communities and cause decrase in the number of native species or almost completely eliminate them from patches. As a result of the developing relationship of an invading plant a secondary, repeating combination of species is formed in which alien species play the main role (Falinski, 1998).

Only in the north western part of RS was recorded 40 Jerusalem artichoke stand. A half of polygons less than 100 m^2 were recorded in urban parts of north western area of Republic of Srpska, 15 polygons (100-1000 m^2) were recorded betwen Prnjavor and Derventa, Banja Luka and Čelinac, as well as five polygons (1000-10.000 m^2) (Photo 8_{1-34}).

Conclusion

Considering already conolized area by Jerusalem artichokea, number of finding stands in the studied region, high density of individuals/m^2, as well as recorded flooding waves in RS ponit out to certain further spreading of *H. tuberosus* as an invasive weed species. The most sever areas are in the river banks of Vrbanja and Sava, as well as areas along the fish pond between Prnjavor and Derventa.

Regarding to the current research in the north western part of Republic of Srpska jerulasem artichikea is in significant expansion, resulting in negative ecological, economic and social impact. Regarding to those research priorization process for mentonied area on local level is of a great importance. Under the given circumstances, undertaking comprehensive studies on the species characteristics and distribution potential on one hand and developing eradication and control methods, on the other are highly recommended.

Abstract

Floods in Spreča river basin (northeastern Bosnia and Herzegovina) carry all the negative elements that are naturally occurring and through anthropogenic activities.
The level of contamination in the soil above the threshold increases the risk of entering the food chain and thus for human health.
Particularly at risk is the quality of agricultural crops that are exposed to adverse effects, and there is accumulation of certain toxins in plants.
The aim is to study the contamination of soil and plant material caused by floods in the lower course of the river Spreča in the area of municipalities Lukavac and Gračanica.
Three profiles were opened on the three different soil types in those municipalities, and soil samples in disturbed and undisturbed condition were taken. General chemical and physical properties of the soil were analyzed in details and the level of the soil contamination with heavy metals and organic pollutants (PAH's) was determined. We also analyzed samples of plant material from cultures that were cultivated at the present microlocalities.
Based on determined state of soil and plants contamination, recommendations were given for the introduction of a permanent monitoring system for agricultural soils and plants in this area.
Keywords: *floods; contamination; heavy metals; PAHs;*

Introduction

The Government of Federation of Bosnia and Herzegovina (FBiH) adopted the conclusion in which Federal Institute of Agropedology is entrusted to conduct detailed research in the lower course of the river Spreča and to establish a three-year monitoring of the state of pollution of soil and plant material with heavy metals and organic pollutants (PAHs). The main task of the research is to determine the level of contamination of agricultural land and plant material (maize) with organic pollutants (PAHs) and heavy metals, such as: lead (Pb), cadmium (Cd), zinc (Zn), nickel (Ni), chromium (Cr), arsenic (As), cobalt (Co), mercury (Hg) and copper (Cu). Limit values for heavy metals and organic pollutants were determined in accordance with the Law on Agricultural Land ("Official Gazette of BiH" No. 52/09), the Regulation on determining the permitable amount of harmful and hazardous substances in soil and methods of their usage ("Official Gazette of the Federation of Bosnia and Herzegovina "No. 72/09). For the plant material professional literature was used.
The aim of the research is to determine the level of contamination by heavy metals and PAH's in the flooded agricultural lands in the downstream river Spreča and their distribution in corn (root, stem, fruit). It is very important to be able to evaluate the possibilities of agricultural production and the safety of maize in the researched areas near flooded region.

Materials and methods

In the area of the lower course of the river Spreča we have examined the following parameters: soil texture by the International pipettes "B" method,

acidity of the soil in H_2O and 1M KCl (on pH meter Eutech PC2700) by method BAS ISO 10390:2009, dichromatic determination of humus (on colorimeter Hach Lange LICO 500), gas-volumetric determination of carbonate (on Scheibler's calcimeter) by method BAS ISO 10693:2000, heavy metals in extracts of soil with aquaregia (on atomic spectrometer AAnalyst 400 Perkin-Elmer) by methods BAS ISO 11466:2000 and BAS ISO ISO 11047:2000), heavy metals in plant material by wet digestion with HNO_3-$HClO_4$ mixture, direct determination of Mercury by Thermal Decomposition and Amalgamation (on SMS 100 Mercury Analyzer), PAHs determination by method BAS ISO 18287:2008 (on GC-FID).

Results and discussion

In the area of the lower course of the river Spreča, downstream of Lake Modrac, 3 pedological profiles on different soil types were opened. **Profile 1** was opened in Dobošnica, 35 m away from the Spreča river bed. The plot is sown with maize crops. This locality is represented with marsh *Gley soil - Eugley*. This land belongs to the class of hydromorphic department of gley soil. This land is characterized by groundwater which is mostly below 80 cm. Groundwater constantly fills the lower part of the profile, creating anaerobic conditions. The upper part of the profile is saturated with water only during one part of the year, and there is alternation between reduction and oxidation processes. (Resulović H.,Čustović H. i Čengić I. 2008). A total of 6 samples were taken in undisturbed condition, 2 samples in a disturbed condition and 1 sample of plant material – maize.

Soil profile No.1 (C.P.Dobošnica II)

Table 1. Average values of physical properties of the soil

Depth in (cm)	Bulk density (g/cm^3)	Volume density (g/cm^3)	Pore volume in (%)	The absolute capacity in (vol. %) for		K (cm/sec)	Designation of water permeability
				water	air		
0-14	2.56	0.89	64.76	52.09	12.67	0.44485	Very intensely permeable
14-39	2.57	1.05	59.06	45.06	14.00	0.04969	Very intensely permeable

The true specific density is very uniform in both layers. Bulk density was slightly lower in the first layer then in the second one. The air capacity is good for arable cultures (wheat and oats). Water capacity is in the first layer large, and in the second one slightly smaller. According to Gračanin, the first layer is determined as highly porous. The total porosity of the second layer is slightly lower. Permeability of the soil indicates that it is a very intensely permeable soil in both layers.

Table 2. Textural composition of the soil (texture mark by Ehwald)

Depth in (cm)	The percentage content of soil particles with a diameter in mm				Texture mark by Ehwald
	Coarse sand 2 – 0.2	Fine sand 0.2 – 0.02	Powder 0.02-0.002	Clay < 0.002	
0-14	1.70	39.00	43.80	15.50	**Loam**
14-39	1.47	39.23	43.70	15.60	**Loam**

The soil in both layers of this profile, according to the texture composition, belongs to the category of Loam. This profile is represented with coarse sand at smallest, and powder at the most.

Table 3. The chemical properties of the soil profile

Depth in (cm)	pH value in		The content of humus (in %)	The content of $CaCO_3$ (in %)
	H_2O	KCl		
0-14	8.53	8.01	3.74	32.15
14-39	8.72	8.02	3.37	34.13

Chemical analysis of soil indicates that this soil is highly alkaline, with pH value in H_2O from 8.53 to 8.72, and in 1 M KCl from 8.01 to 8.02. The humus content is medium. The content of calcium carbonate (CaCO3) is very high, so it is a very calcareous soil.

Table 4. The content of heavy metals and PAHs in soil and maize

Elements in soil (mg/kg of soil)	Depth of profile in (cm)		Parts of the plant (Corn)		
	0-14	14-39			
	Texture mark by Ehwald				
	Loam	Loam	Root	Stem	Fruit
Lead (Pb)	43.80	40.83	2.36	0.21	0.06
Cadmium (Cd)	**1.77**	**1.80**	0.90	0.07	0.02
Zinc (Zn)	71.80	70.83	19.25	11.75	11.87
Cobalt (Co)	28.77	28.27	5.90	0.26	0.04
Copper (Cu)	44.97	44.60	15.50	5.70	2.24
Chromium (Cr)	50.33	51.87	**42.00**	0.80	0.69
Nickel (Ni)	**340.67**	**321.67**	**180.20**	0.16	0.02
Mercury (Hg)	**2.443**	**2.715**	0.088	0.006	0.005
Arsenic (As)	11.22	12.28	1.50	n.d.	n.d.
Content - organic pollutants PAHs (mg/kg)					
PAHs	**4.265**	**4.837**	**1.747**	**1.34**	**1.481**

The contents of lead, zinc, cobalt,chromium, copper, and arsenic are below the limit values for that soil type -Loam. There is an elevated level of cadmium, in both layers, above the limit value of 1,00 mg/kg. Elevated level of nickel, is also present in both layers, and it is above the limit value for clay soil of 45,00 mg/kg. The limit value for mercury in clay soil is 1,00 mg/kg, and its content is elevated in both layers. The content of total PAHs, in both layers, is above the permited limit value of 2,00 mg/kg. According to the available literature (Kloke et al, 1984.), the presence of heavy metals in maize samples has been established. Red color represents content, critical for planth growth.

Profile 2 was opened in Donja Lohinja, 30 m away from the Spreča river bed. The plot is located in K.O. Donja Lohinja - Pribava, and k.č. is 2897. This plot is represented with *Alluvial soil - Fluvisol*. This type of soil belongs to hydromorphic department. Formed in the valleys of watercourses, it represents recent river alluviums applied in layers. Build of a profile is Ah - I - II-III. There were taken 12 samples in undisturbed condition, 4 samples in the disordered condition and 1

Soil profile No.2 (C.P.Donja Lohinja)

sample of plant material - maize crops.

Table 5. Average values of physical properties of the soil

Depth in (cm)	Bulk density (g/cm^3)	Volume density (g/cm^3)	Pore volume in (%)	The absolute capacity in (vol. %) for		K (cm/sec)	Designation of water permeability
				water	air		
0-26	2.95	1.32	54.91	40.47	14.43	0.39211	Very intensely permeable
26-66	2.67	1.62	39.36	28.69	10.67	0.00071	Medium permeable
66-110	2.76	1.43	48.18	36.01	12.17	0.01661	Very permeable
110-160	2.74	1.49	45.58	36.15	9.43	0.01478	Very permeable

The true specific density is greatest in the first layer of the profile, and lowest in the second. Bulk density is the lowest in the first, largest in the second,and in deeper layers of the profile almost evenly distributed. Water capacity is quite high in the first layer, and decreases in the following layers. According to Gračanin, the first layer is porous, whereas the others have a small porosity and decreases the penetration of the root system in the deeper layers. Permeability of the soil indicates that it is a very intensely permeable soil in the first layer, very permeable in the third and fourth, while in the second layer is medium.

Table 6. Textural composition of the soil (texture mark by Ehwald)

Depth in (cm)	The percentage content of soil particles with a diameter in mm				Texture mark by Ehwald
	Coarse sand 2 – 0.2	Fine sand 0.2 – 0.02	Powder 0.02-0.002	Clay < 0.002	
0-26	7.93	54.67	24.70	12.70	**Sandy Loam**
26-66	5.83	69.27	15.30	9.60	**Loamy sand soil**
66-110	10.12	73.08	9.70	7.10	**Sandy soil**
110-160	3.15	69.95	16.20	10.70	**Loamy sand soil**

In results shown above, least represented are the particles of coarse sand and clay, whereas mostly presented are fine sand particles.

Table 7. The chemical properties of the soil profile

Depth in (cm)	pH value in		The content of humus in (%)	The content of $CaCO_3$ in (%)
	H_2O	KCl		
0-26	8.47	7.63	1.95	4.34
26-66	8.43	7.08	0.56	0.16
66-110	8.44	7.61	0.54	1.01
110-160	8.19	7.49	0.46	0.93

The high pH values of water, in all layers, indicates very alkaline soil. The humus content is weak in all layers. The content of calcium carbonate (CaCO3) is low in all layers, and the land is poorly carbonated. The exception is the first layer, which is due to the value of 4.34% CaCO3, determined as medium calcareous soil.

Table 8. The content of heavy metals and PAHs in soil and maize

Elements in soil (mg/kg of soil)	Depth of profile in (cm)				Parts of the plant (Corn)		
	Tekxture mark by Ehwald						
	0-26	26-66	66-110	110-160	Root	Stem	Fruit
	Sandy Loam	Loamy sand soil	Sandy soil	Loamy sand soil			
Lead (Pb)	19.07	14.20	10.17	13.50	2.15	0.27	0.08
Cadmium (Cd)	0.97	**0.70**	**0.63**	**0.57**	1.00	0.08	0.04
Zinc (Zn)	42.73	35.17	30.07	34.33	18.40	8.54	10.85
Cobalt (Co)	30.40	28.80	23.57	26.00	**10.90**	0.12	0.24
Copper (Cu)	23.17	20.70	15.80	19.23	14.05	8.14	2.20
Chromium (Cr)	45.83	**68.17**	**60.77**	**60.73**	**33.35**	0.46	0.30
Nickel (Ni)	**498.33**	**467.00**	**352.33**	**429.33**	**245.70**	0.13	0.18
Mercury (Hg)	0.595	0.087	0.082	0.086	0.252	0.015	0.01
Arsenic (As)	4.828	4.225	3.525	4.15	2.20	n.d.	n.d.
Content - organic pollutants PAHs (mg/kg)							
PAHs	0.786	0.221	0.017	0.009	**0.294**	**0.212**	**0.413**

The contents of lead, zinc, cobalt, copper, mercury and arsenic is below the limit values. Elevated cadmium is present in the last three layers, ranging from 0.57 mg/kg to 0.70 mg/kg. Limit value for sandy soil is 0.50 mg/kg.
The content of chromium is increased in the last three layers, ranging from 60.73 mg/kg to 68.17 mg/kg and is above the limit value of 50.00 mg/kg for sandy soil. The increased nickel content is in all layers, ranging from 352.33 mg/kg to 498.33 mg/kg. Limit value of Ni for the sandy soil is 30.00 mg/kg.The total content of PAHs in all four layers of the soil is below threshold limit value of 2.00 mg/kg.
According to available literature (Kloke et al, 1984), the presence of heavy metals was categorized in samples of corn. The red color represents the metal content, that is critical for plant growth.

Profile 3 was opened in Stjepan Polje, 160 m away from the Spreča river bed. The plot is located in K.O. Gračanica, k.č. 5208. The sowing crop on the land is maize. *Eutric brown* soil is represented on alluvial deposits. This type of soil belongs to the class of automorphic department of cambic soils. Build of a profile is Ah - BV - IC. We had taken 12 samples in undisturbed condition, 4 samples in the disordered state and 1 sample of plant material - maize crops.

Soil profile No. 3 (C.P.Stjepan Polje)

Table 9. Average values of physical properties of the soil

Depth in (cm)	Bulk density (g/cm^3)	Volume density (g/cm^3)	Pore volume in (%)	The absolute capacity in (vol. %) for		K (cm/sec)	Designation of water permeability
				water	air		
0-18	2.68	1.25	53.11	39.44	13.67	0.09267	Very intensely permeable
18-38	2.54	1.54	39.25	37.25	2.00	0.00000	Watertight
38-76	2.64	1.28	51.50	33.90	17.60	0.01153	Very permeable
76-125	2.65	1.35	49.00	39.83	9.17	0.00328	Very permeable

The true specific density is the same in all the layers, except for slightly lower value in the second layer. Bulk density is the lowest in the first and the largest in the second layer. The air capacity is good in the first and third layer, while the value in second layer is very small. Water capacity is in all layers quite uniform and this ground can store medium amounts of water. According to Gračanin, soil is porous in the first, third and fourth layer, while the second layer is watertight. Water permeability of soil indicates that it is a very permeable soil except the second layer, where sole is created. This is impermeable layer.

Table 10. Textural composition of the soil (texture mark by Ehwald)

Depth in (cm)	The percentage content of soil particles with a diameter in mm				Texture mark by Ehwald
	Coarse sand 2 – 0.2	Fine sand 0.2 – 0.02	Powder 0.02-0.002	Clay < 0.002	
0-18	1.79	40.52	34.20	23.50	**Loam**
18-38	0.63	35.97	38.80	24.60	**Loam**
38-76	0.46	35.45	38.20	25.90	**Loam**
76-125	0.30	29.10	40.30	30.30	**Loamy clays**

At least represented are the particles of coarse sand. The values of fine sand particles decreases with depth. According to the texture composition, soil is characterized as Loam.

Table 11. The chemical properties of the soil profile

Depth in (cm)	pH value in		The content of humus in (%)	The content of $CaCO_3$ in (%)
	H_2O	KCl		
0-18	7.52	6.72	2.55	0.21
18-38	7.18	6.32	1.79	0.18
38-76	7.46	6.48	1.30	0.16
76-125	7.17	6.36	1.18	0.09

The values of pH in H_2O range from 7,17 to 7,52, respectively in 1M KCl from 6,32 to 6,74, and they indicate a neutral to slightly alkaline soil. The humus content is medium in the first layer, and its value decreases with depth. The content of calcium carbonate (CaCO3) is low, so it is a poor calcareous soil.

Table 12. The content of heavy metals and PAHs in soil and maize

Elements in soil (mg/kg of soil)	Depth of profile in (cm)				Parts of the plant (Corn)		
	Texture mark by Ehwald						
	0-18	18-38	38-76	76-125	Root	Stem	Fruit
	Loam	Loam	Loam	Loamy clays			
Lead (Pb)	22.27	20.23	21.00	23.47	1.18	0.30	0.11
Cadmium (Cd)	**1.03**	0.90	0.83	0.93	0.80	0.02	0.01
Zinc (Zn)	52.83	51.87	52.63	54.57	15.50	29.30	14.10
Cobalt (Co)	35.37	36.80	36.83	36.33	**3.40**	0.44	0.19
Copper (Cu)	32.67	35.17	36.37	40.20	14.00	6.40	2.05
Chromium (Cr)	**84.27**	74.23	73.53	74.47	**33.35**	0.46	0.30
Nickel (Ni)	**475.00**	**547.33**	**542.00**	**539.33**	**142.90**	0.15	0.11
Mercury (Hg)	0.141	0.113	0.121	0.140	0.04	0.01	0.01
Arsenic (As)	6.493	6.742	6.813	5.803	0.60	n.d.	n.d.
Content - organic pollutants PAHs (mg/kg)							
PAHs	0.400	0.049	0.002	0.001	**0.275**	**0.267**	**0.23**

The content of lead, zinc, cobalt, copper, mercury and arsenic is below the treshold value. Cadmium content of 1,03 mg/kg in the first layer is slightly above the treshold for a loam soil (1,00 mg/kg). The content of chromium in the first layer is above the limit value of 80,00 mg/kg for loam soil.The increased nickel content is present in all layers. Limit value of Ni for loam soil is 45,00 mg/kg. The total content of PAHs in all layers is below the treshold limit value of 2,00 mg/kg. According to available literature (Kloke et al, 1984), the presence of heavy metals is categorized in samples of corn. Yellow color represents content that exceeds the normal value, and red the content critical for plant growth.

Conclusions

Within conducted monitoring of land in the downstream river Spreča, three soil profiles on different soil types were processed. Profiles 1 and 2 are very alkaline, while the profile 3 is neutral. In all profiles, the soil has medium to low humus content. Very calcareous soil is represented in profile 1, while low carbonated is in profiles 2 and 3. Organic and inorganic pollutants were examined througout soil depths and in plant material. The profile 1 is recorded with increased content of cadmium, mercury and nickel, and the content of PAHs. In plant material, critical values of chromium and nickel at the root of maize and PAHs in all plant organs were detected. In the profile 2 there was an increased content of cadmium, chromium and nickel. PAHs are below the limit value. At the root of maize critical values of cobalt, chromium and nickel, and PAHs in all plant organs were detected. In the profile 3 we found an increased content of cadmium, chromium and nickel. PAHs are below the limit values. At the root of maize increased values of cobalt, a critical value of chromium and nickel, and PAHs in all plant organs were detected. In the stem and fruit of the maize, in all three soil profiles, the tested heavy metals values are within permissible limits, according to the available literature (Kloke et al, 1984). Elevated levels of cadmium, chromium, nickel and PAHs in this area are most likely caused by the anthropological influence, while for nickel it can be attributed to the lithological origin.

THE RELATIONSHIP BETWEEN ANALYZED PHYSICAL, WATER AND CHEMICAL CHARACTERISTICS OF DIFFERENT AGRICULTURAL SOIL TYPES IN TUZLA CANTON

Jasminka ŽUROVEC, Sabrija ČADRO

Faculty of Agriculture and Food Sciences, University of Sarajevo, Bosnia and Herzegovina

Abstract

Canton Tuzla with a total area of 2,650 km^2 (265,000 ha), of which 68.37% (149,966.7 ha) is agricultural land, represents a very important basis for long-term development of agriculture and food industry in Bosnia and Herzegovina. Despite its importance however, the physical and chemical properties of the most important agricultural soils in this area make them less suitable for intensive agricultural production. A better understanding of soil physical, chemical and water properties of the most important agricultural soils in Tuzla Canton and analysis of their relationships, which is the main objective of this work, was done through analysis of: (i) chemical and physical properties of agricultural soils in this area; (ii) soil water properties through process of soil water retention and conductivity; (iii) correlation between the most important properties of selected agricultural soil types. Used research methods in order to meet the set goals were field work, laboratory work and data processing. Due to the obtained high value of the correlation coefficient between the analyzed physical, chemical and water characteristics for three types of agricultural soils in Tuzla Canton, one can say that usage of physical and chemical characteristics for the assessment of water characteristics in this area is justified. From the aspect of physical characteristics, this especially refers to content of clay, silt and sand, with which volumetric water content achieved strong or very strong correlations, such as correlation between clay content and plant water capacity (0.893 – 0.986).

Keywords: *Tuzla canton, soil characteristics, agriculture, correlation coefficient*

Introduction

Canton Tuzla with a total area of 2,650 km^2 (265,000 ha), of which 68.37% (149,966.7 ha) is agricultural land, represents a very important basis for long-term development of agriculture and food industry in Bosnia and Herzegovina. It is characterized, in its properties and quality, with very uneven land fund with dominant IVa, IVb, V and VI soil quality group (118,096.5 hectares or 78.8%) (Resulović et al. 2000). Most agricultural soils within the area are medium to heavy textured with high clay content (Vlahinić et al. 1967, Mehmedbašić, 1974). This Canton is an area rich in water, but also an area with a wide range of water issues, especially in agriculture. Unfavorable soil water - air regime is primarily due to its poor soil water and physical properties (Resulović, 2000). The rational and sustainable management of water and soil water regime is among the most powerful means of increasing agricultural production, while reducing its oscillations. Such management is achieved primarily by comprehensive analysis of physical, water and chemical properties of the soil and then, based on them, construction of adequate hydro-ameliorative facilities, which include facilities for drainage, irrigation and conservation of land and water. The possibility of different soil types for adsorption and retention of water, especially readily available water (RAW) is of great importance for agriculture. It is widely known (Jamieson 1958, Vlahinić 1967, Peterson 1967, Saxton 2006) that the texture, structure and content of organic matter in the soil have direct influence on its water - air properties. Research done by Debnath et al. (2012), based on analysis of influence of different physical and chemical characteristics of soil on its water

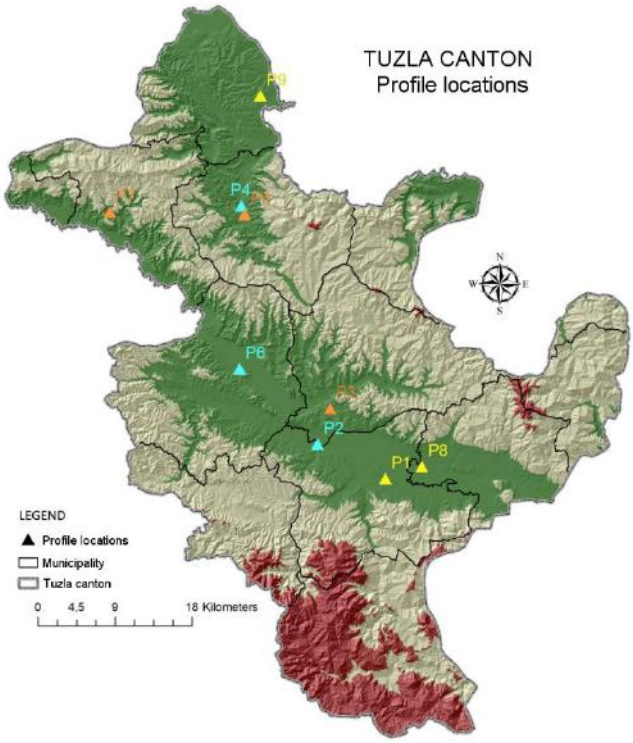
capacity, and taking into account the altitude, indicate that organic carbon, clay content, sand content and porosity directly affect the water capacity of the soil. A significant positive correlation was found between the water capacity of soil and organic carbon (r = 0.811 **) and clay content (r = 0.669 **), while a negative relationship was found with the bulk density (r = -0.315), sand content (r = -0.232), silt content (r = -0.252) and total porosity (r = -0.228). Also, higher pH values resulted in higher values of water capacity (r = 0.211). A better understanding of soil physical, chemical and water properties of the most important agricultural soils in Tuzla Canton and analysis of their relationships, which is the main objective of this work has been carried out through analysis of: (i) chemical and physical properties of agricultural soils in this area; (ii) soil water properties through process of soil water retention and conductivity; (iii) correlation between the most important properties of selected agricultural soil types. On the basis of above mentioned analyses and goals, possibility of indirect determination of curtain soil characteristics, especially soil water characteristics, based on other relatively easy to determine soil characteristics can be defined.

Materials and methods

Soil map of Bosnia and Herzegovina (Institute for Agropedology Sarajevo, 1990) was used to select three most important soils for agricultural production in the research area. On these three selected soils (Luvisol, Pseudogley and Fluvisol), nine soil profiles (up to 1 m deep) were opened. Undisturbed and disturbed soil samples were taken from each soil profile and each horizon in three replicates, making it 81 samples in total. Analyses of soil physical, water and chemical characteristics were carried out in laboratories of Institute for Pedology, Agrochemistry and Melioration at the Faculty of Agriculture and Food-science and the Federal Institute for Agropedology, Sarajevo. The following analyzes had been carried out: Soil physical characteristics through analysis of soil texture (*international pipette B method*) and bulk density (*gravimetric method in Kopecky cylinders*); Soil water characteristics through soil water retention (Θv) at a given matric potentials using a pressure-membrane extraction apparatus and Richards method (1941). Following matric potentials (Ψ) were used: -0.33 bar (pF 2.54: field water capacity), -6.25 bar (pF 3.8: lento-capillarity point) and -15.5 bar (pF 4.2: permanent wilting point). Totally (TAW) and readily (RAW) available water capacity of soil was calculated from following relation between filled water capacity (FWC), lentocapillary point (LCP) and permanent wilting point (PWP): TAW = FWC – PWP; RAW = FWC – LCP. Saturated hydraulic conductivity (K_{SAT}), was analyzed using undisturbed soil samples in Kopecky cylinders. K_{SAT} was measured in laboratory permeameter apparatus and calculated on basis of Darcy law. Analyzed soil chemical characteristics were active (H_2O) and substitution (KCl) pH reaction (electrometrically in suspension 1:2.5 - pH meter) and content of humus, using colorimetric method (spectrophotometry). Data processing was performed using correlation analysis in MS Excel. Strength of correlation is defined by the Roemer-Orphal scale.

Results and discussion

After the insight into soil map of BiH (1:50.000) and reviewing the situation in terms of spatial distribution and the importance for agricultural production, three soil types in the area of Tuzla canton were selected for this research: Luvisol, Pseudogley and Fluvisol. These are soils that are often used in agricultural production, occupying significant areas, mostly in the lowland part of the Canton (intensive agriculture favorable relief forms), and require a certain degree of melioration improvement. Figure 1 shows soil profiles and sampling locations in Tuzla canton. Profiles P3, P5 and P7 represent luvisol; Profiles P1, P8 and P3 pseudogley; and profiles P2, P4 and P6 fluvisol. After taking soil samples from the field and the laboratory analysis, the following average soil physical characteristics (Table 1) for these three soil types are determined.



All three soils in general are heavier textured, with significant clay content (28.21 - 59.55 %) which increases with depth. Fluvisol has a slightly higher sand content and the presence of skeleton compared to the other two soil types. Bulk density is within the limits of normal agricultural production. However, higher values in the second horizon (1.34 to 1.41 g/cm^3) in all the three soils, and a high content of clay (29.82 - 35.27%) indicate near surface presence of impermeable soil layer.

The average value of the volumetric water content (%) at different soil water capacity levels or matrix potentials (Ψ), as well as hydraulic conductivity (cm/h) for the three analyzed soil are shown in Table 2.

Figure 1: Soil profiles and sampling locations

MWC – maximum water capacity, FWC – field water capacity, LCP - lentocapillary point, PWP – permanent wilting point, TAW – totally available water, RAW – readily available water, KSAT – saturated hydraulic conductivity

The highest average value of a volumetric water content (VWC) at MWC is in the surface horizon (Ap) of Pseudogley, respectively 55.37%. Field water capacity (FWC) is the highest in the lowest (Bt) horizon of Luvisol (51.78%). In the case of VWC at the plant wilting point (PWP) the maximum value is in the Bt horizon of Luvisol (28.09), and the minimum at the surface horizon (Ap) of Pseudogley (12.25%). The amount of water at RAW capacity represents the most accessible form of soil water for plants and it is the main indicator of its retention characteristics. Pesudogley has the best retention properties from three analyzed soils. The Ap and Sw horizons of this soil can hold up to 25.07% of the volumetric water content. In terms of saturated hydraulic conductivity (K_{SAT}), the most permeable soil is Fluvisol, where average filtration coefficient in Ap horizon reaches 30 cm/h and gradually decreases with depth (down to 18.14 cm/h). Luvisol has the lowest values of K_{SAT}, especially in the second horizon (0.22 cm/h). Average basic chemical characteristics of three analyzed types of agricultural soils are shown in Table 3. Fluvisol proved to be the soil with best chemical characteristics. pH reaction of this soil ranges from slightly acid to neutral (6.16 – 6.91), and high humus content (3.31 %) slightly decreases with depth. Humus content is also high in Ap horizon of Pseudogley, strongly decreases with depth.

Table 3: Soil basic chemical characteristics

Soil type	Horizon	Depth (cm)	pH		Humus (%)
			H_2O	KCl	
Luvisol	Ap	0 - 20	6.09	5.13	2.87
	E	20 - 45	6.26	5.33	1.63
	Bt	45 - 100	5.94	5.07	1.14
Pseudogley	Ap	0 - 23	5.48	4.65	4.25
	Sw	23 - 55	5.02	4.21	1.64
	Sd	55 - 100	5.73	4.75	0.62
Fluvisol	Ap	0 - 20	6.96	6.16	3.31
	I	20 - 60	7.29	6.44	2.19
	II	60 - 100	7.69	6.91	1.52

On the basis of the results for all the analyzed soil characteristics (physical, chemical, and water), and based on all the individual measurements (27 for each soil type), the correlation analysis had been conducted for each type of soil in particular (Tables 4, 5 and 6). We will mainly focus on the impact of physical and chemical characteristics on the soil water properties.

In Luvisol (Table 4), higher clay content results in higher values of the LCP, PWP, FWC and MWC and lower values of TAW and RAW. According to the strength of correlation, clay

content has the following effects on water characteristics of Luvisol: LCP (r = 0.937) > PWP (r = 0.932) > FWC (r = 0.895) > TAW (r = -0.558) > MWC (r = 0.454) > RAW (r = -0.266) > K_{SAT} (r = -0.191). Bulk density has a strong negative relationship (r = -0.911) with the MWC, and the greatest impact (r = -0.406) on the hydraulic permeability compared to all other observed soil characteristics. Regarding soil chemical characteristics, pH does not have any significant effect, except to RAW with a middle correlation coefficient (r = -0.427). However, the humus content has a strong negative impact on the water content in the LCP (r = 0.613), FWC (r = -0.595) and PWP (r = -0.552).

In case of Pseudogley (Table 5), the higher clay content means higher values of LCP and PWP and lower values of MWC, TAW and RAW. The sand and silt content in this soil have a reverse effect. More of these particles means lower values of LCP and PWP and higher values of TAW and RAW. Of the three textural elements of soil, clay content has the greatest impact on water properties, in this order: PWP (r = 0.986) > LCP (r = 0.977) > TAW i RAW (r = -0.754) > MWC (r = -0.724) > K_{SAT} (r = -0.284) > FWC (r = 0.245). Bulk density also has a significant impact on the water properties of Pseudogley, behaving similarly as clay content.

Table 4: Correlation coefficient (r) between different soil characteristics in Luvisol

LUVISOL	*C*	*S*	*Sa*	*Bd*	*MWC*	*FWC*	*LCP*	*PWP*	*TAW*	*RAW*	*K_{SAT}*	*pH H*	*pH K*	*H*

K_{SAT}	-0.191	0.116	0.277	-0.406	0.282	-0.198	-0.215	-0.131	-0.067	0.083	1			
pH H_2O	-0.468	0.431	0.485	0.441	0.152	-0.417	-0.274	-0.237	-0.236	-0.427	0.041	1		
pH KCl	-0.373	0.319	0.419	0.442	0.100	-0.342	-0.195	-0.125	-0.361	-0.452	0.044	0.978	1	
Humus	-0.725	0.715	0.693	-0.053	0.496	-0.595	-0.613	-0.552	0.184	0.143	0.256	0.655	0.585	1

C – Clay, S – Silt, Sa – Sand, Bd – Bulk density, MWC – maximum water capacity, FWC – field water capacity, LCP - lentocapillary point, PWP – permanent wilting point, TAW – totally available water, RAW – readily available water, KSAT – saturated hydraulic conductivity, pH H – pH in H2O, pH K – pH in KCl, H - Humus

Higher bulk density or greater soil compaction results in lower values of MWC, TAW, RAW and K_{SAT} and higher values of LCP and PWP. Regarding soil chemical characteristics, strong negative correlation between pH in H_2O and TAW (r = -0.597) and RAW (r = -0.566) can be noted. The humus content has a significant impact on the soil water properties and behaves similarly to silt, and inversely to the clay content. Humus, of all the analyzed characteristics, has the biggest positive impact on saturated hydraulic conductivity (r = 0.499), which means the higher humus content, the better soil permeability.

Table 5: Correlation coefficient (r) between different soil characteristics in Pseudogley

PSEUDOGLEY	*C*	*S*	*Sa*	*Bd*	*MWC*	*FWC*	*LCP*	*PWP*	*TAW*	*RAW*	*K_{SAT}*	*pH H*	*pH K*	*H*

Bulk Density	0.702	-0.576	-0.457	1										
MWC	-0.724	0.708	0.203	-0.928	1									
FWC	0.245	-0.292	0.053	0.155	-0.207	1								
LCP	0.977	-0.874	-0.465	0.746	-0.732	0.298	1							
PWP	0.986	-0.868	-0.502	0.738	-0.711	0.223	0.991	1						
TAW	-0.754	0.615	0.497	-0.582	0.524	0.435	-0.724	-0.781	1					
RAW	-0.754	0.623	0.479	-0.598	0.549	0.424	-0.738	-0.783	0.995	1				
K_{SAT}	-0.284	0.236	0.179	-0.571	0.573	-0.316	-0.339	-0.313	0.087	0.098	1			
pH H_2O	0.529	-0.556	-0.061	0.023	-0.187	-0.229	0.425	0.487	-0.597	-0.566	0.143	1		
pH KCl	0.240	-0.255	-0.022	-0.332	0.156	-0.243	0.113	0.172	-0.315	-0.280	0.316	0.819	1	
Humus	-0.751	0.593	0.539	-0.891	0.747	-0.112	-0.762	-0.789	0.657	0.645	0.499	-0.056	0.282	1

C – Clay, S – Silt, Sa – Sand, Bd – Bulk density, MWC – maximum water capacity, FWC – field water capacity, LCP - lentocapillary point, PWP – permanent wilting point, TAW – totally available water, RAW – readily available water, KSAT – saturated hydraulic conductivity, pH H – pH in H2O, pH K – pH in KCl, H - Humus

In Fluvisol (Table 6), content of the silt particles have reversed effect compared to the other two soil types. In this soil, silt increases the value of the LCP (r = 0.936), FWC (r = 0.888) and PWP (r = 0.750), and reduces the value of RAW (r = -0.419). According to the strength of the correlation, clay content has the following effect on water properties of fluvisol: LCP (r = 0.991) > FWC (r = 0.907) > PWP (r = 0.893) > RAW (r = -0.535) > MWC (r = 0.493). Increased bulk density results in smaller values of VWC at all water capacities. Substitution (KCl) pH reaction has a strong negative relationship with the TAW (r = -0.726) and a very strong negative relationship with the FWC (r = -0.790). The content of humus in fluvisol, in relation to luvisol and pseudogley, except MWC (r = 0.700) and TAW (r = 0.493) also have a positive effect on values of FWC (r = 0.726), LCP (r = 0.596) and PWP (r = 0.345).

Table 5: Correlation coefficient (r) between different soil characteristics in Fluvisol

Conclusion

All three soils in general are heavier textured, with significant clay content (28.21 - 59.55 %) which increases with depth. Higher values of bulk density in the second horizons (1.34 to 1.41 g/cm^3) in all the three soils, and a large content of clay (29.82 - 35.27%) indicate near surface presence of impermeable soil layer. In average, Pseudogley has the biggest capacity for the plant readily available water (RAW) and good permeability of the surface layer. This soil compared to other analyzed soils showed the best soil water characteristics in terms of agricultural production. Although it has good retention properties, Luvisol has highly impermeable second layer, while Fluvisol has poor retention capabilities due to high hydraulic conductivity. Due to the obtained high value of the correlation coefficient between the

analyzed physical, chemical and water characteristics for three types of agricultural soil in Tuzla Canton, one can say that usage of physical and chemical characteristics for the assessment of water characteristics in this area is justified. From physical characteristics, this especially refers to content of clay, silt and sand, with which VWC achieved strong or very strong correlation. From the chemical characteristics aspect, content of humus has the greatest impact on water characteristics of these analyzed soils.

Abstract

The present study aimed at reinforcing an existing methodological framework for Diagnostic Performance Assessment (DPA) of large-scale irrigation systems with an analytical procedure for evaluating the hydraulic response of pipe delivery networks to changes in flow conditions. This framework is named Mapping System and Service for Pressurized Irrigation Systems (MASSPRES) and was originally conceived within a joint effort between FAO and CIHEAM-IAM Bari for Irrigation System Modernization in the Near East and North Africa (NENA) Region. Sudden changes of flow rate and/or piezometric elevation at the inlet of irrigation distribution systems may impact the water delivery service to farmers at different turnouts or delivery points (hydrants), on the basis of the network's hydraulic response and sensitivity to those flow changes. The analytical procedure entailed the use of a hydraulic simulation model to generate flow scenarios and assess the hydraulic response of the pipe network to flow changes, and the resulting impacts at different hydrants. Two delivery performance indicators were used, namely the relative pressure deficit (RPD), and its likely expected value (EV), which were combined into a composite operational index (OI). The procedure was applied for validation to an existing pipe irrigation system of southern Italy in need of modernization. Different flow scenarios were simulated for the pipe network under study, followed by an evaluation of its response and impacts to delivery targets at hydrants level. Results showed that the proposed procedure and operational index could be useful to identify critical areas of irrigation distribution networks, where failures are likely to occur, and where the attention of operational staff should focus to ensure adequate and equitable water delivery services throughout the irrigation system.

Keywords: *irrigation delivery systems, diagnostic performance analysis, hydraulic response, irrigation system modernization.*

Introduction

Worldwide, the agricultural sector is by far the largest user of fresh water, as it accounts for 67% of the world's total fresh water abstraction and 86% of its consumption (Jacobs et al., 2008). However, a major part of the irrigated areas is served by large-scale distribution systems whose performances are often way below expectations (Renault et al., 2007). In this view, improvements are needed in water resources management, irrigated agriculture and asset management. In the Mediterranean countries the agricultural water demand increase over space and time. Blinda and Thivet (2006) report that agricultural water use currently accounts for 63% of the total water demand, thus it is needed to put the available fresh water reserves under increased pressure. The agricultural sector in those countries uses on average more than 70% of total water, with nearly 50% in the Northern Mediterranean countries, and 79% in the southern Mediterranean countries (Jacobs et al., 2008). In the recent years, several scientists (Burt, 1996; Burt and Style, 1999; Clemmens, 2006; Playan and Mateos, 2006) emphasized that managing irrigation systems and improving the performance of existing

irrigation schemes are very critical activities to enhance their productivity. In this context, current levels of performance must be systematically assessed and the most effective measures for improvements should be identified.

The present study aimed at testing the reliability of the MASSPRESS methodology in analyzing the operation of pressurized irrigation delivery networks for addressing modernization aspects. The study entailed hydraulic simulations on a poor-performing irrigation system located in southern Italy and managed by a local Water Users Organization (WUO), with a focus on analyzing the performance achievable at the hydrant level under different operational scenario, through the application of hydraulic performance indicators. In detail, the study included the following activities: (1) Modeling the capacity and sensitivity of the system; (2) Defining and validating a specific indicator to allow evaluating the hydraulic response of the pipe network to changes in flow conditions; (3) Evaluating how the delivery service at hydrants would be impacted at hydrant level in response to flow changes and to the network's hydraulic behavior.

Materials and Methods

Rationale of the proposed methodology

For pressurized irrigation distribution networks there is no specific definition or indicator of the hydraulic sensitivity, which is a relevant parameter for system design and modernization to evaluate the network's behavior in propagating/attenuating flow perturbations. The approach utilized within the present study entailed simulating and analyzing the performance achievable by the pipe distribution network in terms of delivery service at hydrants. The COPAM simulation model (FAO, 2008) was utilized in this study for the performance evaluation on the basis of the hydraulic behavior of the pipe distribution network. The network's hydraulic behavior and resulting impact on irrigation delivery service at hydrants can be investigated by means of hydraulic simulation models, and can be physically represented in terms of flow rates and pressure heads available to farmers for adequately operating their on-farm irrigation systems downstream of delivery hydrants. In detail, irrigation delivery performance at hydrants can be represented by the values of the relative pressure deficit (RPD) in a plan where the abscissas correspond to the hydrant numbering and the ordinates to the RPD value. This can provide a good understanding of the hydraulic behavior of each hydrant during operation, showing (1) How much pressure head is available at each hydrant under different flow configurations (2) How often the hydrant is unsatisfied with respect to minimal conditions for adequate operation of the on-farm irrigation system by farmers (3) How much variation of pressure head occurs at hydrants as a result of different flow configurations.

Operational index

An innovative approach was tested during the present study that is based on the combination of the hydraulic indicator of relative pressure deficit (RPD), used within the COPAM software package, and a statistical parameter; "the expected value" (EV) of the RPD. Specifically, the EV was integrated with the variation of the RPD values in one equation for the determination of a combined index named Operational Index (OI), which could provide meaningful and detailed information about the impact of flow changes on irrigation delivery service at hydrants. The expected value of a random variable is the weighted average of all possible values that this random variable can take. The weights used in computing this average correspond to the probabilities in case of a discrete random variable, or the densities in case of a random variable. From a theoretical standpoint, the expected value is the integral of the random variable with respect to the measure of its probability. Supposed that the random variable X can take value x_1 with probability p_1, value x_2 with probability p_2, and so on, up to value x_k with probability p_k, and then the expected value of the random variable X is defined as:

$$EV(X) = x_1 p_1 + x_2 p_2 + ... + x_k p_k \quad (1)$$

Since all probabilities p_i add up to 1 (p_1+p_2 + ... +p_k= 1), the expected value can be viewed as the weighted average, with p_i's being the weights

$$EV(X) = \frac{\sum_1^k x_i p_i}{\sum_1^k p_i} \quad (2)$$

Where: EV(X) is the expected value of a random variable With X_i being the value of the variable (in our case the RPD values); $p_{i\ is}$ the probability of occurrence of each value X_i

The use of EV for evaluating the effects of the network's hydraulic behavior at hydrant level thus allows computing the weighted average of the entire set of RPD values accounting for their probability of occurrence. However, the use of EV alone could not provide comprehensive and exhaustive information on the network performance and sensitivity, as more than one hydrant could have the same EV, thus not allowing a comparative evaluation of their sensitivity. In the same value of expected value which means that we can't understand which one is more sensitive comparing to others. As such, the EV must be combined with other indicators to allow determination of hydrants' sensitivity and get information about the most sensitive areas of the network as a result of external changes. Given that the RPD provides detailed information on the spatial variability of the hydrant pressure, and also the range of fluctuation of the pressure head occurring at the different hydrants, it is the most suitable indicator to be combined with the EV. The parameter resulting from the above-indicated combination is named Operational Index (Oi) and is obtained through equation 3 in such a way to indicate how changes in flow conditions affect the hydrants both in terms of available pressure head and range of its variation.

$$OI = (\frac{Adequacy - EV}{MaxEV}) * 10 + (\frac{\Delta RPD}{Max\Delta RPD}) \quad (3)$$

Where: OI: is the operational index (unit less); Adequacy is the zero-value line of the relative pressure deficit, corresponding to the minimum pressure head necessary for adequate on-farm irrigation (ex. Adequacy = 15 m); EV is the expected value of RPD (m); ΔRPD is the range of variation of the RPD value at each hydrant (m). The equation 3 produces values of the OI ranging in a scale between – 10 and + 10

The operational index ranges

As explained in the previous section, the OI provides information about the hydrant's RPD value with respect to the adequacy line; and it also allows knowing the relative distribution of RPD values according to their probability of occurrence. As such, it allows comparisons between hydrant's performance under the same flow conditions (where the hydrant's performance can vary as a result of the different configuration of hydrants in simultaneous operation), and when flow changes occur in the network.

A tentative set of reference standard values was identified to allow ranking and classifying hydrant's performance based on their sensitivity to changes in network's operating conditions. The ranking procedure is composed of the following elements: The maximum range of variation of the OI values set between -10 and +10.

An upper boundary calculated on the basis of the nominal operating pressure stood by the most commonly used pipes for on farm irrigation system downstream of the delivery hydrants. In case of plastic pipes with nominal operating pressure limit of 6 bars (~ 60 m), the upper boundary can be calculated as

$$OI = (\frac{15 - 60}{60}) * 10 = -7.5 \quad (4)$$

A range of "Highly Sensitive" is defined by OI values between -7 and -10

A lower boundary is set according to the minimum value of pressure head at hydrants that is compatible with the proper operation of farm irrigation networks (~ 20 m). The lower boundary is thus calculated as:

$$OI = (\frac{15-20}{20}) * 10 = -2.5 \qquad (5)$$

A field of “Slightly Sensitive” is defined by OI values between 0 and -2.5, whereas the hydrant will be classified as “Sensitive” if the value of OI results between -2.5 and -7.
The field of “Poorly performing” is when the pressure head available at hydrant (H) is lower than the minimum required for proper operation of farm irrigation system.

Table 1. Tentative values of OI for ranking hydrants in terms of sensitivity

	-10		-7		-2.5		0		10
Highly sensitive (HS)	⦶	+	⦶						
Sensitive (S)			⦶	+	⦶				
Slightly sensitive (SS)					⦶	+	⦶		
Poor-performing (PP)							⦶	+	

Description of the study area

The Sinistra Bradano irrigation scheme is located in southern Italy, in the western part of the province of Taranto and covers a total topographic area of 9,651 ha. The system is divided into 10 operational units called districts, each of them subdivided into sectors. The present study focused on the District 10, which is composed of three sub-areas that are served by three distribution sub-networks originating from as many different diversions along the last section of the main canal, namely the Diversion 7 (D7), 8-North (D8-N) and 8-South (D8-S). The various simulations and performance analysis were conducted on the sub-network 7.

Application of the proposed methodology to the selected irrigation districts

A number of simulations were conducted on the irrigation delivery sub-network 7 that entailed three main scenarios described hereafter: (1) a fixed upstream piezometric elevation at 60 m a.s.l. and different values of the available flow rate at the network inlet, varying from Q_{up1} = 220 l s^{-1},to Q_{up2} = 240 l s^{-1} and Q_{up3} = 260 l s^{-1}; (2) the upstream discharge is fixed at 240 l s^{-1} and different values of the upstream piezometric elevation, varying from Z_{up0} = 60 m, to Z_{up1} = 70 m, Z_{up2} = 75 m, and Z_{up3} = 80 m. (3) this scenario consists in evaluating the sensitivity at hydrants without changing the flow parameters at the network inlet. In this case, only the configuration of hydrants in simultaneous operation could change for the same value of flow rate and piezometric elevation at the network inlet. This scenario will provide information on the variability of delivery performance at hydrants within the network as a result of the changes in configuration of hydrants in operation. The three scenarios will result in different delivery performance at hydrants, which can be evaluated and ranked through the Operational Index. Values of the OI can be presented in a plot and show the effect on the hydrants resulting from changes in the flow parameters at the network inlet. The analysis of the above-defined scenarios allowed (i) Identification of “weak” areas within the distribution network, which require operational attention (ii) information about the delivery performance at hydrants when the flow conditions in the network deviate from a specific set point, i.e. changes in available flow rate or piezometric head at the network inlet; (iii) testing the applicability of the set of proposed reference values of the OI, for ranking and classifying hydrants on the basis of their sensitivity to flow changes.

Results and Discussion

Figure 1 show the results of simulations conducted on the first sector, compared by the first thirteen hydrants, showed identical three values of OI, these hydrants are not sensitive to the changes made, while the rest of hydrants showed different OI values as resulting from changes of upstream flow rate. So, passing from Q_{up1} to Q_{up2} and Q_{up3} a similar pattern was observed for hydrants having different OI values. Figure 2 shows that if the upstream piezometric elevation Z_{up} is progressively increase of 5m increments, the OI values will shift

upwards meaning that the network reacts to piezometric elevation increases with higher pressure heads at the delivery hydrants, as expected.

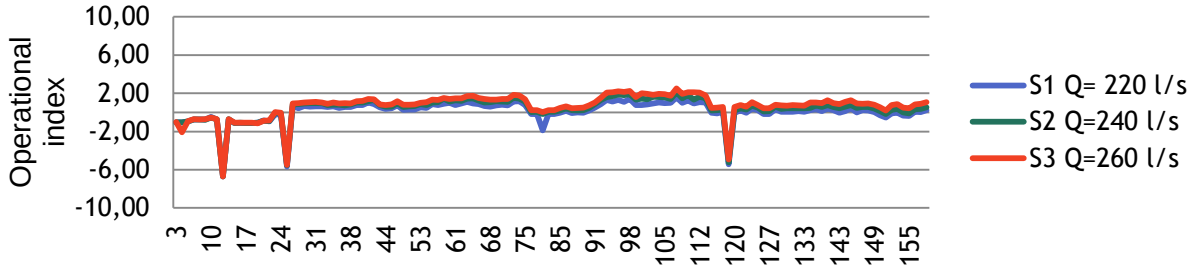

Figure.1.Values of OI resulting from the changes indicated in the first scenario (Z_{up} fixed and Variation of Q_{up})

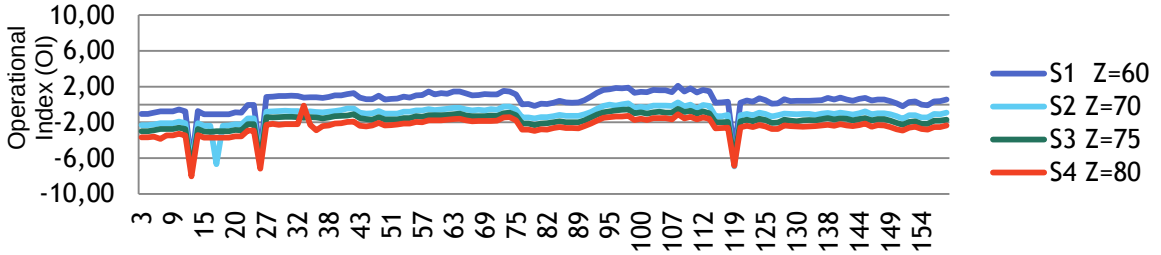

Figure.2. Patterns of the OI values that result from progressive increases of the upstream piezometric elevations (Q_{up} fixed and Variation of Z_{up})

Lamaddalena and Sagardoy (2000) report that at certain number of configurations with respect to the number of hydrants in the network, the system stabilizes and don’t react regarding to the changes made. Indeed, this was confirmed by this scenario where three sets of 500 configurations were generated, indicated in Figure 3. Thus, it can be noticed that three curves are identical, meaning that the network stabilizes and there is no changes with respect to the changes made.

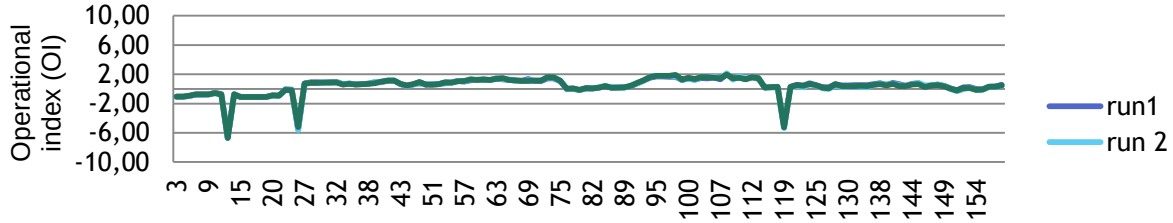

Figure.3. Values of the OI within the configurations for the third scenario (No changes in inputs)

Figure 4 shows the case of hydrants having the same EV but different RPD variation. The hydrants with number 74 and 98 have both EV of -0.14, a range of variation of the RPD Thus, the OI values allow ranking the hydrants in order of sensitivity as follows: Hydrant 98 > Hydrant 74. Figure 5 refers to the case of hydrants having different EV and different values of RPD variation. The hydrants numbered 24 and 127 were compared, that have EV of 0.9 and 0.84, RPD variations of 0.43 and 0.93, whereas the OI values are -1.55 and -0.22, respectively. Based on OI values, the hydrant 24 is considered more sensitive to the changes than the hydrant 127. Figure 6 presents the case of the hydrants with different EV and the same RPD variation. The hydrants numbered 23 and 76 are compared, with EV of 0.22 and

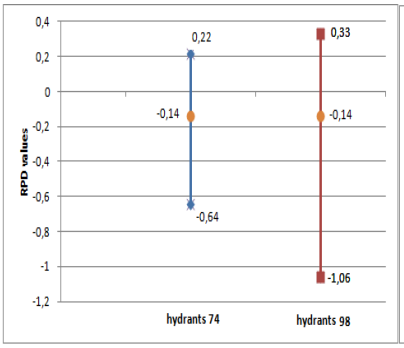

Figure.4. Case of hydrants having same EV and different ranges of RPD variations (Scenario1, Simulation 1)

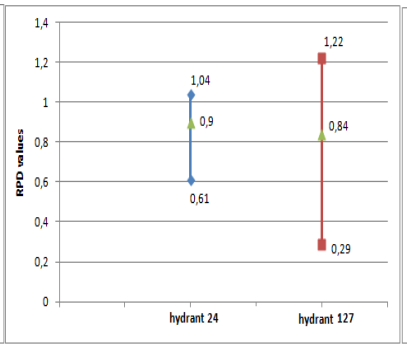

Figure.5.Case of hydrants having different EV and different ranges of RPD variations (Scenario2, Simulation1)

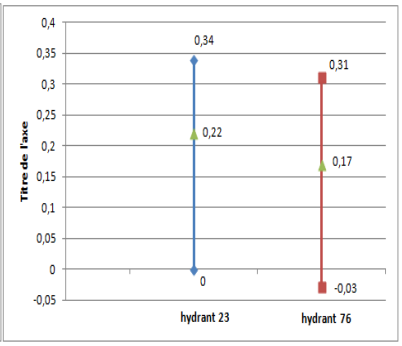

Figure.6. Case of hydrants having different EV and same ranges of RPD variations (Scenario3, Simulation 2)

0.17, RPD variation for both of 0.34, whereas the OI values are -0.13 and 0.01, respectively. Based on OI values, hydrant 76 is considered more sensitive to changes than the hydrant 23.

Conclusions

The operational index developed and applied in this study allowed to better understand the impact of flow changes on delivery performance at hydrants in the pressurized irrigation distribution network analyzed. In addition, it enabled to combine different performance indicators into one single index which includes (a) the probability of occurrence of different values of the RPD, through the statistical parameter of the expected value, (b) the range of fluctuation of the pressure head occurring at hydrants through the variation of the relative pressure deficit (RPD) and (c) the possibility to rank the hydrant performance based on the operational index. This composite index provides information about the relative position of the pressure head occurring at each hydrant with respect to the adequacy line (zero RPD), and indications on the hydrant's sensitivity to changes of flow conditions through the irrigation distribution network.

Abstract

Land suitability evaluation is a way of systematically collecting and analyzing different kind of information. It contains interdisciplinary information that involves integration of criteria from different branches of science. All gathering data analysed and converted into spatial database. Level information is arranged by classifying the main factors for vegetable growing, especially green beans one. The area of this research is Perushtitza Village, Plovdiv Region, Bulgaria. This is a report of multi-criteria land suitability evaluation, in which variety dimensions are incorporated into GIS technical tool. For ranking and important judgment of the criterias, pair-wise comparison using Analytical Hierarchy Process (AHP), developed by Saaty (1977), was carried out. The results are portrayed in the thematic map of the Perushtitza Village. The main objective of this study is to classify available agricultural land area of Perushtitza valley into different suitable classes for vegetable crop cultivation, using GIS application. The core of process is to create assessment map by calculating important indicators for sustainable vegetable cultivation.

Keywords: *vegetables, land suitability evolution, GIS, assessment, Analytical Hierarchy Process (AHP)*

Introduction

Horticulture is one of the most spread cultivation practice in Bulgaria. Its good natural and environmental factors make possible to increase yield over the years. Vegetable production systems in Plovdiv region is land form, farm size and intention of cultivation. Sustainable vegetable farming system is associated with good practices related to people cantered development, sustainable livelihood, agro-ecological practices, sustainable forestry system, community based natural resources management, participatory policy development, indigenous farming system, fair labour condition, good agricultural practises, equitable access to water and others (Baniya, 2008). Farming system corresponds closely with the land use planning. Physical land suitability evaluation is carried out with analysis of soil characteristics, land characteristic and climate characteristic. Sustainability is the ability of an agricultural system to meet evolving human needs without destroying and, if possible, by improving the natural resource base on which it depends (USAID, 1988). Land suitability evaluation can also be defined as the assessment or prediction of land quality for specific use. This process includes identification, selection and description of land use types relevant to the area under consideration; mapping and description of the different types of land that occur in the area and the assessment of the suitability of the different types of crops. In this research selected area is Plovdiv Region and especially Perushtica Village. This region is selected by its plane relief and suitable environmental parameters for vegetable growing.

This study presents the influence of physical land characteristics on green beans development. It includes deeply analyses on soil and relief parameters, needed for successfully crops growing.

Materials and methods

Initially used based information about green beans developing is soil maps, digital cadastral maps into appropriate coordinate system, climate characteristics, summarized parameters for established crops growing. The methodology is based on matching soil and relief characteristics, both named as Physical land characteristics and agronomical requirements of green beans. Using GIS tools for analysing the suitability classification will be assessed. Based on analysing tools and recommended crops parameters are made maps of land suitability accordingly to soil and relief parameters.

The organization of database is presented by Analytic Hierarchy Process (AHP), introduced by Saaty (1977). By making pair-wise comparisons at each level of the hierarchy, participants can develop relative weights to differentiate the importance of the criteria (Hossain et.al. 2007). Structure of assessment about criteria and sub-criteria is made by the alternatives, indicating the degree of suitability with respect to a criterion. Final thematic maps of every one of the studied parameters present level of land suitability for green beans development. By AHP method all parameters are compared using matrix for physical land criteria and sub-criteria about soil and relief.

The local priorities are multiplied by the weights of the respective criterion. The results are summed up to get the overall priority of each alternative. For each level in the hierarchy it is necessary to know whether the pair-wise comparison has been consistent in order to accept the results of the weighting. The Consistency Ratio (CR) is a measure of how much variation is allowed for reasonable results that is expected to be less than 10 per cent for the reasonable result. CR calculation is described as in following formula from the matrix Goal calculation, λmax value can be gained and later it is used to count Consistency Ratio (CR) and Wi which becomes the priority vector. The formula of Consistency Ratio (CR) got from the Consistency Index (CI) is as follows: $CI = (\lambda max - n) / (n - 1)$ and $CR = CI / RI$

Where: λmax: The maximum value; CI: Consistency Index; CR: Consistency Ratio ; RI : Random Index; n: The numbers of criteria or sub-criteria in each pairwise comparison matrix

Random Index (RI) says that the average of consistency of comparative matrix in pairs is 1-10, got from the experiment of *Oak Ridge National Laboratory* and *Wharton School*. The bigger the matrix is, the higher the inconsistency level will be (Permadi, 1992). Matrix Random Index can be seen in table below.

Table 1 Average Random Consistency Index (RI) (Permadi, 1992)

N	1	2	3	4	5	6	7	8	9	10
RI	0	0	0,58	0,90	1,12	1,24	1.32	1,41	1,45	1,49

AHP finally set out the priorities of the alternatives and the weights of each criterion with respect to the Physically land suitability map. GIS technology is used for analyzing information about development characteristics and requirements of green beans. Final thematic map is important for decision-making and prediction of land suitability, accordingly to specific crops, that are green beans ones.

Results and discussion

Agricultural crop land suitability is one of the interdisciplinary approaches that involve integration of criteria from different branches of science. Criterion may be both qualitative as well as quantitative and are involved in analysing different alternatives. Decisions have to be taken at various levels starting from selecting the land utilization types or crops till the allocation of the land utilization types or crops for area that suit best. So the suitability evaluation is a multiple criteria decision making process

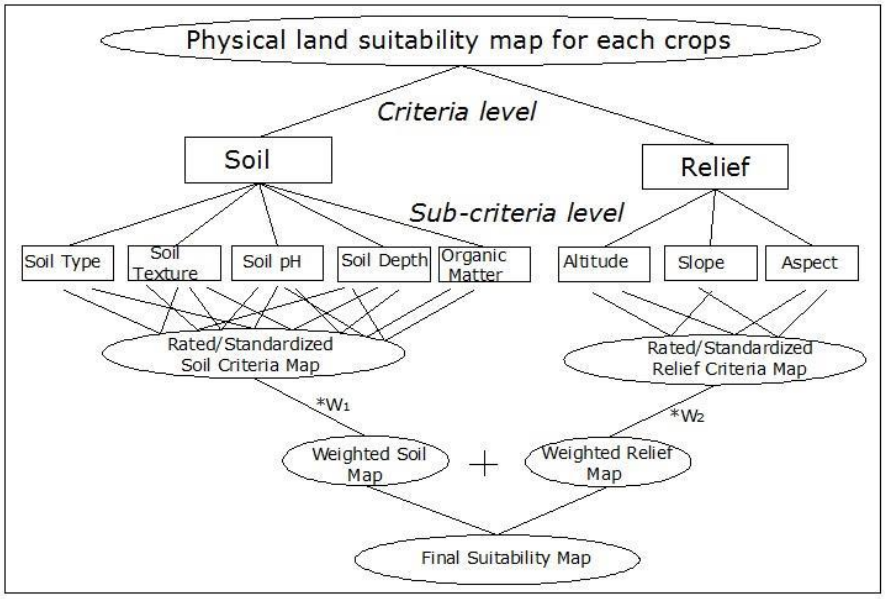

Figure 1. Conceptual model of AHP technique in GIS application

AHP technique presented the structuring of the criterias and sub-criterias required for the land suitability necessary for green beans development and set them in a hierarchical form. The overall goal of the research is suitability evaluation which occupies the top most level in the hierarchy. The next level consists of the main criteria set out to support the goal, and sub-criteria of the criteria occupy position in the next hierarchical level. Such structure allows the incorporation and accommodation of both qualitative and quantitative criteria for assessing land suitability.

Step on the research of assessment rate of soil and relief characteristics for green beans, named “Creating of land assessment database for vegetable crops in Plovdiv Region, Bulgaria” by authors Zh. Arnaudova, V. Stefanova, D. Haytova, comparing between database using matrix structure can be done. Hierarchical organization is followed by the comparison in pairs with respect to each factor of the next higher level. It allows expressing the comparisons in verbal terms which are then translated in the corresponding numbers. The next two tables present sub-classes of soil characteristics and relief ones, using matrix pair-wise comparison.

Table 2: Pair wise comparison matrix of Soil criteria in AHP

Factor	soil type	soil texture	organic mater	Ph	soil depth
soil type	**1**	0,2	0,167	0,333	0,167
soil texture	5	**1**	1	3	0,25
organic matter %	6	1	**1**	3	0,333
Ph	3	0,333	0,333	**1**	0,333
soil depth	6	4	3	3	**1**
∑	21	6,533	5,503	10,336	2,083

Table 3: Pair wise comparison matrix of Relief criteria in AHP

Factor	altitude	slope %	aspect
altitude	**1**	0,25	0,143
slope%	4	**1**	0,25
aspect	7	4,0	**1**
∑	12	5,250	1,393

Using matrix for presenting compare between every one sub-criteria in value, we transform all information into numbers and put it on GIS tools. For achieving weight assessment of land parameters, all values have to be calculated by using the above mentioned formulas. The results are in the next two tables.

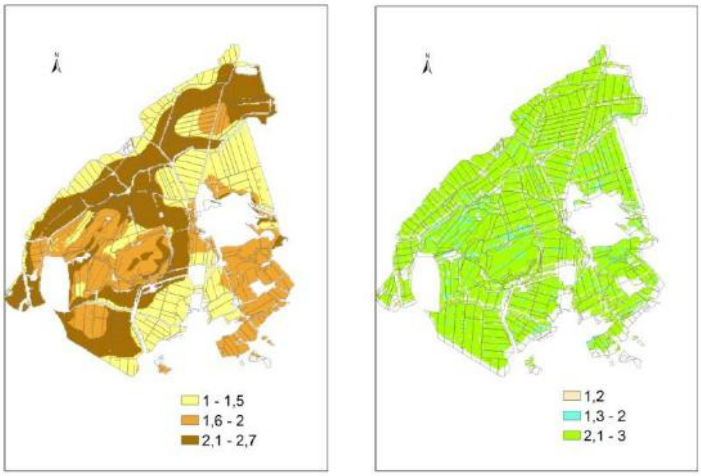
Table 4: Weighted parameters of Soil criteria in AHP

Factor	soil type	soil texture	organic matter	Ph	soil depth	Total	Average	consistency measure
soil type	0,048	0,031	0,030	0,032	0,080	0,221	0,044	5,142
soil texture	0,238	0,153	0,182	0,290	0,120	0,983	0,197	5,335
organic matter %	0,285	0,153	0,182	0,290	0,160	1,070	0,214	5,277
Ph	0,143	0,051	0,061	0,097	0,160	0,511	0,102	5,078
soil depth	0,285	0,612	0,546	0,291	0,480	2,214	0,443	5,520
							CI	0,068
							RI	1,12
							CR	0,06

Table 5: Weighted parameters of Relief criteria in AHP

Factor	altitude	slope%	aspect	Total	Average	consistency measure
altitude	0,083	0,048	0,103	0,234	0,078	3,015
slope %	0,334	0,190	0,179	0,703	0,234	3,062
aspect	0,583	0,762	0,718	2,063	0,688	3,156
					CI	0,039
					RI	0,58
					CR	0,07

Giving priority for every one of the physical environment criteria is calculated and based on expert knowledge and farmer opinions. Local conditions assessment and crops requirements were also made use for this. Accordingly to the expert opinions, the soil characteristics are more imported than relief parameters. Accepted it weight for these two parameters are 80% for soil and 20% for relief. Rated criteria maps are combined with the weightings to provide suitability value for each land unit corresponding to green beans. The score of the criteria obtained from the AHP will be stored as attribute data of each of the land unit of study area. ArcGIS is used to combine spatial data with suitability index so that a continuous land suitability map is generated. Final thematic maps are created and edited, overlaid and visualized on ArcGIS software of ESRI. The results from calculated parameters are presented in Soil and Relief thematic maps.



(a) weighted soil map *(b) weighted relief map*

Figure 1: Land assessment rate of Soil and Relief parameters for *Phaseolus vulgaris* L. in Perushtitza Village

Figure 2: Physical Land Suitability Map for *Phaseolus vulgaris* L. in Perushtitza Village

Once the weight value assigned for each class of each map, all of maps of factors for each land use type will be multiplied together. This study conducted calculations of the weight and fact value of each criteria and sub-criteria, produced the theme layers of each subcriteria, overlaid all the theme layers for having the final suitability classification. The thematic map with suitability value will be generated for every one level and overlaid for final suitability classification accordingly to the study area. As a result the most suitable soil characteristics in the Perushtitza Village are presented with best rated.

Multidisciplinary natural resources teams are required to make GIS systems an effective tool in support of land evaluation and land use planning. Each map demonstrates information, spatial and non-spatial attributive relating to land evaluation objective. Good and positive land assessment of physical parameters in Perushtitza Village is established for green beans (*Phaseolus vulgaris* L.). This state is proven by employing GIS technique. Using AHP method of dealing is complex decision making and can assist with weighting selection criteria, analysing the data collected for the criteria, and expediting the decision-making process. All this information can be beneficial for predictions, planning and getting more increasingly profitable yield by green beans growing.

Conclusion

The aim of land evaluation is to determine the suitability of land for alternative, actual or potential, land uses that are relevant to the area under consideration. Land evaluation is the process of predicting the use potential of land on the basis of its attributes. It is interdisciplinary activities that rely on large amounts of information from different sources. Finally the results with reports and maps have to be dynamic, considering the continuous refinement of the whole land evaluation process. The results are intended to be used for land resource related decision making, both strategic land use planning by the direct land users, that is, the farmers.

Abstract

Development of vegetable crops is height and increased procession in Bulgaria. Plovdiv region is special area because of its green beans production. The main purpose of this report is investigating and analysing some of important factors for sustainable vegetable cultivation, especially green bean (*Phaseolus vulgaris* L.) . The volume of data include information about biological requirements for cultivation: climate, climatic conditions, terrain and soil characteristic, monitoring and agricultural facilities, socio-economic conditions like existing irrigation systems, road systems, mechanization, production transporting, etc. Gathering date from different kind of sources and then presented it on tables, makes work and analyzing easier to be used. Transform all non-spatial information into spatial using computer technology can be made by GIS applications. All information is prepared for using of GIS application by converting it into spatial database. According to specify crop requirements and surrounding environment, GIS analyzing presented more hopefulness and predicted way to show dependence to vegetable characteristics on nature. Land parameters and climate characteristics are part of the physical land characteristics, necessary for vegetable growing. All information is collected from different kind of resources- experiences, researches, literatures, etc. This report emphasize on physical land characteristics and especially soil and relief parameters, which is more important for crops development. About soil characteristics are discussed soil type, soil texture, organic matter, soil pH and soil depth. Accordingly to relief are presented altitude, slope and aspect. Their dependency and spatial transformation are presented by thematic maps

Key words: *vegetable crops, GIS, assessment, spatial database.*

Introduction

Horticulture is one of the most approached cultivation branch in Bulgaria country. Establishing appropriate suitability factors is the construction of suitability analysis. Careful planning of the use of land resources is based on land evaluation, which is the process of assessing the suitability of land for alternative land uses (Fresco et al, 1994). Information on land resources is a key to their careful and effective evaluation. Farming systems involve a complex combination of inputs, managed by farm households but influenced by environmental, political, economic, institutional and social factors. Good knowledge of crop necessaries is one of the steps to be good and profitable farmer. Among the horticultural sub-sectors, vegetable production increased at the fastest rate, especially during the last decade. High rate of vegetables depends on necessaries of the people and natural resources. Most horticultural commodities are commercially produced for the market (except from home-garden), which creates substantial demand for marketing activities.

The aim of this research is to create database for land assessment and analysing some of important factors for sustainable vegetable culture, especially green bean (*Phaseolus vulgaris* L.) Land parameters and climate characteristics are part of the physical land characteristics, necessary for vegetable growing. All information is collected from different kind of resources- experiences, researches, literatures, etc. This report emphasize on physical land

characteristics and especially soil and relief parameters, which is more important for crops development (Kumanov, 1988). About soil characteristics are discussed soil type, soil texture, organic matter, soil pH and soil depth. Accordingly to relief are presented altitude, slope and aspect. Their dependency and spatial transformation are presented by thematic maps.

Study area

Study area is Perushtica Village, Plovdiv Region, Bulgaria where topography, slope, aspect, etc develop considerable difference in the micro-climatic regime within study area the land unit can carefully be delineated. This study includes information from the climate, meteorology and environmental characteristics of the Perushtitza Village, Bulgaria. This region covers 4871.6 ha, including 2298.9 ha land using area. Elevation changes from 150m to 800 m. The relief is various from plane to hilly. The urban part is situated on plane and agricultural land. There is concerned most of the useful area for vegetable growing (Arnaudova, 2011, Popov 2011).

Figure 1. Study area

Material and method

The research needed information on physical land characteristics - climate, topography, soil, land cover and land use. In addition to these, data were collected to assess indicators of land assessment suitability. All necessary information is complex characteristics and depends on biologically requirement of vegetables.

Geographic information

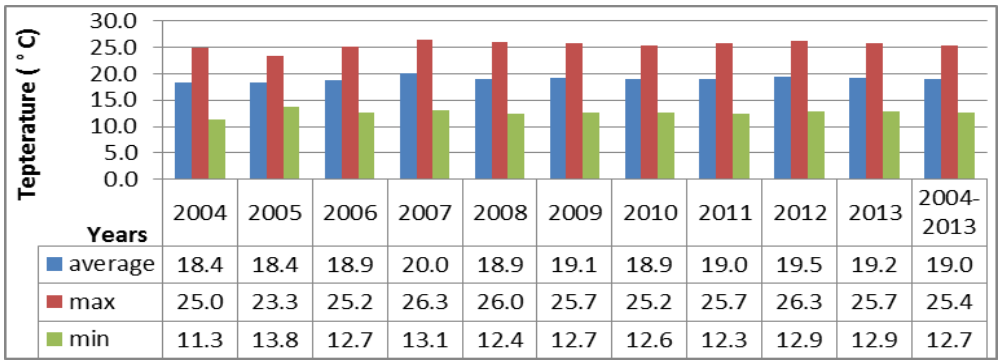
Digital administrative maps of the region, municipality, digital cadastral maps and maps of reclaimed property in the studied area. The digital model formats are ZEM, CAD. Information source: the Geodesy, Cartography and Cadastre Agency. (Arnaudova, 2010)

Digital soil map of the area in scale M 1:10000. Soil maps reflect in detail the boundaries between the separate soil types. Information source: The Soil Resources Agency and the Institute of Soil Science “Nikola Pushkarov”.

Topographic maps in scale M 1:25000 and digital elevation models

Attribute information

Air temperature in °C for period of 10 years (2004-2013), especially the months from April to October. This period is enough to establish dependence between variety of maximum, minimum and average temperatures.



Years	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2004-2013
average	18.4	18.4	18.9	20.0	18.9	19.1	18.9	19.0	19.5	19.2	19.0
max	25.0	23.3	25.2	26.3	26.0	25.7	25.2	25.7	26.3	25.7	25.4
min	11.3	13.8	12.7	13.1	12.4	12.7	12.6	12.3	12.9	12.9	12.7

Figure 2. Distribution of air temperature for period of 10 years (2004-2013)

Crop requirements for green bean (*Phaseolus vulgaris* L.) are presented on Table 1. It includes one of the most important characteristics, on which depends good vegetables development.

Table.1 Crop requirements for suitability of green bean (*Phaseolus vulgaris* L.)

Parameters	Potential Ratings		
	High	Moderate	Low
Temperature (° C)	22 -25	15 -22, 25 -28	< 10 & > 30
Soil texture (%)	25-30	30-40	>40
Organic matter content (%)	>2,5	1.5-2	<1.5
Soil reaction (pH)	6.6 - 7.5	< 4.5-6.6 & 7.5 >8.2	
Irrigation	Regular	Partly available	Rained
Soil depth (cm)	>80 cm	50-80cm	<50cm
Slope (degree)	Flat to 1	1 - 5	5 - 8
Aspects (direction)	South	South East	North
Soil Fertility	High	Moderate	Low

Assessment rate

In land suitability analysis, a map represents each evaluation criterion with alternatives (S1, S2, S3) indicating the degree of suitability with respect to a criterion. These classes have to be rated, how important is the class S1 with respect to a particular criteria to contribute for the final goal (suitability). In this particular land suitability analysis the criteria are mainly related to climate factors, elevation structure, soil characteristics. The next table explains suitability criterions.

Table 2. Suitability rate

Suitability classification	Explanation
High suitable (S1)	Suitable capacity of locations is high and satisfies all criteriaset up.
Medium suitable (S2)	Suitable capacity of locations is medium and satisfies of the criteria set up, but some criteria are not satisfied.
Low suitable (S3)	Suitable capacity of locations is low and satisfies some of the criteria set up, but most of the 2criteria are not satisfied.

The methodology is based on matching soil/land characteristics against agronomic requirements of crop and then the suitability classification will be assessed. The selection of criteria is the crux of the suitability analysis. Physical land suitability evaluation is based on biophysical conditions of the study area. The process of selecting the main criteria and sub-criteria is iterative in nature. Literature review, analytical study and the local opinions were basic tools for selection of evaluation criteria (Baniya, 2008).

Results and discussion

All collected information is classified by suitability rate and prepared for using of GIS applications. Using suitability classification for land assessment, gathering data can be presented by thematic maps, using GIS tools

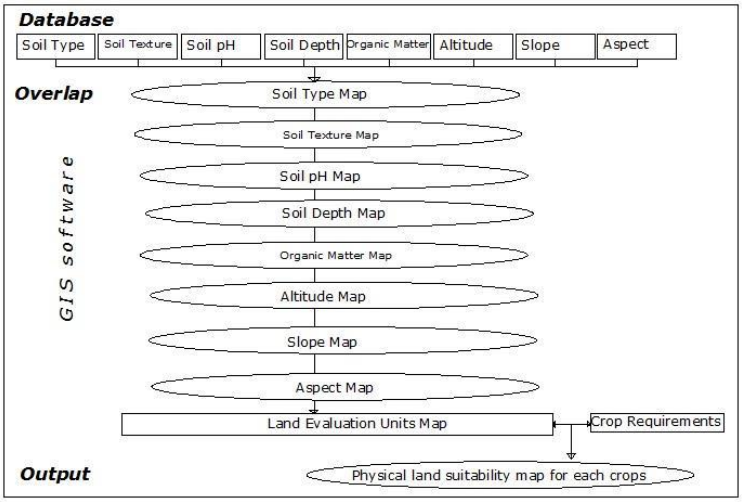


Figure 3. Conceptual model for assesment physical land suitability

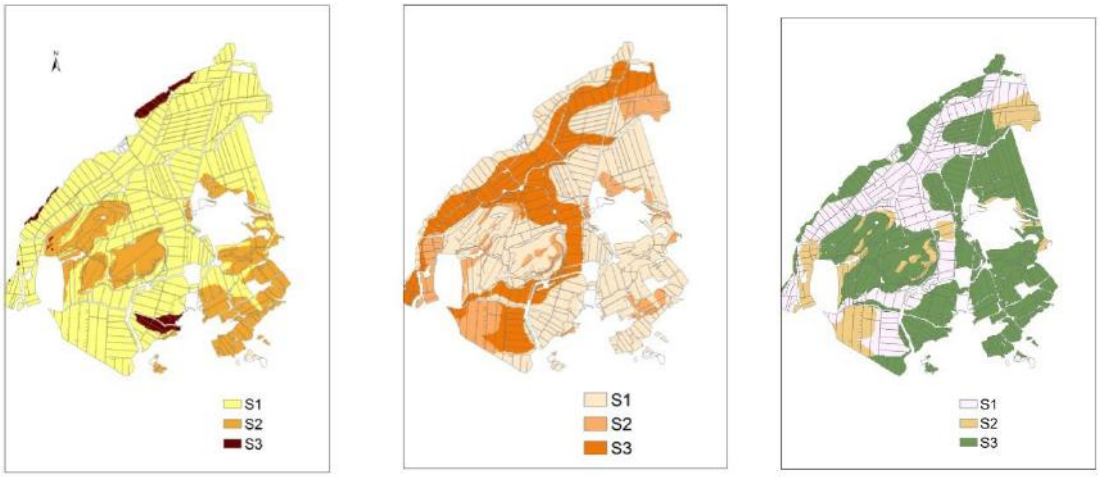
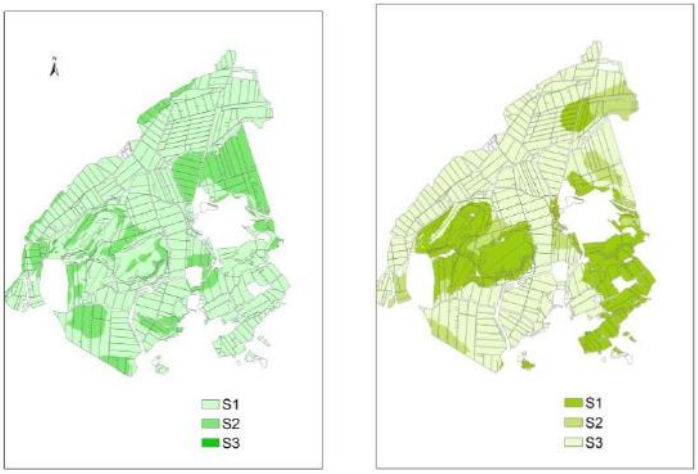
Research methods include collection of available and new field work data, data analysis using various tools and techniques. Several sources were used to gather up all data.



(a) soil type (*b) soil texture* *(c) soil depth*



(d) Reaction of soil (Ph) *(f) Soil organic mater*

(a) elevation *(b) aspect* *(c) slope (%)*

Figure 5. Suitability topographic characteristics maps in Perustitza Village for (*Phaseolus vulgaris* L.)

Land suitability evaluation is needed for various purposes in the context of present day agriculture and has to be carried out in such a way that local needs and conditions are reflected well in the final decisions.

Most spread soil types in the region are suitable for the vegetable cultivation. Respecting the soil physical characteristic - soil texture and soil depth are differently. Texture is one of the important parameter of soil. Most of the physical characteristics of soil depend upon texture class. (*Phaseolus vulgaris* L.) prefers loamy to sandy loam soil. Requirements for rootable soil depth is minimum 60 cm. These soils are about 40 % of whole cultivated area in region.

Organic matter content of the soil is an important parameter related to soil fertility. The most organic matter is ranging to 2% or medium suitable for vegetables. Figure 3 (a), (b), (c), (d), (f).

Refers to the climatic and infrastructure characteristics of studied area, the suitability rate can be defined to the S1- high suitability region for green bean growing. This assessment can be useful for more farmers and profitable for marketing centres. Figure 4 (a), (b), (c).

Conclusion

The most of cultivated area in Perushtitza Village are suitable for green bean cultivation. More of the physical land characteristics fitted on crop requirements with best rated.

Making suitability thematic maps the prediction and planning of profitable yields is more accessible to the farmers.

The selection of the main criteria and sub-criteria for each soil and topographic characteristics are first step to suitability evaluation process. Assessment of socio-economic and environmental suitability evaluation is carried only on those areas which are physically suitable.

Land evaluation is part of the process of land-use planning and the results should be useful for rational land use planning. Land use planning is a tool to help policy makers, decision makers, and land users, to use land in a way, that current land use problems are reduced and specified, social, economic or environmental goals are achieved.

Abstract

The goal of this research was to establish vertical distribution of soluble salts in ameliorated soils of Neretva River estuary located in the Adriatic Sea coast of Croatia. In the study area covering 670 ha in central part of estuary 77 soil pits were excavated. Each soil profile was segmented in 4 depth zone (0-30, 30-60, 60-90 and 90-130 cm) from which soil samples for laboratory analysis were collected. In a total of 308 soil samples basic soil chemical properties (pH, humus, $CaCO_3$, P_2O_5 and K_2O), soil texture and electrical conductivity (EC), Cl^-, SO_4^{2-}, Na^+, Ca^{2+} and Mg^{2+} in 1:1 soil:water extract were determined. Investigated ameliorated hydromorphic soils developed on delta sediments (quartenary marine mineral and organic deposits and alluvial deposits) had very wide ranges of analyzed chemical properties and texture. Soil conductivity ($EC_{1:1}$) varied in wide range from 0.42 - 8.00 dS/m (non-saline to strongly saline soil). Average soil $EC_{1:1}$ in surface and sub-surface horizons (depth zone 0-30 and 30-60 cm) were 2.06 and 2.38 dS/m respectively what makes them slightly saline. Deeper depth zones 60-90 cm and 90-130 cm were moderately saline with average values of soil EC 3.05 and 3.34 dS/m. Investigation of vertical distribution of soil salinity showed that soils of this intensively agro-exploited areas (citruses, other fruits and vegetables) are exposed to degradation: primary salinization caused by the capillary rising of groundwater and secondary salinization by using of brackish water for crop irrigation.

Keywords: *soil, salinity, agriculture, amelioration*

Introduction

Soil salinity of the irrigated land in the Neretva River estuary are result of primary or natural soil salinity processes (i.e. intrusion of highly salinized water in land) and secondary or anthropogenic (irrigation with brackish water, application of inorganic/organic soil supplements, fertigation). The influence of the salinization processes in Neretva River estuary was studied in numerous studies (Ondrasek et al., 2011; Romic et al 1999, Klačić et al, 1998; Salopek, 2008) and suggests their potentially large influence on the irrigated agriculture land. The intensive rainfall between two growing seasons and favorable soil properties (light texture and good water permeability) enable leaching of accumulated salts from rhizosphere into deeper soil layers and thus ensure the sustainability of the agricultural system. Soil salinization processes are very dynamic and may lead to problems for agriculture production so their consequences should be monitor. Previous investigations mainly analyzed horizontal distribution of salt in topsoil, as well as irrigation water quality, while data for vertical distribution of salt in soils of this area are missing. The goal of this research was to establish vertical distribution of salts in ameliorated soils of central part of Neretva River estuary.

Materials and methods

Study area

The study area is located in the Neretva river estuary in the Adriatic Sea coast of Croatia (43^0 $01^{'}$ $42^{"}$ E and 17^0 31' 10"N) covering 670 ha of agricultural land (Fig. 1). According to Köppen (1918) climate classification researched location belong to the climate type Csa, which means

that the area has a Mediterranean climate with hot and dry summers and wet winters. The mean monthly temperature was 15.7°C, and mean annual precipitation was 1231 mm (meteorological station in Opuzen, 1981-2000.) The climatic conditions are suitable for growing Mediterranean crops and vegetables. Geologically, terrain consists of the delta sediments (Marinčić et al. 1971) composed of Quaternary alternately accumulated marine, freshwater and lagoon sediments. The bed of the Neretva River at the mouth is a very deep (9 to 11 meters) and therefore allows the penetration of sea water upstream, especially during the low water levels of the Neretva River. This is especially noticeable in the summer, particularly during high tide. Before amelioration in the 60's of the 20th century this location was typical brackish marsh environment. The terrain elevations of study area ranging between -0.50 and 0.5 m. Today, the area is protected from flooding and the raising of brackish water in the channels by the pumping system. This area is used for growing vegetables, citruses and other fruits. Using WRB classification (FAO 2006), soils are classified as Fluvisols Calcaric and Molic and Gleysols Molic hydroameliorated by channels. Due to the degree of salinity these soils are classified as non-saline, salinized and saline soils.

Figure 1. Location map of the study area

Soil sampling and chemical analyses

In the study area covering 670 ha in the central part of Neretva River estuary 77 soil pits were excavated. Each soil profile was segmented in 4 depth zone (0-30, 30-60, 60-90 and 90-130 cm) from which soil samples for laboratory analysis were collected. A total of 308 soil samples were taken. On collected soil samples laboratory analysis were carried out by standard methods (JDPZ, 1966): pH potentiometrically, humus content by Kotzman method, total carbonate content by volumetric method (Scheibler), content of the available phosphorus by Troug method, potassium by AL method and texture by International B pipet method. Electrical conductivity (EC) was determined in 1:1 soil to water extract conductometrically, chlorides by Mohr method, sulfates by turbidimetric method, sodium by flame photometric method, Ca and Mg by AAS method.

Results and discussion

Statistical parameters of basic chemical properties and soil texture are shown in the Table 1. Investigated soils are weakly acid to alkaline, in average alkaline in all horizons. Deeper horizons, below 60 cm have higher pH regarding upper horizons. Coefficients of variation (CV) are small (2.62-3.61%) and a frequency distribution is symmetrical. Investigated soils are slightly to strongly carbonated in all horizons. The average carbonate content increases

with depth from 25.17% in depth zone 0-30 cm to 39.34 % in zone 90-130 cm, what is in agreement with above described increasing of pH values with depth. The average humus content decreases from 4.71% and 4.46% in the first two depth zones (0-30 and 30-60cm) to 2.93% and 2.72% in the third and fourth depth zone (60-90 and 90-130cm). Analyzed soils had a wide range of humus content in all depth zones, CV with a depth increasing from 42.09% in first depth zone to 83.24% in the fourth depth zone (90-130 cm). A frequency distribution of the humus content in first two depth zones is symmetrical. An asymmetrical distribution with a long tail to the right (higher values and positive skew) has the humus in the third and fourth depth zone. Depth zones 0-30 cm and 30-60 cm is very poorly to very richly supplied with available potassium. In average, depth zone 0-30 cm is richly supplied and zone 30-60 cm well supplied with K_2O. Depth zone 0-30 and 30-60 cm are averagely very poorly supplied with available phosphorus, although it vary from very poorly to slightly supplied in surface horizon. Very high CV, as well as asymmetrical frequency distribution (higher values and positive skew in both horizons) indicates differences in land management (fertilization).
According to texture the first three depth zones are averagely silty loam. The fourth depth is loam, with very variable content of coarse sand and clay (CV 144.23% and 68.00% respectively), as well as asymmetrical distribution (skewness 1.99 and 1.18 respectively). The average clay content decreases with depth from 25.06% (zone 0-30 cm) to 12.04% (zone 90-130 cm.). The most variable fraction in all depth zones is coarse sand with CV from 130.82% (zone 0-30 cm) to 187.39 % (zone 60-90 cm) and asymmetrical distribution in all depth zones.

The average electrical conductivity ($EC_{1:1}$) increases from 2.06 dS/m in the first depth zone (0-30 cm) via 2.38 dS/m in the second depth zone (30-60 cm) to 3.05 and 3.34 dS/m in the

third and fourth depth zone (60-90 cm and 90-130 cm), Table 2.A frequency distribution of the EC in first two depth zones has a symmetrical distribution. In the third depth zone distribution of frequencies is becoming close to asymmetric. An asymmetrical distribution with a long tail to the right (higher values and positive skew) has EC in the fourth depth zone.
In order to be able to interpret $EC_{1:1}$ should be converted into ECe values. Various authors used different correlation equations and factors to convert 1:1 soil: water extract to saturated paste extract equivalents: USDA (1954), Hogg & Henery (1984), Landon (1984), Zhang et al. (2005), Smith and Doran (1996) and Sonmez. et al. (2008)). In this paper we used proposal of Whitney (1998) which takes into account different texture classes. According to this proposal, in Table 2 are given the description of the salinity classes for mean, minimum and maximum $EC_{1:1}$ values of the each depth zone. First and second depth zones are slightly saline, third and fourth depth zone are moderately saline. The ranges and coefficients of variation (CV) showed the great variation and with depth increased. Degree of salinity in the first, second and third depth zone varies from non-saline to strongly saline (0.42-7.46 dS/m) and in fourth depth zone varies from slightly to moderately saline (1.33-8.00 dS/m).
The chlorine (Cl^-) and sodium (Na^+) concentrations had a wide range, a large coefficient of variation, and a symmetrical distribution in the all depth zones (Table 2). In the first depth zone Cl^- and Na^+ concentrations were 4.06 and 3.78 meq/L respectively with a tendency of a slight decline in the second depth zone. In the third and fourth depth zone the average Cl^- and Na^+ were increased and amounted 5,39 meq/L and 5,24 meq/L, respectively. Analysis of the original data showed that in 21 of the total 77 soil profiles, first depth zone has a higher Cl^- and Na^+ concentrations and higher nutrient content of phosphorus and potassium. This topsoil salt accumulation was mainly caused by the use of brackish water for irrigation.
The average sulphate (SO_4^{2-}) concentration gradually increased with depth between 18.59 meq/L in the first depth zone up to 40.92 meq/L in the fourth depth zone, with symmetrical frequency distribution. The average magnesium concentration (Mg^{2+}) increased with depth from 3.53 meq/L in the first depth up to 13.73 meq/L in the fourth depth zone. Mg^{2+} concentrations were in wide ranges in all depths zones with great CV. In second depth zone Mg^{2+} had asymmetrical distribution with a positive skew, while in other depth zones frequency distribution were close to asymmetrical (skewness 0.96-0.99). The average Ca^{2+} increased with depth, 19.96 meq/L in zone 0-30 cm to 28.29 meq/L in zone 90-130 cm. A frequency distribution of Ca^{2+} concentrations were symmetrical in first 60 cm, while in deeper depth zones were asymmetrical with negative skew (lower values and a long tail to left). Sodium adsorption ratio (SAR) vary from 0.1 to 7.3 with great CV and asymmetrical distribution with positive skew. In all depth zones SAR is below 13 what is considered limit value for sodic soils. Greater variation and higher skewness were registered in deeper depth zones (60-90 and 90-130 cm).

*Salinity classes according to Whitney (1998)

Relationships between soil texture classes and electrical conductivity ($EC_{1:1}$) are shown in Table 3. According to LSD test at 5% confidence interval difference of the $EC_{1:1}$ in sandy soil texture classes are statistically significant different (lower) in all depth zones regarding heavier texture classes. The absolute differences between loamy and clayey texture classes were not statistically significant.

Table 3. The mean $EC_{1:1}$ values of the different soil texture classes

Conclusion

Electrical conductivity evaluated using 1:1 soil to water extract ($EC_{1:1}$) varied over a wide range (0.42-8.00 dS/m), so soils were classified as non-saline, salinized and saline. Vertical distribution of the electrical conductivity ($EC_{1:1}$) is characterized by a gradual increase from 2.06 and 2.38 dS/m in the first and second depth zone (0-30 and 30-60 cm) to 3.05 and 3.34 dS/m in third and fourth depth zone (60-90 cm and 90-130 cm). A similar vertical distribution (gradual increase with depth) has sulphate ion. The chlorine (Cl^-) and sodium (Na^+)

concentrations in the first depth zone were 4.06 and 3.78 meq/L respectively, with a tendency of a slight decline in the second depth zone. This topsoil salt accumulation was mainly caused by the use of brackish water for irrigation. In the third and fourth depth zone the average Cl^- and Na^+ were increased and amounted 5.39 meq/L and 5.24 meq/L, respectively. The results showed that primary salinization caused by the capillary rising of groundwater and secondary salinization by using of brackish water for crop irrigation is present in Neretva River estuary. The sustainability of this agro ecosystem, is based on the intensive rainfall and favorable soil properties, especially light texture and good water permeability that ensure leaching of salts from the root zone to deeper soil horizons.

Abstract

Food security is a major concern in the developing countries, food production must increase significantly to meet future demand in a way that assures balance between the available and limited natural resources. According to the FAO roughly one-third of the edible parts of food produced for human consumption gets lost or wasted globally, i.e. about 1.3 billion tons per year. Food losses and waste are generated through the whole food chain.

Changes in food consumption patterns in Egypt had implications also in terms of the amount of food lost and/or wasted. Unfortunately, there are few data regarding food waste in Egypt. Therefore, the current exploratory study aims to have a general overview about household food waste in Egypt. An online survey and face-to-face interviews were conducted from February to May 2015 with a random sample of 181 adult Egyptians representing about 64.6% female and 35.4% male. The majority of the respondents were young (59.1% are less than 44 years old) and have high education level. Food waste is prevalent in Egypt as just 13.8% of respondents declare that they do not throw any food. Data show that food waste increases during the fasting month of Ramadan. The most wasted food products are fruits, vegetables, cereals and bakery products. Only 21.5% of respondents declared that the economic value of food waste generated each month is more than 6US$. Most of Egyptian respondents have a good understanding of food labels that is probably due to the high education level of the sample. About 42% of respondents throw weekly at least 250 g of still consumable food. To reduce food losses and waste in Egypt it is important to set a strategy at all food chain levels. There is also an urgent need to raise people's and organizations awareness towards this problem and further exploration on food waste at lower educational levels and poor people, which might be quite different.

Keywords: *Household Food Waste, Behavioral Change, Survey, Egypt*

Introduction

Food waste takes place at two levels; retailers and consumers (Gustavsson *et al.*, 2011). At the retailers' level food is wasted due to various reasons *i.e.* poor storage facilities, while at the consumers' level it is related to purchasing behavior and attitudes, knowledge regarding labeling information, insufficient purchasing planning. Additionally, economic, social and environmental factors could affect food losses and waste (FLW), as small scale farmers might lack cash to face production costs, climate change either high temperatures or freeze, or for social reasons i.e. marriage of sons or daughters.

FAO alerted about increased rate of food losses and waste in Egypt which reaches about 50% in vegetables and fruits, 40% in fish, 30% in milk and the amount of wheat losses and waste reaches 1.5 million tons/per annum. Additionally, wheat, tomato and orange losses and waste cost the government about 11 million EGP/annually, and about 650,000 tons of maize besides 350,000 tons of beet are wasted annually. Food security problem will not be solved via

increased production only but by conserving produced food from waste and damage (Egypt time science, 2015).
Egypt has two main sub-systems for food subsidy, first wheat flour and bread subsidy, second ration card program which provides fixed monthly quota of some commodities. This subsidy system suffers from increasing budget and waste, as waste occurs at different stages of bread supply chain starting from pre-post wheat harvest, storage, transportation, conversion of wheat to flour until consumption (Ramadan, 2014).
To authors knowledge, there are no direct policies or action plans at the government level that deal with food waste. In the Ministry of Agriculture and Land Reclamation there is the agricultural strategy 2030 that deals through its programs and action plans with food safety and agriculture waste. In the Agricultural Research Centre there are some institutes that tackle the issue of food safety within research context *i.e.* Food Technology Research Institute, Food Safety Information Centre, Economic Research Institute.
Food Technology Research Institute for instance conduct applied researches in food processing and preserving to improve the quality of food products and produce safety high nutritional value food with affordable prices. In addition to utilization of agricultural wastes and food processing factories wastes to reduce the pollution and to increase the economical returns through value added food. Finally it is necessary to reduce the loss during food processing (Food Technology Institute, 2015).
Ministry of Supply and Internal Trade provides food subsidy programs, yet no food waste reduction programs, although there is a consumer protection agency. The ministry aims at improving 164 wheat barns or silos "Shownaa", in order to reduce wheat losses and waste, recycling food oil waste, applying a system for recycling household food waste and leftovers to fertilizers (Ministry of Supply and Internal Trade, 2015). In Ministry of Industry and Foreign Trade, there is Law No. 67 of 2006 that is concerned with consumer protection (Ministry of Industry and Foreign Trade, 2015). There was an attempt in 2011 to establish the National Authority for Food Safety, but was not completed.
In spite of this, few NGOs initiated their own programs that care about food waste i.e. Egyptian Food Bank (EFB) provides some schemes to feed poor people and at the same time urged hotels and restaurants to re-use all food waste (leftovers) and re-pack it in order to be distributed to those who suffer from food insecurity and as one of the means to reduce hunger. EFP has three pillars to end hunger, first, anti food wastage awareness, by holding awareness programs for individuals, hotels and restaurants in order to save the food wasted everyday from homes or from buffets in events and occasions; second, awareness for hotels and restaurants, EFP signed a protocol with the Egyptian Hotel Association in order to save the excess untouched food from hotel events' buffets and restaurants by packing it in foil trays to be distributed to the nearest NGO, elderly residence or orphanage in the area instead of throwing it away; third, awareness for individuals, EFB directed campaigns to individuals at their homes, to distribute the excess untouched food to the nearest needy (Egyptian Food Bank, 2015).
Recently, there are some initiatives at individual household levels that pack any food leftovers or waste and distribute it to poor people; also some charity religious organizations (Masjid) that provide food in the Holy Month Ramadan to poor people as well. Additionally, an association named "Egyptian Chefs Association" organized with others a conference about "The Farm to Fork" that focused on three main themes, the Farm, the Kitchen and the Fork. Part one, the Farm, covered issues related to produce, from organic farming, to managing loss and keeping water usage to a minimum (Egyptian Chefs Association, 2015).
Therefore the current study is a primary attempt to explore and analyze the situation of food waste behavior and to quantify its economic value due to lack of such studies in the Middle East and North Africa Region (MENA) and Egypt in particular.

The present study mainly aims at evaluating the household food waste in Egypt focusing in particular on food purchase behavior and household food expenditure estimation, knowledge of food labeling information, attitudes towards food waste, quantity and value of food wasted, extent of household food waste, and, finally, willingness to behavioral change for food waste prevention and/or reduction.

Materials and Methods

In order to fulfill the current study's objectives, literature review from various resources *i.e.* reports, researches, databases were used. Additionally, a survey using a structured questionnaire that was adapted to the Mediterranean context from previous questionnaires and studies on food waste provided in English and Arabic languages in December 2014 and was uploaded using social media websites *i.e.* Facebook and emails, and a number of questionnaires was collected using face-to-face interviews. The questionnaire was available online from February till the end of May 2015 and the participation was entirely volunteer.

The questionnaire consisted of 26 questions. It included a combination of one option and multiple choice questions. It was developed into 6 sections that reflects the study's objectives. In the introductory part of the questionnaire the concept of food losses and waste was introduced to inform the respondents.

From 207 questionnaires received, 26 of them were not considered because the questions were not fully answered thus there were missing data. Therefore, the total number of the sample is 181 adult Egyptians.

Data were analyzed using descriptive statistics (e.g. means, max, min, percentages), in order to get a general picture of frequencies of variables, using Microsoft Excel.

Results and Discussion

The study's results provide an overview on the main characteristics of the respondents (profile) from one hand and fulfill the objectives from another hand.

Main characteristics of respondents

The results revealed that about 64.6% of the respondents were females and about 35.4% males, which could be attributed to the fact that most men consider food issues are part of women's responsibilities. Most of the respondents (33.1%) fell within the age category of 35-44 years and 23.8% between 45 and 54. About 44.2% were MSc/PhD holders, and 34.8% hold university degree, 17.1% technical degree. This shows that social media is accessed mainly by educated people. Additionally, 81.8% have paid work (full time or part time), and 6.6% were retired. Half of the respondents (53.6%) are married with children and 18.8% are partnered (sharing same household). As for household composition, the number of members are 4-6 persons represent about 69.1% of the total sample, 24.3% whose family is composed of 1-3 persons, this indicates that medium and big size families still dominate the Egyptians even among educated people, who were assumed to follow family planning programs.

Food purchase behavior and household food expenditure estimation

This part tackles respondents food behavior and an estimation of their food expenditures in order to understand their attitudes towards food. It was found that about 44.2% purchase their food directly from open markets and 28.7% purchase from supermarkets and hypermarkets and 23.2% purchase from mini/small markets.

In Egypt, most people buy their food from more than one place, meaning that they could buy from open markets, weekly markets in rural areas, mini markets or super markets or from farmers, but buying directly from farmers is not common as rural people might buy directly from their neighbors or from the weekly village markets and in some cases city people when travelling to other governorates might buy from road outlets or farmers selling their production on the road.

From once weekly to twice weekly respondents frequently purchase their food representing about 25.4% and 26.0% respectively from the total studied respondents. Some respondents buy everyday (17.7%) and those who buy every two days represent also 17.7%, others prefer to buy the basics on monthly basis (6.6%). That could be attributed to poor planning when purchasing food even if the results showed that about 44.2% of the respondents use a list prior to purchasing food, but this could be because the nature of the respondents regarding their education and social status (high and medium class).

Most of the Egyptians spend noticeable amount of their wages on food, this was evident by this study and the household survey carried in Egypt by Central Agency for Public Mobilization and Statistics (CAPMAS). It was clear that about 71.3% of the respondents spend more than 630 EGP on food, even it is considered as compared with high income countries the lowest. According to CAPMAS (CAPMAS, 2014), Egyptians spend about 37.6% of their income on food and non-alcoholic beverages, of which 3.5% on bread and cereals, 11.1% on meat, 2.3% on fish and sea food, 6.0% on dairy products, 2.7% on oils and fats, 3.2% on fruits and finally 5.2% on vegetables.

Almost half of the respondents were attracted “sometimes” to food offers representing about 44.2% of total respondents who are attracted to special food offers which normally takes place at super and hyper markets or by bargaining at small shops or small and weekly markets, followed by 33.1% respondents who are attracted to such offers, even if sometimes these offers are done on items that are almost expired, but poverty have another word and action, and often people do not pay attention about expiry date.

Knowledge of food labeling information and attitudes towards food waste

The results show respondents knowledge about food labels which might eventually lead to reducing food waste among consumers and the respondents attitudes towards food waste and food habits. It was indicated that about 86.7% of the respondents understand and have knowledge about “use by” label as food must be eaten or thrown away by this date. This result could be attributed to the educational level of the respondents. Whereas only 11% regarded the “best before” label as food is still safe to eat after this date.

It was evident that 85.6% of the respondents do worry about food waste and they try to avoid it and 8.3% are aware about food waste problems but have no intension to change their current habits. About 53% of respondents indicated that they dispose “very little” amount of uneaten food, as they try to minimize household food waste since they are worried and aware about food waste impacts, and about 29.3% throw reasonable amount of uneaten food. Unfortunately, respondents indicated that food waste increase in the Holy Month of Ramadan as mentioned by 75.7% of the respondents whereas 24.3% were negative about it.

Regarding food waste management, 41.4% of the respondents give the remained food to animals, but this happens in rural areas, as well as some urban districts were people raise mainly poultry. 34.8% said they dispose it in the garbage.

Tracking consumers food habits could explain their attitudes towards food waste and its quantity, in that regard the results showed that 57.5% of the respondents cook a main meal from raw main ingredients from 3-6 times/week. About 67.4% eat a meal left over from a previous day (less than twice/week), 50.8% eat out, this if to be true is the case in urban and big cities, but in rural areas maybe the image is different.

Quantity and value of food wasted and extent of household food waste

This part of the results deals with the quantity and value of food wasted to help quantify the amount and extent of food waste. The results showed that 63.5% of the respondents spend less than 2% of their income and about 19.3% of respondents spend from 3-5% of their income on cereals and bakery products that are wasted. Whereas 75.7% of the respondents spend less

than 2% of their income on roots and tubers, 84% spend less than 2% of their income on pulses and oil seeds that are wasted (table 1).

Table 1: Respondents estimation for purchased food groups wastage (in percent).

Items	Less than 2%	3 to 5%	6 to 10%	11 to 20%	Over 20%
Cereals and bakery products (bread, rice, pasta, etc.)	63.5%	19.3%	9.9%	0.6%	6.6%
Roots and tubers (potatoes, etc.)	75.7%	14.9%	4.4%	3.3%	1.7%
Pulses and oil seeds (e.g. peas, chickpeas, olives, sunflowers)	84.0%	11.0%	2.2%	1.1%	1.7%
Fruits	75.1%	14.9%	5.0%	1.7%	3.3%
Vegetables	65.7%	19.9%	9.9%	1.7%	2.8%
Meat and meat products	93.4%	2.8%	1.7%	1.7%	0.6%
Fish and seafood	91.2%	6.6%	1.1%	0.6%	0.6%
Milk and dairy products	81.8%	12.2%	3.3%	-	2.8%

Source: Authors' survey

As for the extent of food waste 58% of the respondents do not throw away food that is still consumable and about 17.7% throw less than 250 gr, finally 16.6% throw between 250 and 500 gr. As for the economic value of wasted food, it was revealed that for about 78.5% of the respondents the economic value of wasted food is less than 35 EGP (less than 5$), while for 14.9% of the respondents economic value of wasted food is between 42 and 140 EGP (6 - 20$).

It is evident that Egyptians' food purchases during Ramadan soar beyond all other monthly consumer averages, straining the efforts of ministers concerned with supply and domestic trade to keep up with demand. According to a recent study carried out by the National Centre for Social and Criminal Research (NCSCR), 83 percent of Egyptian families alter their food consumption habits during Ramadan in a way that augments their food bill for this month by 50 to 100 percent. If total annual consumer spending in Egypt comes to around LE 200 billion, LE 30 billion of this is spent in Ramadan, which is to say at a rate of LE 1 billion a day, the bulk of which goes to food in this month of "fasting". The NCSCR study observes that during this month

Egyptians spend 66.5% more on meat and poultry, 63% more on sweets, and 25% more on nuts and nibbles, and they host 23% more banquets and dinner parties. The study further notes that at least 60% of food on an average Egyptian family, and more than 75% of food in a banquet, goes to waste, which is to say tossed into the rubbish bin, during this month. According to statistics from the National Census Centre, in the first week of Ramadan Egyptians consume 2.3 billion loaves of bread, 10,000 tons of fuel, 40 million chickens, 200 percent more yoghurt and ghee, and some LE 9 million worth of dried fruits, which accounts for 35 percent of the annual trade in this festive staple (WikiIslam, 2015).

Willingness to behavioral change

This part deals with the notion of consumers’ willingness to change their behavior regarding food waste, thus to explore first the respondents’ perception of food waste reasons. It was evident from the results that most of respondents are familiar with such reasons, for instance 49.2% mentioned food is left in the fridge for too long time, followed by 43.1% of them that said food expired, and 40.3% indicated food has mold.

In addition respondents listed the following reasons: food does not have a good smell or taste, leftover, food does not look good and wrong preservation representing about 39.2%, 37.05%, 32.6%, 20.4% of the respondents, respectively. Packaging not being in proper size was at the end of the reasons representing about 6.1%.

Eventually, since respondents have clear vision about food waste causes or reasons, then could be willing to reduce such waste. Though, willingness is accompanied with information, so about 40.9% of the respondents mentioned that they will reduce food waste if the packaging was more suitable, followed by if they were better informed about the negative impacts of food waste on the environment, and better informed of the negative impacts of food waste on the economy, representing 38.7% and 37.0%, respectively.

In regard of respondents willingness to reduce food wastage, results indicated that 40.9% of the respondents have this will if the packaging of food was more suitable, 38.7% if better informed about the negative impacts of food waste on the environment, followed by 37.0% of the respondents who indicated they have the will if they were better informed of the negative impacts of food waste on the economy, 23.2% if labels were more clear and finally 21.0% of respondents mentioned their will is related to paying higher taxes on the basis of what they throw.

Finally, as for the information needed to reduce food waste, 53.0% of the respondents said that they need recipes with leftovers, 50.8% need tips on how to conserve food properly, 33.1% need organizations and initiatives that deal with food waste prevention and reduction, finally 28.2% need information on the freshness of products.

Conclusion

Reducing FLW is a multi-sectorial, multi-disciplinary and multi-factorial task. It requires networking and coordination between public institutions and private sector agencies in agro-industries, food quality and safety, NGOs, etc. Policies and regulations are key drivers for all actions aiming at reducing FLW but along with an effective participation and collaboration of all previous actors (FAO, 2014). Neither coordination and collaboration among relevant actors dealing with food losses and waste do exist, nor policies and regulations, but rather poor initiatives and scattered efforts.

The respondents showed particular characteristics which was related to their educational and income level. This requires to widen the scope of any coming studies to study different categories, and governorates either Upper or Lower or even Coastal areas to see the differences and variations when dealing with food waste. That will be through studying their behaviors by its three components; knowledge, attitude and trend from gender perspectives and then studying FLW that is the main cause of food insecurity in the developing countries in general and Egypt in particular. By this way food policies that deal with losses and waste will be formed on solid basis and upon current conditions and by the effective participation of all actors. Finally establishing the high council for food security that combines all relevant actors could be the key towards sustainable food systems in Egypt.

THE IMPACT OF PRESCRIBED FIRE ON THE VEGETATION OF WADI EL-RAYAN WETLANDS (A PROTECTED AREA), WESTERN DESERT, EGYPT

Mohamed Talaat EL-HENNAWY[1]*, Mohamed Sameh ANTAR[2]

[1]Western Desert Parks of Egypt, DG, Nature Conservation Sector, Egyptian Environmental Affairs Agency, Cairo, Egypt

Abstract

The effect of man-made fires on the productivity of the key species *Phragmites australis* in Wadi El-Rayan wetland ecosystem was assessed. Three sites around the Upper and Lower Lakes were selected to monitor the fire effects during the period from 2005-2007. 2 sets of results were obtained showing the single effect of fire rather than the combined effect of fire followed by grazing in the same area. This study has been implemented during an accepted PhD study in the same area.

The rate of phytomass development for *P. australis* wetland in Wadi El-Rayan showed a continuous increase in the grazed area after fire rather than that in non-grazed area showed an increase followed by a decrease, however, the value of phytomass is much more in non-grazed area. The rate of phytomass accumulation in the lower lake showed a similar trend to that in the upper lake in non-grazed area. However, the absolute value of phytomass increase reached 56.7, 71.8 & 72.1 times more in the Upper Lake than those in the Lower Lake at winter, spring and summer seasons respectively.

A simple GIS time-based map comparison was provided to help understanding the time change of the vegetation figures of Wadi El-Rayan wetlands.

Keywords: *GIS, Phytomass, Vegetation, Prescribed Fire, wetlands, Wadi El-R*

Introduction

Wadi El-Rayan Protected Area WRPA declared by the prime-ministerial decree No. 943 in 1989 according to the law No. 102/1983 of the protected areas in Egypt and administered by the Nature Conservation Sector (NCS) of the Egyptian Environmental Affairs Agency (EEAA). WRPA is one of Egypt's 28 protected areas. The human interference in the protected areas is regulated by the environmental laws and regulating decrees. (Figure 1)

A well-developed reed beds had formed around WR Lakes (Upper and Lower) since the late seventies, with the *Phragmites australis* (Cav.) Trin. Ex Stud. As the dominant species invading the peripheries of Rayan Lakes (El-Hennawy, M. T., 2010). The Upper Rayan Lake shows more and well developed *P. australis* community due to the reasonable salinity level of the lake (around 1500 ppm), however, in the Lower Lake the salinity reaches 12000 ppm in some areas and up to 15000 in the extreme areas, which arrest the establishment and extent of the plant.

Firing in Wadi El-Rayan is a man-made practice feature affecting the wetland ecosystem, which is never previously studied. The cause of fires in Wadi El-Rayan is always a matter of guessing. It might be attributed to the production of new sprouts for un-authorized cattle and buffalo grazing in some locations around the Upper Lake by the local poor community inhabiting the villages located around the peripheries of the protected and wetland areas. Stopping the firing in the Lower Rayan Lake has strengthen the guessing that the cause of fire is for producing a palatable new sprouts for the grazing animals, that the wetland areas and vegetation development around it is extremely retarded the last years due to water decreasing level.

FIGURE 1: Map of Egypt Parks With the study site Wadi El-Rayan Highlighted in Red

Studying the fire effects on the wetlands led to several facts and reports. The use of fire in coastal marsh management is described as a means to remove dead vegetation, re-establish lower succession stages, or return the marsh to an early hydric community. Fire prevents accumulation of organic matter and thus impedes elevation of the marsh and succession to upland communities. (Diaber, 1974). The literature indicates no adverse effects of fire on fish or aquatic invertebrates. Ruffed grouse, sharp-tailed grouse, spruce grouse, and ptarmigans obtain new habitat from fire. Habitat changes following fire benefit some large mammals but neither harm or benefit most small mammals. (Kelsall, *et al*, 1977).

Disturbance related to chance perturbations, water depth, and the incidence of fire accounted for much of the variation in the sedge meadow community. Annual burning (presumably by local residents) maintains the meadows against invasion by shrubs, increases nutrient mineralization, and provides a pronounced change in albedo which permits earlier spring growth. (Auclair, *et al*, 1973)

Immediate and long-term effects of fire on wildlife are reviewed. Included are discussions of changes in species composition and energy flow following fire, changes in density and overall abundance of wildlife following fire, and various case histories to support the major points presented. The evolution of birds and mammals in burnable habitat (including the effects of fire upon wildlife speciation as a result of fire) and adaptation of birds and mammals to flammable habitat are examined. With reference to wetlands, burning results in open water and encourages seed-bearing plants which are valuable waterfowl foods. (Bendell, 1974).

Today, the same conditions are still there especially in the Upper Lake and reflected on the greater area and density around it rather than around the Lower Lake. Common reed germination may be decreased at salinity levels greater than 5000 ppm (Briea, 2006). This is very clear in the Lower Rayan Lake, when the water level decreased after 1999 and the shoreline of the lake greatly retarded, the soil has dried up and the existed vegetation has died (except the woody species such

as *Tamarix*). The reed stolons run towards the new shoreline for long distances trying to reach the moist, but the visible growth rate and vitality and vigor are so weak due to the high salinity of the lake in these areas which reaches more than 12000 ppm. It is easy to notice the stolons and new seedlings of *Phragmites* trying to establish themselves in these areas (El-Hennawy, M. T., 2010). The study of fire effect on the phytomass of the *Phragmites australis* on Wadi El-Rayan wetlands will be the matter of this study.

Materials and methods

Three sites were selected to study the accidental fires in the wetlands of WRPA. GPS coordinates for the location were recorded immediately after fire. Two sites were located around the Upper Lake and one site located at the south of the Lower Lake. One of those sites was permitted to cattle grazing after fire around the Upper Lake. The fire sites were visited by three months intervals after the firing time. In each site, an average of two-randomly selected clip quadrate (1.00 m^2) was used for phytomass assessment (Sarvis, 1923 and Weaver & Clements, 1957). The above ground vegetative parts were clipped, cleaned and sorted out. Fresh samples were dried at 100-110 ^oC for constant weight. The productivity figures presented in this study are based on dry weight basis. The whole site was detected for vegetation and lakes area change through 2005 to 2015. All image processing has been conducted using Intergraph ERDAS Imagine v. 2013 and ESRI ArcGIS v. 10.2 Software.

Results and discussion

A. The Effect of Fire on The Rate of Phytomass Accumulation

1. The Upper Lake

The rate of phytomass accumulation increased by 209.3% from winter to spring, and decreased by 31% from spring to summer. Figure (2) showed the variation of phytomass after fire took place in autumn 2005 in the Upper Lake.

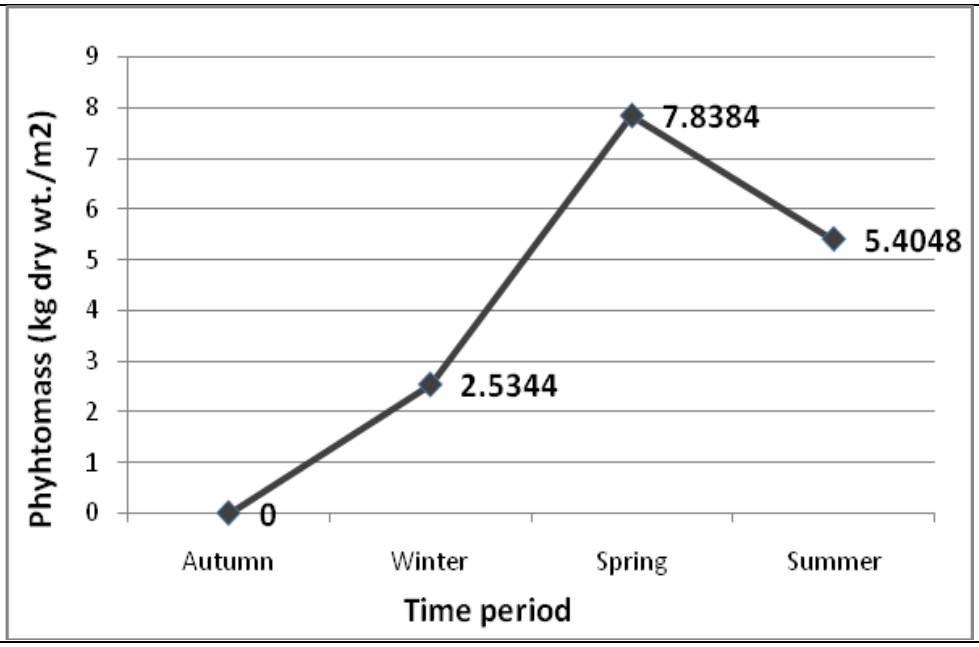

FIGURE 2. Variation of phytomass after fire in the Upper Lake area (Autumn 2005)

2. The Lower Lake

The rate of phytomass accumulation increased by 144.3% from winter to spring, and decreased by 31% from spring to summer. Figure (3) showed the variation of phytomass after fire took place in autumn 2005 in the Lower Lake

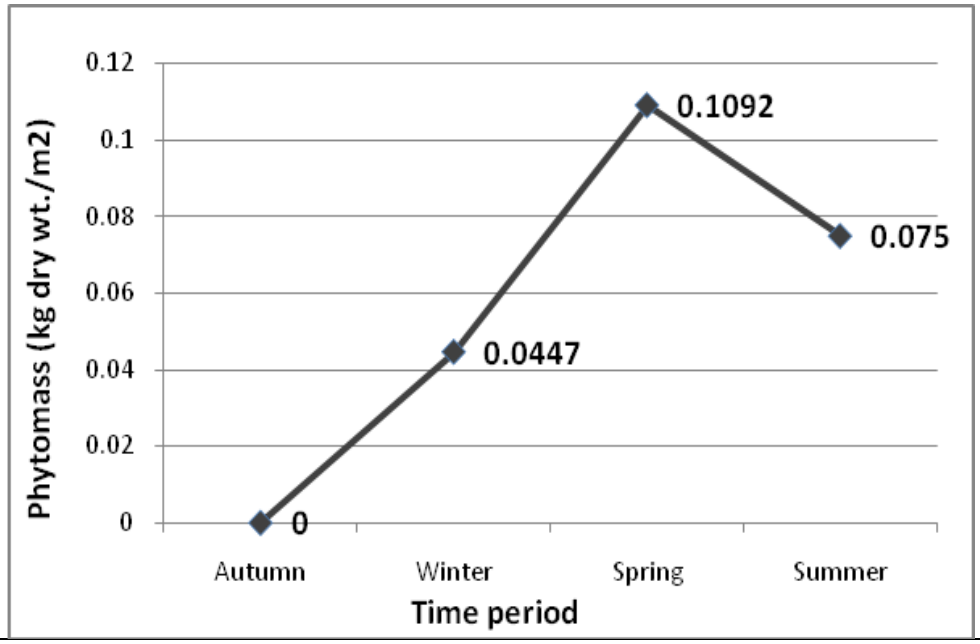

FIGURE 3. Variation of phytomass after fire in the Lower Lake area (Autumn 2005)

As a conclusion, the same trend was realized for the phytomass accumulation rate in both lakes of Wadi El-Rayan, after firing in a three-month interval, which is an increase followed by a decline in summer season.

However, the absolute values of the phytomass varied widely from the Upper and Lower Lakes sites after firing. It was found that the absolute values of phytomass were significantly higher in the Upper Lake compared to the Lower Lake (Figures 2, 3 and 4) in the period of the study.

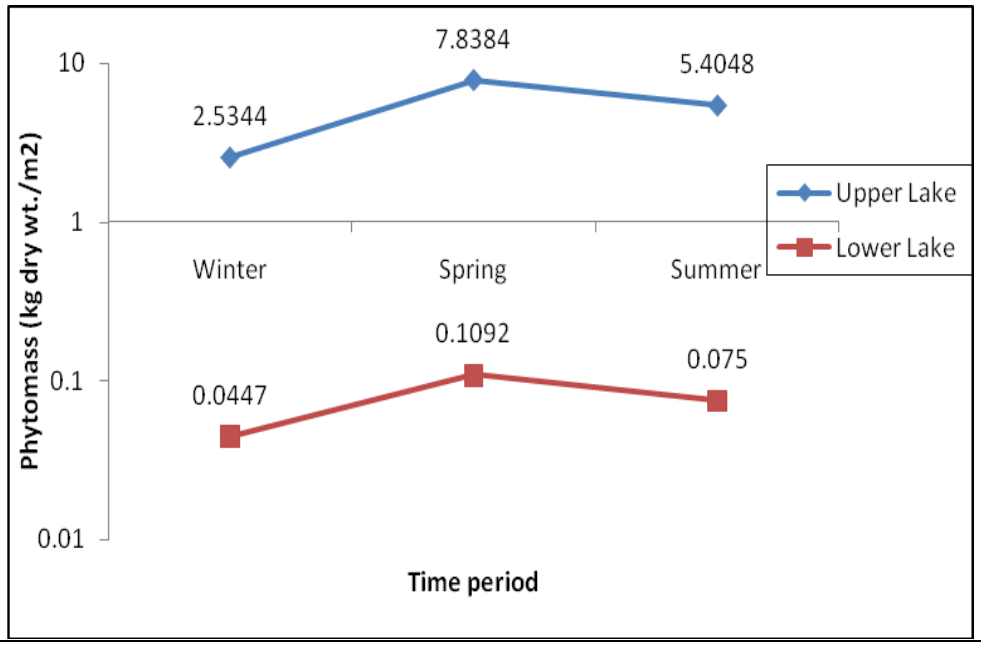

FIGURE 4. variation in the absolute values of phytomass in Upper and Lower Lakes after firing

B. The Combined Effect of Fire & Grazing on The Rate of Phytomass Accumulation
The rate of phytomass accumulation was assessed in the Upper Lake area after occasional fire followed by cattle grazing. The rate of phytomass accumulation was continuously increased by 147.9% from winter to spring, and 56% from spring to summer. Figure (5) showed the variation of phytomass after fire took place in autumn 2005 in the Upper Lake.

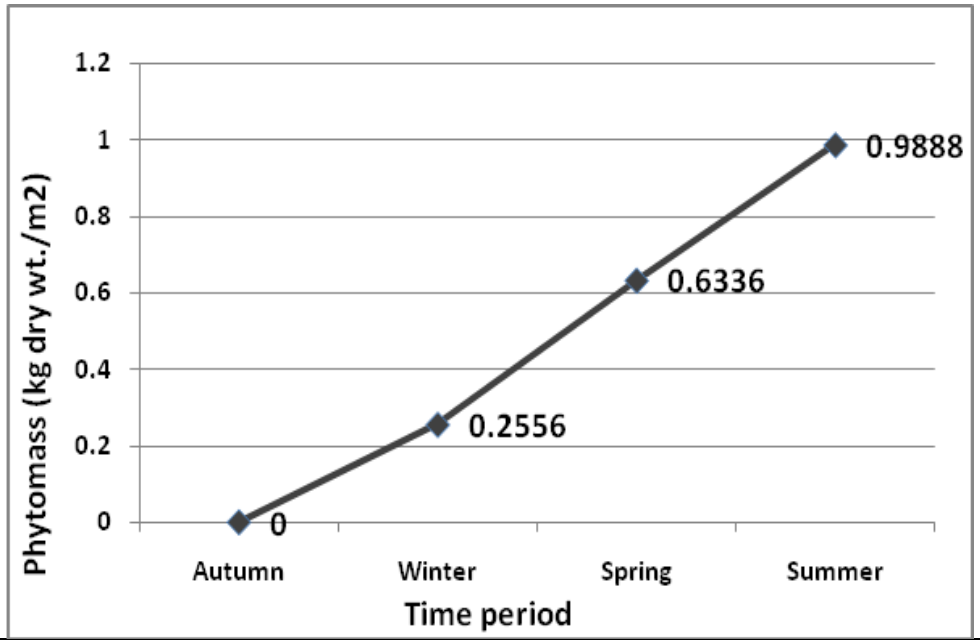

FIGURE 5. Variation of phytomass after fire & grazing in the Upper Lake area (Autumn 2005)

C. The change detection in wadi el-rayan protected area
A positive relationship between the water body of the lake area and the area of vegetation cover was shown by Figure (6). The area of vegetation cover changed from 973.42 acre in 2005 to 1324.58 acre in 2015, along with a tiny increase in the water body area of the Upper lake with only 134.5 acres and mostly occurred in the Upper lake.

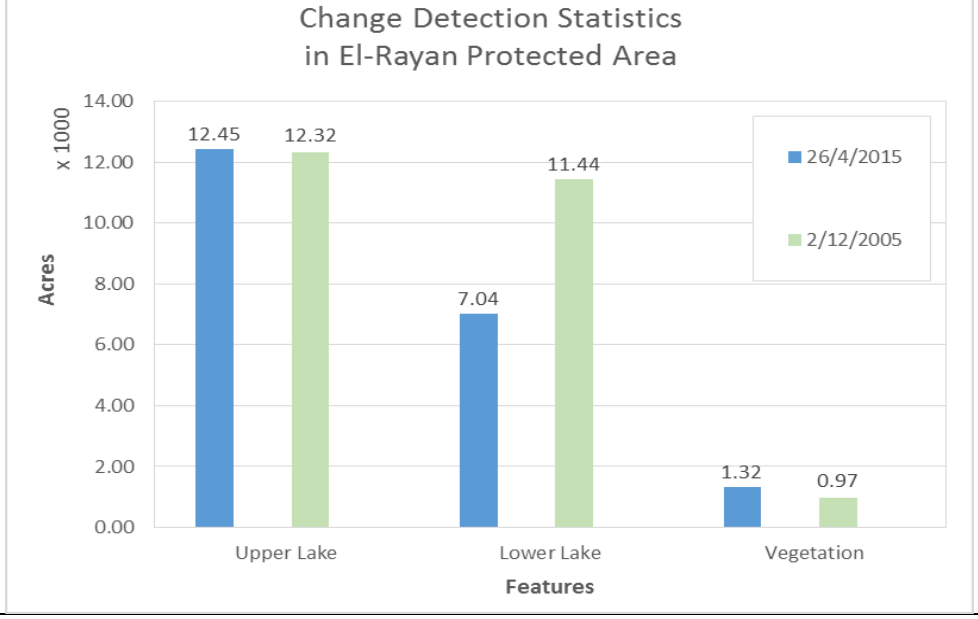

FIGURE 6: The change detection from 2000 to 2015

	Area (Acres)	
	26/4/2015	**2/12/2005**
Upper Lake	12453.90	12319.40
Lower Lake	7038.96	11439.40
Vegetation	1324.58	973.42

Figure 6 also shows remarkable decrease of the water body of the Lower lake area and the area of vegetation cover. It decreased from 11439.40 acre in 2005 to 7038.96 acre in 2015 with a noticeable decrease in the vegetation cover.

Figure 7 shows the change in vegetation and water areas of the Upper and Lower lakes of Wadi El-Rayan from 2005 to 2015.

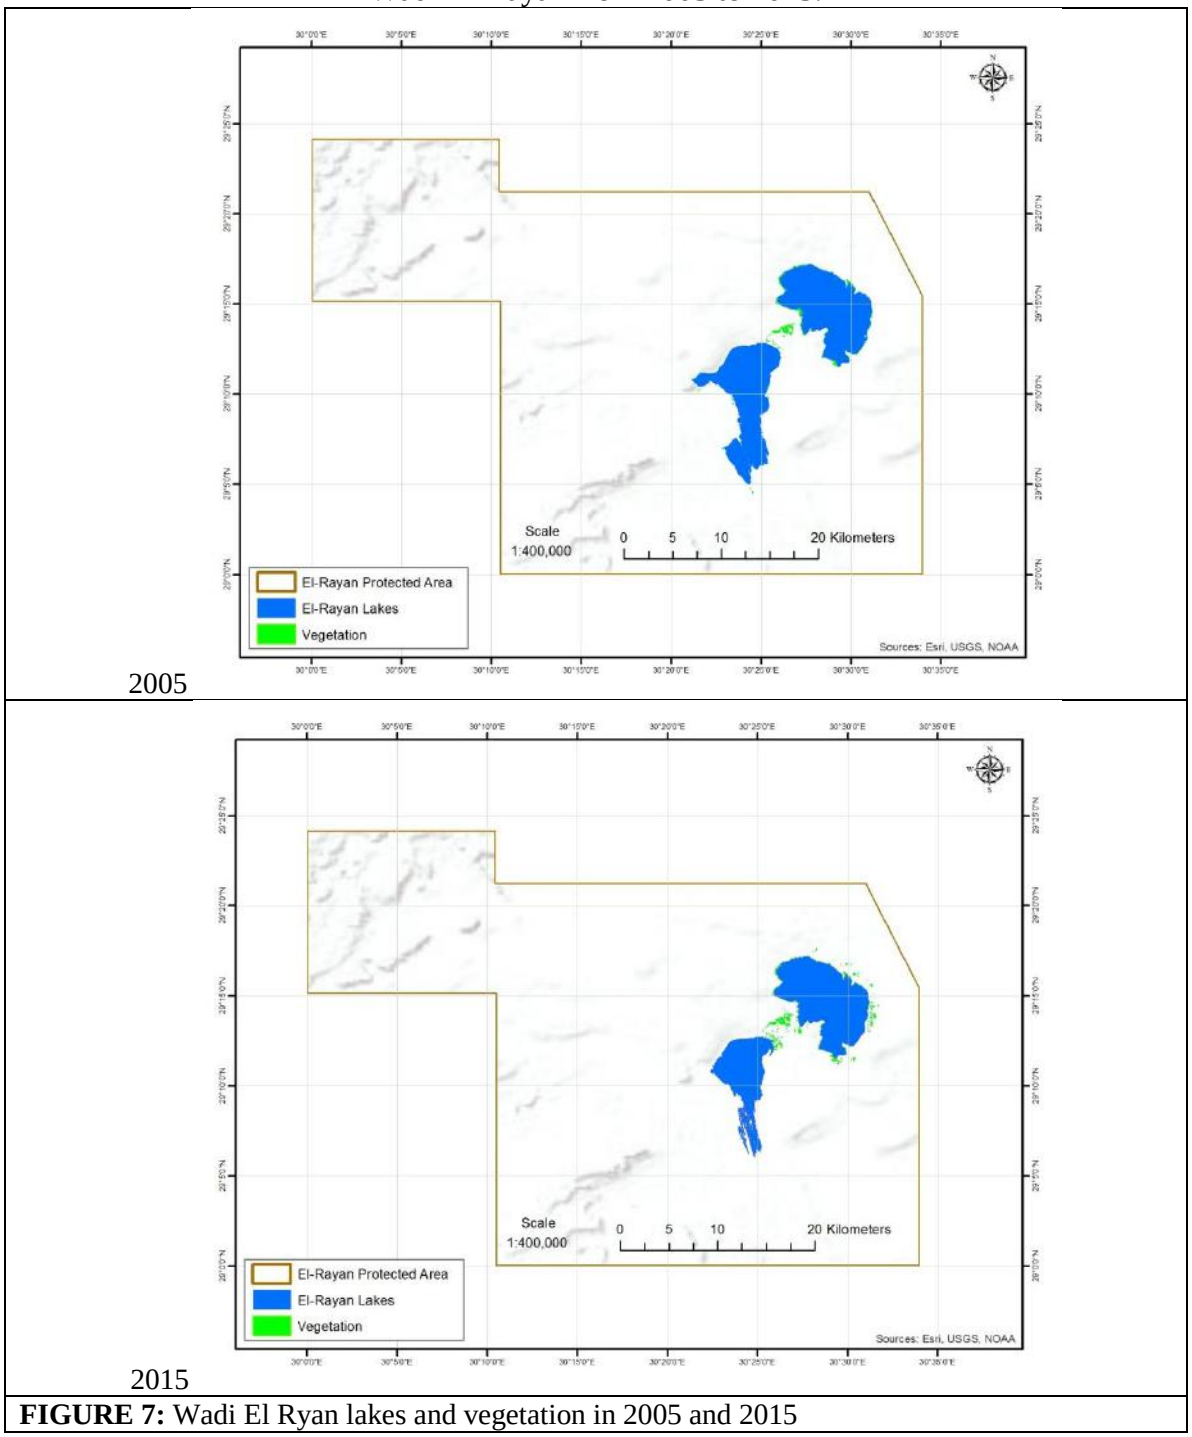

FIGURE 7: Wadi El Ryan lakes and vegetation in 2005 and 2015

Conclusion

The monitored fires in this study were dated September 2005-2007 on the wetland cover around both of the Rayan lakes. The rate of phytomass development for *P. australis* wetland in Wadi El-Rayan showed a continuous increase in the grazed area after fire, while that in non-grazed area showed an increase followed by a decrease, however, the value of phytomass is much more in non-grazed area.

The rate of phytomass accumulation in the lower lake showed a similar trend to that in the upper lake in non-grazed area. However, the absolute value of phytomass increase reached 56.7, 71.8 & 72.1 times more in the Upper Lake than those in the Lower Lake at winter, spring and summer seasons respectively.

Common reed sprouts rapidly from surviving rhizomes after fire. Sprouts may appear as soon as 5 days after fire (Ward, 1968). This is almost the case in Wadi El-Rayan Upper Lake. Fires that took place in the Rayan Lower Lake may retard its vegetation sprouts up to more than one month. Rarely is common reed abundance decreased by fire, and post fire recovery is typically rapid. In the case of Wadi El-Rayan, a huge stock of the common reed rhizomes existed especially in the area of the Upper Lake and the connecting channel.

Common reed post fire abundance (cover, biomass production, and/or density) is rarely different from pre-fire abundance by the 2nd or 3rd post-fire year (Ward, 1968; Ailes, 1993). It is not uncommon for burned sites to have greater common reed abundance than unburned sites (Greenall, 1995; Thompson & Shay 1985).

For the case of Wadi El-Rayan, the same trend was realized for the phytomass accumulation rate in both of Wadi El-Rayan lakes, after firing in a three-month interval, which is increasing followed by decreasing rate.

In Wadi El-Rayan case, it is not urgently needed as the sedge meadows are still there. The edaphic factors are also supporting the same composition as the soil particle analysis shows frequent silt and clay particles than sand; the latter is supporting the shrubby and woody stage such as *Tamarix nilotic*a growing frequently on the external borders of the *Phragmites australis* wetland especially in the lower Rayan Lake with frequent sandy soils. So, even there are no recorded investigations about the effects of fire on the wetland productivity in this area, it is not recommended to allow firing processes.

The study of the fire impact on the productivity of Wadi El-Rayan wetland was very helpful in providing suitable management actions to conserve the integrity of the ecosystem.

Fires in common reed marshes can be used to benefit wildlife, but can also negatively impact nesting birds. Prescribed fires should avoid destroying currently used nesting habitat.

Grazing must not be allowed in case of weak management system which can not limit and monitor it within the proposed boundaries or seasons.

The produced GIS maps were very helpful to show the picture of the identified high/low wetland vegetation productivity sites in addition to the potential grazing sites among these sites taking in consideration the seasons and sites of actions.

BIOCHAR FROM MUNICIPAL WOOD: A KEY STRATEGY TO PRODUCE ADDED VALUE PRODUCTS FROM WASTES

Hadi JAVIDI, Ali M.NIKBAKHT*

Urmia University, Iran
*Corresponding Author: alinikbakht87@yahoo.com

Abstract

Solid woody wastes collected from pruning of municipal trees is a major source for producing energy and added valued materials in countries, though millions of tons of such biomass are feasible. In this study, the pyrolysis of wood collected from pruning of plane tree at different temperatures and different sizes has been investigated. Pyrolysis process was performed in a fixed bed batch reactor under adiabatic conditions. The ultimate goal was the production of maximum ratio of biochar mass from wood waste. Humidity, temperature, durability and the effect of size in 400, 500, 600, 700° C were tested in triplicate. The particles in 4 sizes were prepared. All parameters were weighed before and after pyrolysis to obtain the biochar mass fraction. According to the results obtained from the pyrolysis process, the best temperature to yield desirable output qualitative attributes was obtained to be 600°C and the most optimal resistance time was measured to be 10 minutes in which there would be sufficient time for gaseous carbon to reproduce as the Biochar. In term of the size of the components, the cubes with the 1 cm^3 in size and weight of 0.6 g/cm^3, need less energy to convert to Biochar and carbon and give high quality Biochar production as a final product.

Kewords: *Pyrolysis, Biochar, Activated Carbon, Solid Woody Waste*

Introduction

The use of alternative -energy from biomass has increased recently and this is due to the sharp decline in oil reserves and rising demand of energy in the world,which has gotten theattention of politicians from different countries considering the cost of energy production (Demirbas, 2001; Yang et al., 2010).Biomass:materials and products are often used as fuel such as trees, fast-growing grass, agricultural residues,waste materials such as straw, sugarcane fiber, rice husk, forestry and forest residues,waste of wood construction and industry (Crocker et al., 2006; Medlock et al., 2001).It also contains a small amount of nitrogen, sulfur and ash compared to conventional fossil fuels,which if burned, greenhouse gases including NO_x, SO_2,and soot is less emitted compared to current fossil fuels (Zhang et al., 2006; Borjesso et al., 1996).

Synthetic gas which is the product of biomass pyrolysis can be used in combination with other elements to generate heat and power in the industry. Part of the emitted synthetic gases are H_2, CO and CO_2, that when converted to synthetic fuel, can be beneficial to the environment or can be selectively used to convert hydrocarbon with high molecular weight to catalyst.

In order to convert the fast-growing grass to produce bio- oil in the process of pyrolysis, a great deal of research on the pyrolysis reactor design, pyrolysis conditions, product characteristics, and final quality improvement was done. However, very little attention has been paid for the detailed study of pyrolysis process and the results of the pyrolysis products at different temperatures. In future studies, the chemical composition and physical behavior of bio - oil can be determined better by specifying the pyrolysis process and its products.

Damirbas, 2004 has studied biochar production from agricultural residues such as the corncob, olive husk, and teawaste. In this research,the temperature range of 670 °C to 1070 °C and particle size of 0.5 to 2.2 mm have been considered in order to produce biochar.

The process of biochar production as a whole is divided into three stages (Damirbas 2004):

1 Biomass →Water + Unreacted Residues
2 Unreacted Residues → $(Volatiles + Gases)_1 + (Char)_1$
3 $(Char)_1$→ $(Volatiles + Gases)_2 + (Char)_2$

In the first stage, only some moisture and volatiles are gone; in the second stage, the initial biochar is achieved; and in the third stage which is done at high speed, pure carbon formation and chemical changes occur and carbon is left in Biochar. According to the chemical equations below, maximum thermo chemical reaction has taken place in the pyrolysis process:

4 $C + 2H_2 \leftrightarrows CH_4$
5 $C + O_2 \rightarrow CO_2$ and $C + CO_2 \leftrightarrows 2CO$
6 $C + CO_2 + H_2O \leftrightarrows CO + H_2$

In the chemical formula 6, the emitted gas from the process can be used as gaseous fuel.
The output Biocharfrom the process can be calculated in accordance with the following formula (Nunes et al., 1996):

$$Biochar\ yield = \frac{\left(\frac{A_b}{A_c}\right) - \left(\frac{A_b}{100}\right)}{1 - \left(\frac{A_b}{100}\right)} \quad 7$$

Where b is the weight percentage of dry biomass and c is the percentage weight of dry Biochar. The study of agricultural residues such as rice straw, straw and corncob in the temperature range of 300 to 700 °C was conducted by Chen et al. 2008 including the investigation and drawing of diagrams showing the amount of lost material by wood waste. With an increase in temperature, the amount of lost material increases and the amount of Biochar which is left decreases.
Samples temperature has been increased from the room temperature up to 800 °C with the temperature rate of 20 °C /min with the flow rate of nitrogen and a mixture of nitrogen and oxygen by 6%, 14 % and 21% of oxygen. Lost materials in pyrolysis process have been studied and analyzed using TG and DTG curves (Chen et al., 2008).

Material and methods

In this experiment, a pyrolysis reactor (single batch, fixed bed) and thermal conductivity measuring device of wood were used. Samples from plantain cut in the spring of 2014 were used. Samples were prepared in four different sizes of 0.01 mm^3- chips - 50 mm^3, 20 * 5 * 0/5 mm -cubes with a volume of 1 cm^3 and one 1 in^3 - 15 /625 cm^3 which have been shown in Figure 1 to 4, respectively. A piece with the format of 10*2.5*1 cm was prepared from the same tree, measuring thermal conductive of samples. Humidity changes this quantity.
Standard ASTM E871 was used to calculate the moisture content of wood and for this purpose the wood was put in the oven at a temperature of 103 °C for 16 hours and the humidity was measured and calculated according to this standard. Firstly, all the initial weight values were measured using an accurate digital scale with three decimal digits, Shinko, Japan, and secondly, moisture content was measured and the weight was recorded accurately in accordance with standard ASTM E871. Samples were located in the reactor subsequently.
Heat rate was applied at 40 °C/min.the sample was placed in crucibles inside of the reactor. Thermocouples were embedded in the crucibles and the resistance timewas calculatedby forth sensor after reaching the desired temperature. A relative vacuum was provided by a vacuum pump to maintain the oxygen level of the process medium. After leaving samples in a

vacuumed glassy environment, they werechilled at room temperature and then weighed with the digital scale.

Results and discussion

The results in Table1 show the percentage of biochar production at different temperatures with 5-minute residence time, in the specific dimensions.

Table1. Effect of temperature and Biochar size on the production yield (%) at the resistance time of 5 minutes

(C°) Temperature	400	500	600	700
0.01 mm^3	44.2344	37.5325	22.4338	21.4225
50 mm^3	39.8262	27.5821	23.7686	23.7081
1 cm^3	32.8392	28.5213	23.8267	27.3194
15.625 cm^3	29.3371	24.3799	22.4069	21.6264

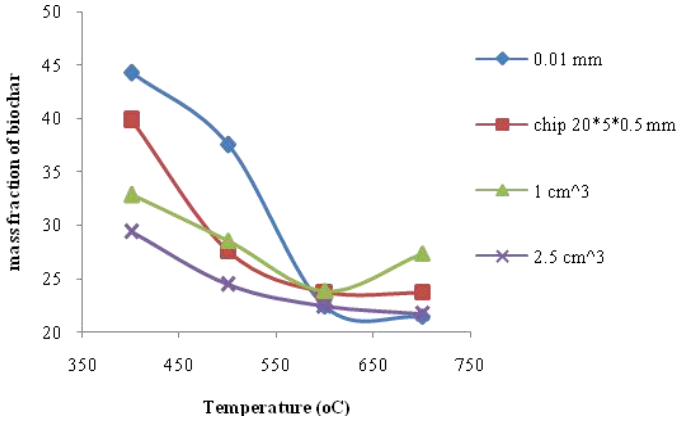

Figure 1. Variation of mass fraction of biochar with temperature and size (within a fixed time of 5 minutes)

Figure 1 shows the percentage of biochar production to temperature within a fixed time of 5 minutes, at temperatures of 400, 500, 600 and 700 °C. The residence time of the product in the reactor is calculated when the internal temperature of the reactor reaches the desired temperature. This chart has been prepared for four different sizes of the wood from plantain tree, which includes cartridge with the average size of 0.01 mm^3, Chip with the average size of 50 mm^3, and two other samples with similar cubes, including the weight of 700 mg per cm^2 which is equal to a cube with sides of 1 cm and a cube with sides of 2.5 cm.

According to the Figure 1, it can be concluded that with increasing temperature over a period of specified time at high temperature, the rate of biochar production decreases.The decline of biochar production could be attributed to a rise in temperature and along with it, an increase in gas production.Since the amount of generated heat increases, there is not enough time for a certain amount of gas with carbon to return on produced biochar, to react with it.

At higher temperatures due to the proximity to the gasification step,a large amount of the product is converted to gas, hence sublimation process occurs in which the majority of carbon at high temperatures reacts with hydrogen and oxygen, which have been decomposed from water vapor, and is emitted in the form of methane and carbon dioxide.However, at low temperatures,the reaction time is larger and the energy of carbon molecules is less, thus the production of biochar increases.

The percentage of biocharproduction decreases with temperature and in its smallest size, according to the Figure1, it becomes approximately half the original sizefrom 500 to 600 °C.

With the experimental particle sizes getting larger, the percentage of biochar production decreases slightly.In the case of the cubes of 1cm^3, biochar productiondecreases when the temperature increases from 400 to 600 °C.
For cubes with 1cm length for each side, biochar production reduces with temperature in the range of400 to 600 °C. In the contrary, the biochar production increased for the 700 °C which is due to the return of a significant amount of fumes that contain carbon on biochar. For smaller considered dimension of wood pieces, biochar production decreases with temperature. The reason can be attributed to the small size of particles and their high level of exposure to heat. Consequently, the outer layers of small pieces turn into gas quickly by increasing the temperature which reduces the amount of biochar production. Damirbas 2004 stated that the purity of carbon in biochar and the amount of the emitted gases increases with temperature. Chen et al., 2008, calculated the lost material in the pyrolysis process. The results released that the amount of removed material increases with temperature.
Iman, 2012 announced that increasing in the moisture content, caused the less biochar production and more released gases. Park et al., in 2012 reported that with an increase in temperature, the amount of gas and oil increases and biocharproduction decreases.
At 600 °C and a low heat rate, the amount of lost material is more than other cases and other temperatures.

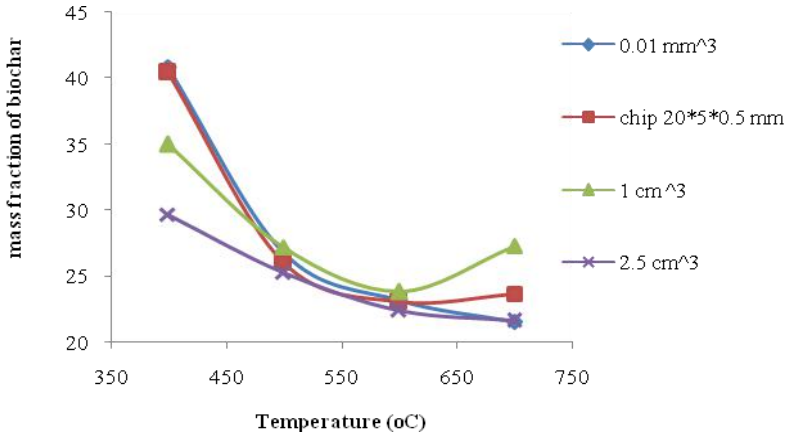

Figure 2.Variation of mass fraction of biochar with temperature and size (overthe fixed period of 10 minutes)

Figure 2shows the amount of biochar production to the temperature over the fixed period of 10 minutes at the temperatures of 400,500, 600 and 700 °C and the fact that in this case, the amount of biochar production is more than theprevious experiments (Fig. 2).Because in this case carbon has more time to react withbiochar and turn into biochar; here, with an increase in the temperature, the amount of biochar which is left will decrease as well.

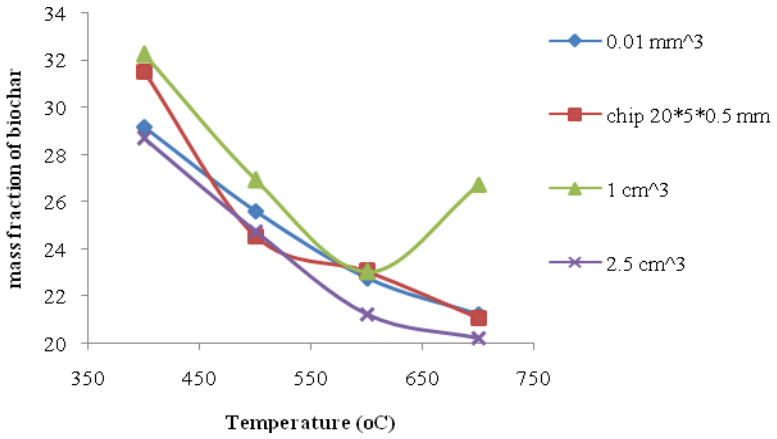

Figure 3.Variation of mass fraction of biochar with temperature and size (over the fixedperiod of 15 minutes)

Figure3 shows the percentage of biochar production in relation with the temperature over the fixed period of 15 minutes at temperatures of 400,500, 600 and 700 °C. In this case, the amount and percentageof biochar is less compared to the previous experiments.In the third experiment, since the most optimal time is given to the carbon,the carbon which is on biochar reacts with water vapor molecules in specified heatagain, and higher levels of carbon molecules are emitted from the reactor in the form of carbon dioxide and methanegas.In this instance with an increase in the temperature the amount of biochar which is left will decrease. (If is possible put one or two citation of similar results or investigation as in experiment 2 and 3)

Conclusion

Every year municipal waste from pruning trees is considered as a major source for producing energy and value-added materials in the countries with no administrative approach in this regard in Iran. In this research, the pyrolysis of wood waste and urban pruning of plantain at different temperatures and in different sizes have been studied. According to the results obtained from pyrolysis process and the comparison of the parameters with each other the best and recommendedtemperature was 500-600 °C and the optimal resistance time was in the maximum temperature of 10 minutes. At this temperature there is more opportunity for carbon to return to biochar.Moreover,in terms of the size of the pieces, cubes of 1 $cm^3$and weight of 0.6 g/cm^3 need less energy to convert tobiochar and active carbonand also they have high quality.

Abstract

Nowadays, environmental pollution is a crucial issue that humans are facing repeatedly. Population growth, urban development, industrial expansion, and irregular/excessive interventions of human in nature have all contributed to the rapid environmental degradation. Most of the important soil contaminants are heavy metals, mainly resulting from human activities like mining, industrial waste materials, vehicle emissions, herbicide and detergent application, fuel/energy manufacture, urban wastes, fertilizers, paints, etc. Mercury, arsenic, cadmium, lead and chromium are the most prevalent pollutants responsible for environmental pollution, in particular, rhizosphere zone and adversely affect the health of the ecosystem. Chemical substances, hazardous waste materials, domestic waste and sewage directly and/or indirectly impact soil texture and structure in a way that at later stages mitigate the decomposition activity of soil microorganisms and eventually make the soil infertile. Recently, several studies have been conducted across the globe over possible remediation approaches to successfully reduce the soil contaminations (SC). This review strives to reemphasize the SC issue, its effect on ecosystem health, efficient methods leading to removal of the heavy metals of contaminated soils, and rehabilitation and retrieval of soil resources in such a way that the soil can be used for healthily agricultural purposes.

Keywords: *Soil resources, environment, heavy metals, pollutants, agriculture*

Introduction

The soil is considered as one of the natural purifiers; and in addition to supplying nutrients to living organisms, it has purifying properties. This feature is mainly achieved by physical (water permeability within pores), chemical (absorption and evaporation) and biological (decomposition and decay of organic matter) attributes (Feizy, 2010). 95% of human food is achieved by earth (Khaksarian, 2010). Therefore, planning for possessing a producing and healthy soil is essential for human survival. Entering materials, biological organisms or energy into the soil trigger its quality alteration and deform its natural status (Rahmani, 2003). Unfortunately, soil now gets polluted due to anthropogenic activities. Traditionally, soil, air and water have been traditionally utilized as hosts for disposal of wastes. The nature of these waste products can be divided into four major categories: agricultural, municipal, industrial and nuclear waste materials (Razavi Tosi, 2005). Some of them are presented in the Figure 1.

Air pollution caused by automobile fumes can also trigger soil contamination and have a negative effect on local air quality. Pouring such toxic materials as solvents and detergents can also extend soil contamination (Kordavani, 2010). As one of the important components of the environment, soil is the most significant recipient of industrial and agricultural wastes. Upon entering the soil, these materials become part of a cycle that will impact soil biological, geological and chemical processes in a number of ways. Thus, information on the nature of these pollutants as factors contributing to ecosystem disorder and their chemical behavior

within the soil is mandatory for imposing scientific management for cleansing and efficiently neutralizing them.

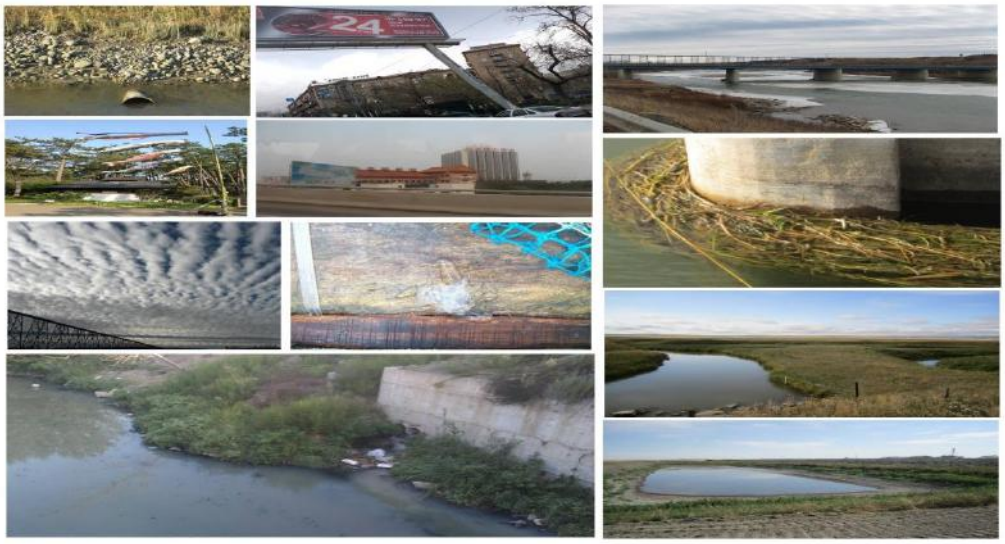

Fig.1. The composite image show polluted water discharge in Canada; city based air pollution in Armenia; wilderness area in Japan, garbage center in Canada; industrial pollution and water borne sewage and debris in the US, air pollution in Canada, polluted channel and disposal of waste water into a local river (Zarjoub River) Rasht, Iran; and polluted industrial waste water storage in North America and India (Photo courtesy: Saikat Kumar Basu & Peiman Zandi).

Heavy metals are natural constituents of the earth's crust. At a lower concentration they appear to be less harmful and can even act as trace elements useful for living organisms. However, these metals are very toxic once they appear in their stable oxidation states. They react with the bio-molecules of the living beings to constitute stable biotoxic compounds (Duruibe et al., 2007). In comparison to plastic and petroleum (organic contaminants), they linger more persistently in the nature. Depending upon the soil pH and speciation they can be mobile and either transfer to an aquifer or become available to living organisms easily. Their toxic properties may result in drinking water contamination, contaminated food chain and facilitate higher concentrations of air pollutants near the emission sites (Hashim et al., 2011).
Overall, the remediation process in contaminated soil and groundwater can be conducted through the following: wholly destruction of pollutants, extraction of contaminants out of disposal wastewaters, keeping the pollutants in the forms of stabilizing (non mobile) and less toxic, elicitation of non-contaminated materials and their relevant recycling of contaminated substances, and to avoid further expansion of polluted materials to other environments (Hashim et al., 2011).

Industrial pollutants and heavy metal accumulation in soil

The elements present in sewages are known as special elements and the main reason of such nomination refers to the reality that they are rarely found in common soils except in agricultural soils that are irrigated by municipal waste waters (Mirsal, 2013). These elements, in brief, are: arsenic, cadmium, cobalt, chromium, copper, mercury, molybdenum, nickel, selenium, vanadium, zinc, iron, aluminum and lead (Hopenhayn-Rich et al., 1996). These heavy metals are very important, even at low levels of concentration because of being unable to be decomposed and also their physiological adverse effects. Some of these adverse effects comprise disruption in soil biological activities, toxic effects on plants and adverse effects on human health because of the influx of substances in the food chain (Davies, 1995).

Arsenic (As): This element is a devastating environmental pollutant, is mostly employed in dyeing, tanning, and textile industries; and can be found easily in the laundry powders and detergents. With reference to having terrific toxicity, it is now widely applied in the production of fungicides, insecticides and pest expulsion poisons. Similar to phosphorus conduction in the soil, it is also hardly mobilized and/or removed from topsoil area. The permissible limit for 'Ar' in the edible products has defined 2.6. The municipal sewage seems to be the main trajectory agent responsible for soil contamination (Watt et al.,1993).
Arsenic (Sodium Arsenite) is a white metalloid solid element widely distributed in the nature and present at an average concentration of 2 mg/kg. To form organic and inorganic compounds, arsenic can combine with other elements. Compared to organic arsenic compounds, inorganic arsenic compounds are thought to be even more toxic and detrimental for health. The researchers have found that arsenite is more toxic than arsenate (Ahmed et al., 2008; Hashim et al., 2011). Arsenic occurs in crystalline, powder, amorphous or vitreous forms in all rock, soil, water and air. Industrial processes such as smelting, mining, and coal-fired power plants, agricultural pesticides (22% of the world production of arsenic) and chemicals for timber preservation (70% of the world production of arsenic), all contribute to the presence of arsenic in air, water and soil (Bodek et al., 1988). Arsenic results in the inhibition of growth, photosynthesis and reproduction in plants and even lethality depending on the species and time of exposure. Arsenic is also associated with skin damage, kerratosis and skin cancers and problems of the circulatory system (Scragg, 2006).
Cadmium (Cd): Cadmium is a heavy metal that is one of the greatest concerns in the environment, because of its toxicity to animals and humans. Plants can easily uptake cadmium and transfer it to other organs (Campbell, 2006). Cadmium has a chemical similarity to Zn, an essential micronutrient for plants and animals. Its substitution with Zn may cause the spoiling of metabolic processes in plants (Campbell, 2006). Effects on birds and mammals are mainly due to kidney damage (Weggler et al., 2004). Once it is in the environment, it can remain present for a long time. It can be transported from one location to another, in particle forms that are either blown by the wind or washed away by water. The most important symptoms of cadmium toxic effects on plants are stunning and chlorosis (McLaughlin et al., 2000). It is well consumed in the paint and plastic manufacturing industries. Non contaminated soils usually contain less than 1 ppm Cd, but in the soils around the factories the mentioned amount has reported to be near 1700 ppm (Jackson and Alloway,1992; Watt et al.,1993).
Cobalt (Co): Cobalt is a hard, brittle metal that occurs naturally in the environment and is a common by-product of nickel and copper mining activities (OMEE, 1993). Burning coal or oil and use of cobalt containing chemicals can enter this metal to the environment. It can be accumulated in plants (very small amounts of cobalt) when they are grown in the contaminated soil. Cobalt cannot be destroyed once it has entered the environment; however, it may change forms by combining with other chemicals (Chaney, 1982). Cobalt is used greatly in the production process of different alloys, colors, glazes, coatings and writing inks, usually it does not exceed 10 ppm in the soil. Studies show that Co often adsorbed on clay colloids, and only has transaction with other heavy metals like Cu and Zn. It generally has low concentration in the soil and sewage as well as factories waste waters (Razavi Tosi, 2005; Kordavani, 2010). The element has not yet caused or reported to have any adverse complications in the available literature.
Lead (Pb):The amount of lead concentrated in the environment is basically originated from natural and human (anthropogenic) activities. Despite having recession status in the market, its secondary production is increasing due to its non-ferrous, recycled nature. It is also used as an additive factor to improve gasoline performance. Some of the plant anti-pest toxins are slightly composed of the element (Kordavani, 2010). Unfortunately, the so-called heavy metal first pollutes the air, and then transfers into the soil with the aid of rain. The allowance level

determined for ‘Pb’ consumption in human solid feeds should not overlap 600 µg per day due to its nature of bioaccumulation. According to the daily reported records, humans take in 10 to 100 µg Pb through inhalation, whilst the range goes upper than 300 µg a day via nutrition pathway (Jackson and Alloway,1992; Alloway,1995a).

Aluminum(Al): Aluminum toxicity is one of the greatest limitations to agricultural production in acid soils. It is estimated that approximately 50% of the cultivable soils in the world possess high acidity, principally in the tropical regions (Venturini-Soriano and Berthon, 2001). Despite advances in the management of Cerrado soils, the correction of soil acidity to neutralize the toxic Aluminium in layers 20 cm below the surface is costly and difficult to operationalize. Thus, even in well-managed soils, subsurface layers might have a high acidity and high degree of saturation with toxic forms of Al, limiting root development in a cultivar sensitive to this element (Sánchez and Salinas,1981). Aluminium causes rapid inhibition of root growth (Kochian et al. 2004). Aluminium sensitive cultivars have poorly developed root system and are unable to explore the deeper layers of the soil, limiting water and nutrient uptake. As a result, cultivars sensitive to Aluminium toxicity are also susceptible to water stress (Taylor,1988).

Copper(Cu): Copper is a transition metal which is the third most used metals in the world (VCI, 2011). It is essential for the growth of both plants and animals. In plants, Cu is especially important in seed production, disease resistance, and regulation of water. In the soil, Cu strongly complexes to the organic and will be found in solution as ionic copper, Cu (II). At pH 5.5, the solubility of Cu is dramatically increased (VCI, 2011). Copper is essential for the plants and animals, but in high doses it can cause adverse effects on the plants and humans. Directly, it has negative effects on crop growth and yield, and indirectly, it slightly enters into the human food chain or bio-accumulates with a potentially negative impact on human health (Martínez and Motto, 2000). Fortunately, despite its complex interaction with the environment most copper introduced into the ecosystem rapidly converts to an innocuous and stable form.

Mercury(Hg): Mercury is one of the most hazardous environment pollutant metals (harmful to human and aquatic creatures) partially enters the soil or surface water by direct disposal of electric lamps, explosives, and wastewaters made by factories and application of fertilizers (Alloway,1995a). Mercury is greatly released into the air by human activities like mining, smelting, fossil fuel and solid waste combustion. Naturally, it enters the soil through normal degradation of soil, rocks and minerals through weathering. The toxic form of ‘Hg’ in the marine environment is known as Monoethylmercury which is usually travel via marine food chains and later on underlies serious damage to humans.

Nickel(Ni): Nickel is a transition element that occurs in the environment only at very low levels, and does not accumulate in the living organisms. It's essential in small doses, but once the maximum bearable amounts are exceeded, it can be dangerous. The animals that live near refineries have various kinds of cancer due to the nickel toxicity. The major sources of nickel contamination in the soil are fossil fuels and nickel mining (Khodadoust et al., 2004). In acidic soils, Ni becomes more mobile and often leaches down to the adjacent groundwater and as a part of wastewater streams can also end up in surface water. Microorganisms can also suffer from nickel accumulation. Plants or animals don't accumulate nickel, so it can enter into the food chain (Pourbaix, 1974).

Zinc(Zn): Zinc is another transition metal which occurs naturally in soil, water and air, but its concentrations are rising unnaturally, due to the man-made additions. Industrial activities such as waste combustion, steel processing and mining add most of Zn to the soil. The acidity of waters can be increased by zinc (Davies and Jones,1988). The groundwater can be contaminated by water-soluble zinc that is located in soils. Plants often can uptake Zn, but they can't handle additional zinc due to the accumulation of Zn in soils. Finally, Zn can

interrupt the activity of microorganisms and earthworms in the soil, thus retarding the breakdown of organic matter and disrupt plant activities (Greany, 2005).

Chromium(Cr): Chromium has an antifouling feature and is widely employed in materials like metal pigments in cements, paints, rubber, etc. To avoid the leakage of metals into the marine ecosystems it has been accepted worldwide to decrease the level of antifouling treatments. The most common ways of releasing chromium into the environment are outflowing of water or gas from dumping ground (landfill), chemical plant, trash incinerators, or even occasionally from contaminates rocks or top soils (Greany, 2005).

Vanadium(V): Vanadium is frequently found in crude oils, and is known as a toxic element in the environment. Some of living organisms lodging near the contaminated environments are suffering due to induction of some inhibitory effects in enzymatic activities, breathing disorders, liver and kidney malfunctioning, DNA alteration, and male sterility. Vanadium can be accessed through some environmental species such as plants, vertebrates, algae, and aquatic organisms (Greany, 2005).

Manganese(Mg): Manganese can be reached everywhere in the globe. Higher concentrations of manganese is toxic to animals. Manganese may comprise almost dust particles in the air, small particle in the water as well as solid materials in the soil. Manganese pollutions in the air mainly occur from human industrial activities and fossil fuel combustion (Greany, 2005). Manganese released from human sources can transfer into ground water, surface water and sewage water. Pesticides containing Mg can also enter soils. In plants, Mg has a double-sided symptom, deficiency and toxicity.

Agricultural contaminants

These include application of chemical toxins and manures, utilization of polluted waters and sewages for agricultural purposes and lack of proper management in irrigation. Chemical fertilizers alter soil features, i.e. alleviates soil permeability for water and soil and tighten the soil (Jackson and Alloway,1992). Chemical manures like phosphate fertilizer contain small amounts of cadmium and lead which some of these toxic substances can be absorbed by the plants and eventually enters the human body and causes disease in the long run in case of improper application of these substances. Animal fertilizers that are extensively produced every year, can possibly enter nearby rivers and pollute the river and surrounding soils. In some types of watering patterns, a pond provides for accumulation of water, which leads to: a) leaching of nutrients from the soil and their further carriage into the deep soil where plants cannot access them anymore. Hence, they cause the need for fertilizer again and b) too much evaporation of water causes solutes to deposit on the soil surfaces, making it stiff.

Chemical toxins make the soil polluted too. A number of pests, particularly insects get resistance against pesticide. For this reason, we have to either increase the frequency of spraying or augment the concentration of corresponding toxins. These toxins do not degrade in a simple manner and remain in the soil for many years (Alloway, 1995b; Davies,1995). They might be sublimated without chemical change, absorbed by the surface particles of soil, leave the soil through runoff or leaching or undergo chemical, non-chemical and photodecomposition reactions (Hopenhayn-Rich et al.,1996). In order to rehabilitate and restore the contaminated soil, the following actions might be suggested (Peereboom-Stegeman ,1987; Culbard et al.,1988) : utilization of water to remove pollutants from soils, employment of aerial and chemical solvents, elimination of contaminants by direct burning (Davies,1995), contribution of natural organisms to dissociate the pollutants atoms from soil, addition of material to the soil for preservation and maintenance and prevention of dissemination of pollution to other areas (Alloway, 1995b).

Conclusion

The groundwater contamination either from the natural soil or even from anthropogenic sources is a global concern over public health. Fighting against soil contamination in developing countries is easier than in industrial and developed countries with respect to agriculture, because developing countries are in earlier stages than industrial ones; and chemical manures and phytoxines in developing countries are not consumed as much as in developed ones. Therefore, in these countries, authorities should consider all aspects before taking any effective actions over increasing the level of agricultural and industrial productions of expanding cities. Based on complete understanding of environmental conditions and polluting factors, they should select a way which is proportional to environmental and social conditions of that specific area so that pollution is prevented as much as possible. To do so, the level of farmers' knowledge pertaining to the problems and their aftermath should be enhanced beforehand. To prevent soil pollution, countervailing measures should be in order to improve and reconstruct the contaminated soils, in addition to employing animal manures, as far as possible, rather than chemical fertilizers so that the crops can be consumed without any serious problem. Furthermore, by utilizing chemicals in a more modulated manner, it is possible to not only raise the crop productivity, but also ameliorate the amount of heavy metals in the soil area. As a living and feeding ground for many organisms, and also the determinant basis of ecosystem, soil plays an effective role in all levels of the food chains and food webs in the ecosystem and the environment. Thus, we should preserve this precious asset by proper management and careful surveillance through proper land-use activities.

Abstract

The Asiatic lions (*Panthera leo persica* Meyer, 1826) and the Asiatic cheetahs (*Acinonyx jubatus venaticus* Griffith, 1821) are two critically endangered species of big cats endemic to the Asian continent and currently restricted to distribution in isolated habitats in India and Iran, respectively. Both species had wide distribution in the past, stretching from the Arabian peninsula through Iran and Afghanistan to the vast Indian subcontinent. Unfortunately due to heavy anthropogenic pressure and lack of conservation efforts both species have been wiped out from most parts of their previous range of distribution. Both species have made a come back in these two countries and probably we could now look for a program in slowly repopulating the older habitats of these two species starting with the two current host countries of Iran and India. A Joint Conservation Initiative (JCI) between Iran and India with formal conservation agreements could help procuring the species beyond their current habitats for starting a captive breeding program for Asiatic lions in Iran and Asiatic cheetahs in India. If these programs are successful, it could easily help in releasing the species to selected appropriate habitats in these two countries. A long term success could help in the future repopulation of the Asian habitat that used to be co-inhabited by both these majestic species in the past.

Keywords: *India, Iran, Asiatic cheetah. Asiatic lion, conservation*

Introduction

The recent reports of deaths of over ten critically endangered Asiatic lions (*Panthera leo persica* Meyer, 1826) as a consequence of flash floods in the western Indian state of Gujarat have been an alarming incident involving the loss of precious and vulnerable global wildlife. Although, once in a while incidents of deaths of Asiatic lions are reported; but this is possibly the first time after the conservation of the species was initiated in western India that such a large number of deaths of the majestic Asiatic lions were reported due to a natural disaster. Unconfirmed local reports place the death tolls even higher and tentatively somewhere between 15-19. The sad deaths of the lions are once again a reminder as have been suggested against by several researchers, naturalists, wildlife experts and conservationists in restricting the critically endangered Asiatic lions in one premier natural habitat, called Gir Sanctuary in the western Indian desert state of Gujarat that borders with Pakistan (Chellam and Johnsingh, 1993; Johnsingh et al., 2007; Singh and Gibson, 2011) The local population of Asiatic lions has been estimated to cross the carrying capacity of the Gir Sanctuary and are often reported to be overcrowded and densely populated with shrinking prey bases (Johnsingh et al., 2007; Johnsingh et al., 2007; Singh and Gibson, 2011). The current population if Asiatic lions in India are estimated ~400+ (Johnsingh et al., 2007; Singh and Gibson, 2011). The lion populations are in dire need of relocation to additional habitats within India to reduce the pressure on the Gir Sanctuary.

Challenges of conservation

The stock population of the Gir Sanctuary thus needs to be sub divided into smaller sub populations and distributed under the supervision of the Federal and State Environment and Forest departments, respectively; for successful, long term and sustainable maintenance of healthy lion populations well separated from each group for genetic and ecological purposes. Else the highly vulnerable lion population; although currently showing improvement in terms of numbers, runs the grave risk of undergoing genetic bottlenecks due to higher chances of inbreeding among close family members (Singh et al., 2002; Mukherjee and Borad, 2004). Furthermore, there are also looming dangers of similar natural calamities and catastrophes as mentioned above, issues of unaccounted contagious diseases, reduced prey bases and increased competition for premier hunting grounds and sufficient breeding spaces among different clans inhabiting the Gir Sanctuary; that may also negatively impact the population of Asiatic lion in the near future (Mukherjee et al., 1994; Saberwal et al. 1994). The challenges of anthropogenic pressures in and around the Gir Sanctuary perimeter is also a big issue for the expanding lion population in the region; so that there will be chances of habitat fragmentation as well as human-animal conflicts in the future (Johnsingh et al., 2007; Singh and Gibson, 2011). Unless proactive wildlife management steps are adopted at the earliest to reduce the pressure on the current habitat, the majestic Asiatic lions may be gone before even we realize how vulnerable this critically endangered species is currently (Shankaranarayanan et al., 1997; Singh et al., 2002; Johnsingh et al., 2007).

Iran is an important nation in this regard undergoing similar challenges with Asiatic cheetah (*Acinonyx jubatus venaticus* Griffith, 1821) conservation (Marker and Amy, 2004); the last refuge for the majestic species (Olmsted et al., 1992; Hunter et al., 2007; Charruau et al., 2011) like the Asiatic lion with an isolated habitat in India. The Iranian population of Asiatic cheetahs is falling beyond somewhere around only 100-200 individuals left in the wild (Olmsted et al., 1992; Hunter et al., 2007; Charruau et al., 2011). Most of the Iranian cheetahs are now restricted predominantly in the eastern dry desert region of Iran in different national parks of the provinces like Kerman, Khorasan, Semnan, Tehran, Markazi and Yazd (Karami, 1992; Olmsted et al., 1992; Farhadinia, 2004; Hunter et al., 2007; Farhadinia and Mahmoud-Reza, 2010). Other cheetah sub populations are dispersed sporadically in Iran and are not well recorded (Marker and Amy, 2004). No sightings from adjoining Afghanistan and India have been reported over half a century now (Hunter et al., 2007; Manati and Nogge, 2008). Some unconfirmed reports of Asiatic cheetah observed in the extreme western edges of Baluchistan in Pakistan are available; however, due to extreme poor track record of the country in wildlife and forest conservation, such reports are not given any scientific value (Berwick, 1976; Marker and Amy, 2004; Charruau et al., 2011; Meena et al., 2011).

The path ahead-Joint Conservation Initiative

Historically both species had wide distribution in the past, stretching from the Arabian peninsula through Iran and Afghanistan to the vast Indian subcontinent. Unfortunately, as discussed above due to heavy anthropogenic pressure mostly in the form of unregulated, unrestricted and unmonitored hunting as well as over exploitation for trophy collection; high demands for skins and other body parts; huge drive for personal collections and the zoos around the world and poaching wiped out the species from major parts of their distribution range (Johnsingh et al., 2007; Charruau et al., 2011). Hence, it will be wonderful to expand their habitats beyond their current limited range of distribution and slowly release them to their old habitats where they had once got extinct in the past due to anthropogenic pressure. India and Iran being two biodiverse countries with distinct credentials in successful forest and wildlife conservation; and particularly for their great success in dealing with critically

endangered species need to share their experiences and expertise to help one another to further capacitate their conservation efforts; and empower themselves in the realms of global wildlife conservation. It will be of interest to both nations to initiate a well designed and comprehensive Joint Conservation Initiative (JCI) for captive breeding and release of such critically endangered species to the wild in both India and Iran.

It will be good to bring in some Asiatic lions to Iran for jump starting captive breeding programs in Iran for later releasing them to their native and suitable wild conditions under careful observation and scientific monitoring. Similarly, Asiatic cheetahs could be introduced into India from Iran thereby attempting to introduce the lost species back to the Indian subcontinent. Although the African lions and cheetahs are much plentiful in number (Ott-Josh et al., 1987; Saleh et al., 2001; Charruau et al., 2011); but since they are widely geographically separated from their Asiatic cousins by several millions years back in the history of evolution; the best available option is to experiment carefully and with sincerity with the Asiatic species only in the Asian continent.

Conclusion

If such joint initiatives (or JCI) are made successful by both Iran and India these could serve as global model of international cooperation in wildlife conservation; and both these proud nations could become pioneers in such initiative (JCI) for the whole planet. If these programs are successful, it could easily help in releasing the species to selected appropriate habitats in these two countries. A long term success could help in the future repopulation of the Asian habitat that used to be co-inhabited by both these majestic species (Asiatic lions and Asiatic cheetahs) in the past. Anthropogenic pressures in the past has removed both these species from their original range across Asia; and hence it will be the responsibility of humans again to join forces and efforts together to support an initiative of slowly returning these top predatory species back into their wild Asiatic habitats. Joint Conservation Initiative could serve as a successful bridging platform in the process of reintroduction of Asiatic lions and cheetahs to their broader habitats.

Abstract

Spatial pattern and interdependence of different soil and plant parameters were examined in green bean field experiment carried out at the Mediterranean Agronomic Institute of Bari (MAIB), Italy. The study aimed to identify the spatial distribution of soil and plant parameters and their relationship at transects scale. The experiment consisted of three transects of 30m length and 4.2m width, irrigated with three different salinity levels (1dSm^{-1}, 3dSm^{-1}, 6dSm^{-1}). Soil measurements (electrical conductivity and soil water content) were monitored along each transect in 24 sites,1 meter apart by using TDR probe installed vertically at soil surface. Water storage was measured by using Diviner sensor for calculating directly the evapotranspiration fluxes along the whole soil profile under the different salinity levels imposed during the experiment. In the same 24 sites, crop monitoring involved measurements of Leaf Area Index (LAI), Osmotic Potential (OP), Root length Density (RlD) and Evapotranspiration fluxes (ET). Soil and plant properties were analyzed using both classical and geostatistical methods which included descriptive statistics, semivariograms and cross-semivariograms. Results indicated that moderate to large spatial variability existed across the field for soil and plant parameters, especially under the 6dSm^{-1} salinity treatment. A relatively satisfactory fit of the experimental cross-semivariogram was obtained for the 6dS^{-1}, thus indicating similar spatial structures of the pairs of compared variables. By contrast, the experimental cross-semivariograms observed under the 3dS^{-1} treatment indicated no significant correlation structure between the compared variables. Overall, the results observed in the 3dSm^{-1} were not significantly different from those obtained in the 1dSm^{-1} transect and suggested a general insensitivity of the crop response to those levels of salinity.

Keywords: *Soil and crop properties, Spatial variability, Semivariogram, Cross-Semivariogram*

Introduction

Salinity is a major problem in agriculture sector in arid and semiarid regions. The accumulation of salts over time in the root zone limits the water uptake of plants by reducing the osmotic potential and thus the total soil water potential (Shannon *et al.*, 1994; Sheldon *et al.*, 2004;Corwin and Lesch, 2005). Salinity is rarely uniform with depth and usually varies with time at field scale. The soil physical and chemical factors such as soil texture, water content and salinity distribution in the soil profile are the most dominant influences on yield and growth variability (Dixit and Deli, 2010).

Salinity has been extensively reported to have negative impacts on the majority of arable crops and classified them as sensitive, moderately sensitive and high sensitive crops (Sheldon *et al.*, 2004). Many laboratory and field experiments have been conducted to evaluate crop salt tolerance under uniform salinity along the soil profile. Comprehensive reviews of such studies are well documented by (Maas and Hoffman, 1977; Maas, 1993). However, salinity is rarely uniform in space on both the vertical and the horizontal direction. The spatial variability of soil salinity with water content have shown dominant effects on crop yield

variability (Dixit and Deli, 2010; Coppola *et al.*, 2014). However, the effects of soil salinity on the physiological crop parameters and their spatial variation across field still require depth analysis. Spatial variation of various soil and plant properties may be was studied by using classical statistics and geostatistics intensively. Geostatistics may provide useful information for assessing spatial variability of soil properties and has increasingly been used by soil scientists and researchers in recent years (Jabro *et al.*, 2006; Jabro *et al.*, 2010). Semivariograms and cross-semivariograms have been used to characterize and model spatial variance of data to assess how data points are related with separation distances. There are many studies in the literature on the use of geostatistic analysis to describe the spatial variability of single soil properties (López-Granados *et al.*, 2002; Jabro *et al.*, 2006; Jabro *et al.*, 2010; Yang *et al.*, 2011; Fathi *et al.*, 2014a). However, rarely these studies have reported information on the spatial variability of soil parameters (i.e., water content and electrical conductivity) and the corresponding variability on plant growth at field scale under different water salinity levels.

Therefore, the objectives of this study were to apply geostatistics approach to characterize field scale spatial variability of selected soil-plant properties and to explore the spatial interdependence between soil-plant parameters using cross-semivariogram analysis.

Materials and methods

The experiment was carried out at the research station of MAIB in 2013 south-east of Italy. The soil was pedologically classified as ColluvicRegosol, consisting of a silty loam layer of an average depth of 70 cm on a fractured calcarenite rock. The experiment consisted of three transects of 30 m length and 4.2 m width, equipped with a drip irrigation system, consisting of fourteen dripper lines at 35 cm distance and a distance among drippers along each line of 20 cm, with dripper discharge of 2 l/h. The transects were irrigated with three different salinity levels ($1dSm^{-1}$, $3dSm^{-1}$, $6dSm^{-1}$) by using calcium chloride ($CaCl_2$). Each transect consisted of seven rows of green beans crop, 70 cm apart and plants in each row 40 cm apart. The irrigation volumes were calculated according to the water storage measured by a Diviner 2000 sensor. Twenty-four access tubes, 1 m apart, were installed along the middle line of each transect at 60 cm depth to monitor soil water content using Diviner 2000 sensor. Diviner readings were taken at 10 cm depth intervals up to 60 cm just before and two hours after every irrigation applications. The difference between water storage at field capacity and the storage measured just before irrigation allowed calculating the irrigation volumes to bring the soil water content in the root zone to the field capacity. The apparent electrical conductivity was monitored during the growing season by inserting a TDR probe vertically at the soil surface in 24 sites along the middle line of each transect. Furthermore, plant measurements (e.g., Leaf area index, Transpiration rate, Root length density, Osmotic potential and yield) were carried out to evaluate the physiological state of plants, on the same 24 sites already identified for soil measurements. As crop responses to salinity depend on the electrical conductivity of soil solution (EC_w), a calibration procedure of TDR was also requested for translating ECb values measured by TDR to the corresponding ECw values. In this study, TDR probe calibration was carried out in the laboratory according to the procedure described by Mallants *et al.* (1996).Geostatistical analysis, including semivariogram, cross-semivariogram model fitting procedures, were carried out using GS^+ (Gamma Design Software, 2004, Geostatistics for the Environmental Sciences, St. Plainwell, Mich.) to evaluate the degree of spatial variability of soil and plant parameters.

Results and discussion

Table 1 shows the summary of the statistics of the measured soil and plant parameters. The coefficient of variation (CV) values of measured soil and plant properties in the three different

treatments ranged between 29.29% for electrical conductivity of soil solution (ECw) and 7.17% for soil water content (θ) in the transect treated at $1dS^{-1}$. The standard deviation (SD) of all parameters exhibited the highest values in transect treated with $6dS^{-1}$ saline water, except in the case of LAI. Moreover, the soil and plant data were all normally distributed (with a skewness between 1 and -2) and therefore no transformation was used for geostatistical analysis.

Table1. Summery statistic for selected soil and plant parameters

Soil and plant parameters	Mean	Min	Max	CV%	SD	Skewness	Kurtosis
ECw-$1dS^{-1}$	2.35	0.87	3.69	29.29	0.69	-0.41	-0.33

The semivariograms calculated for soil and plant data (EC_W, θ, ET, LAI, OP, RlD) are depicted in Figure 1.

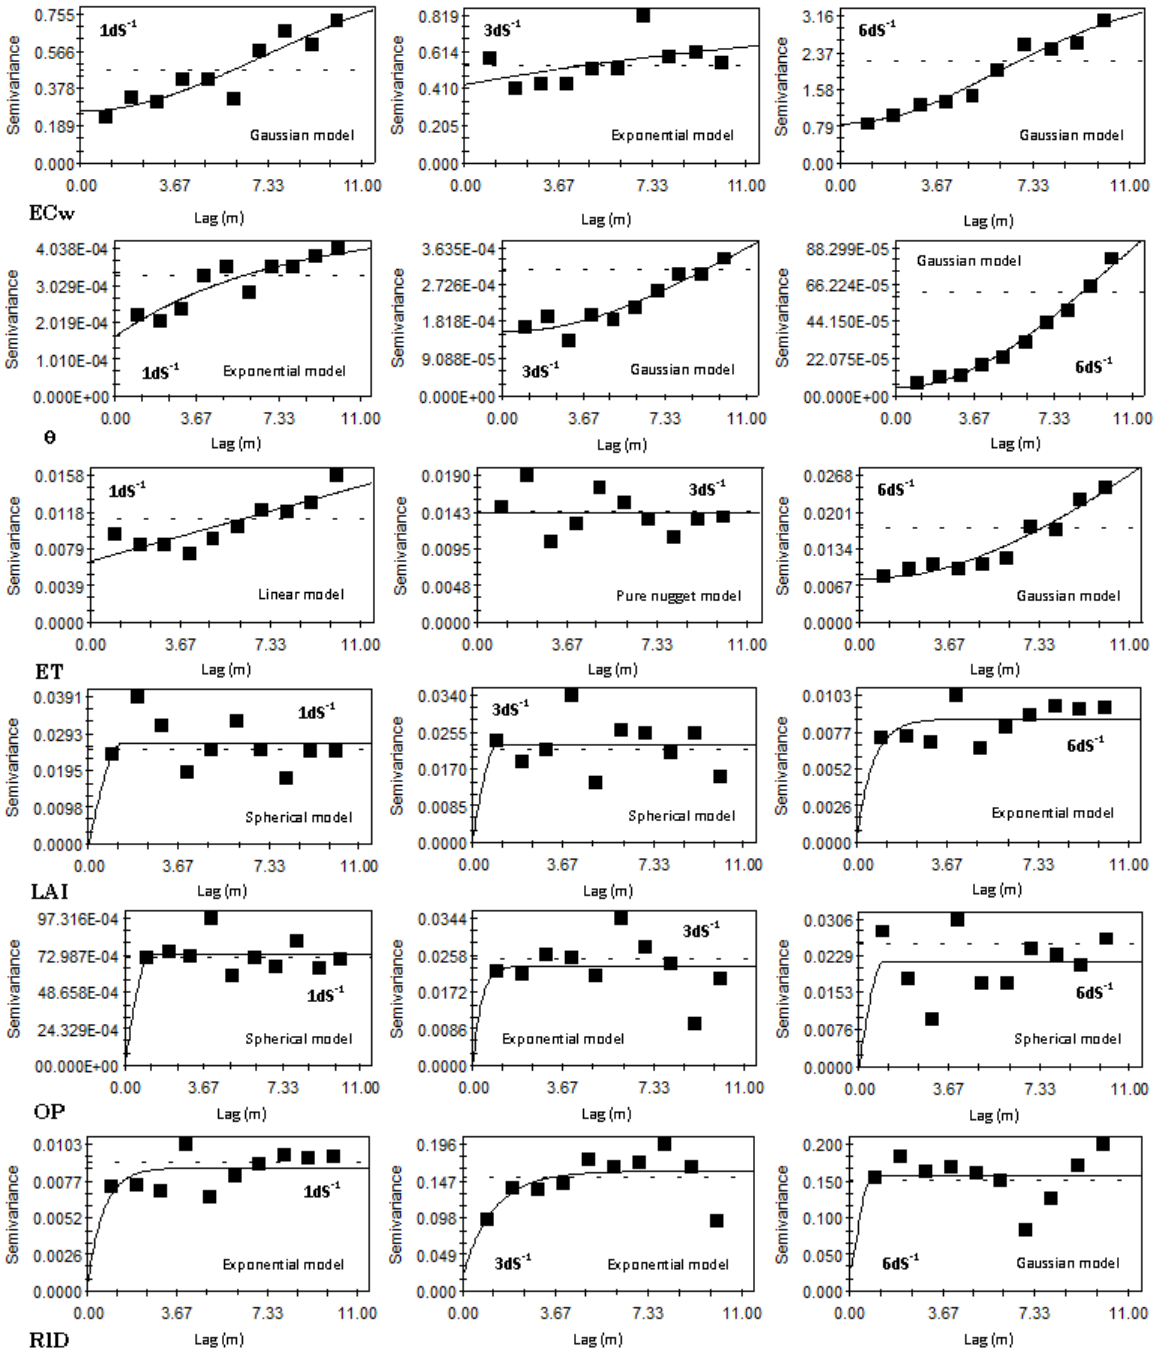

Figure1. Semivariogram models of soil and plant parameters.

Semivariogram coefficients for each soil plant parameters with the best fitted model are listed in table 2. The R^2 values in table 2 show that models fit the experimental field semivariogram data very well for soil parameters (EC_W,θ), as well as for evapotranspiration (ET) in transects treated with $1dS^{-1}$ and $6dS^{-1}$. Simultaneously, the Residual Sum of Squares (RSS) values were very small for semivariogram models of soil and plant parameters monitored in this study, except for ECw. The ratio between nugget (C0) and sill (C0+C) (the so called nugget ratio) was calculated for soil and plant properties and used to investigate the degree of spatial dependence across the experimental field. Many authors reported that if the nugget ratio is ≤

0.25, the variable should be considered to be strongly spatially dependent; if the nugget ratio lies in the range between 26 and 75% the variable has to be considered moderately spatially dependent; finally, if the nugget ratio is greater than 75%, the variable has to be considered weakly spatially dependent (Cambardella *et al.*, 1994; Mallants *et al.*, 1996; López-Granados *et al.*, 2002; Jabro *et al.*, 2010; Fathi *et al.*, 2014b). From the values of nugget ratio for the semivariograms in Figure1, it seems that that there is moderate spatial dependence of EC_w and ET at transects treated $1dS^{-1}$ and $3dS^{-1}$Also, a moderate spatial dependence was found for θ in the transect treated with $1dS^{-1}$. On the contrary, the nugget ratio for the other soil and plant parameters indicated weakly spatial dependence in all the three transects (see table 2).

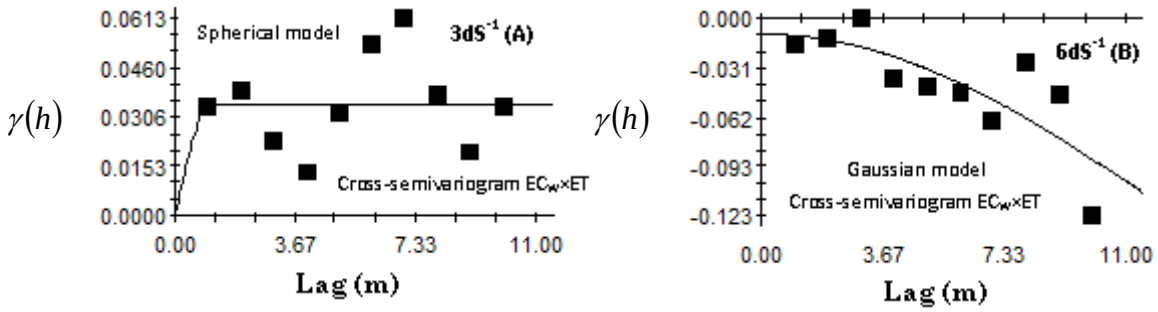
[a] RSS is the residual sums of squares for the theoretical semivariogram models.

The graphs in Figure 2 (A, B, C and D) depict the cross-semivariograms calculated for selected pairs of soil and plant parameters (ECw vs. RLD and ET) in the $3dS^{-1}$ and$6dS^{-1}$ salinity treatments. Cross-semivariograms were calculated to identify any possible effects of soil salinity and its affect on the root length density and evapotranspiration fluxes, as well as their spatial interdependence. In this study different theoretical cross-semivariogram models have been used (namely Gaussian, Exponential and Spherical). Table 3 depicts the parameters obtained for each of the model used.



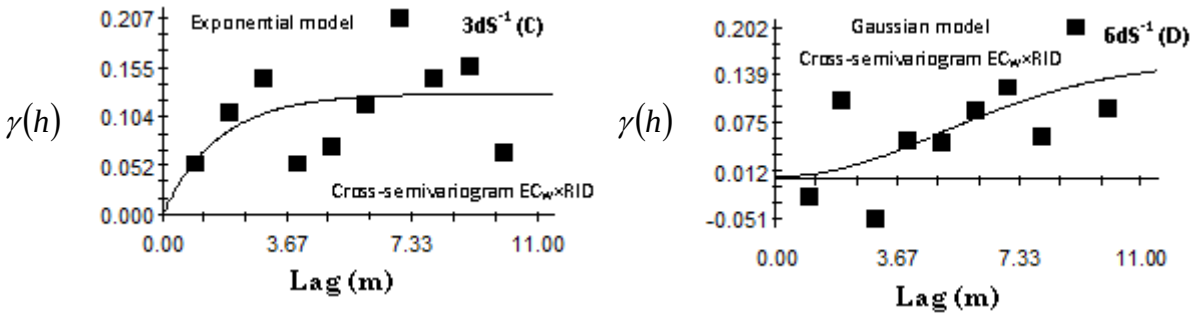


Figure2. Cross-semivariogram models of selected soil and plant parameters.

According to the R^2 values, a relatively good fit of the experimental cross-semivariogram was obtained for all the cases at $6dS^{-1}$, thus indicating similar spatial structures of the pairs of compared variables. By contrast, the corresponding values for the $3dS^{-1}$ treatment indicate an unsatisfactory fit and thus no significant correlation structure between the compared variables. Overall, the results observed in the $3dSm^{-1}$ were not significantly different from those obtained in the $1dSm^{-1}$ transect (data not shown), and suggested a general insensitivity of the crop response to those levels of salinity. As for the $6dSm^{-1}$ treatment, according to the criteria suggested by Cambardella *et al.* (1994) to evaluate cross-correlation between two variables, the cross-semivariograms of the figure 2 suggest positive spatial interdependence at all lags except the lag=1 and 3 (ECw×RlD). On the contrary, a negative spatial interdependence was observed between electrical conductivity of soil solution ECw and ET (see figure 2B). These conflict results of spatial interdependence between some soil and plant parameters might be related with the dynamic of salt and water in the soil profile.

Table3. Coefficients of the theoretical Cross-semivariogram model of soil and plant parameters

Soil and plant parameters	Model	Nugget, C_0	Sill, C_0+C	Nugget Ratio $C_0/(C_0+C)$	Range A(m)	RSS[a]	R^2
ECw×ET $3dS^{-1}$	Spherical	0.00010	0.03490	0.00286	1.12	$1.905*10^{-3}$	0.10
ECw×ET $6dS^{-1}$	Gaussian	-0.01000	-0.32700	0.03058	18.79	$4.104*10^{-3}$	0.61
ECw×RlD $3dS^{-1}$	Exponential	0.00010	0.12820	0.00078	1.66	0.0191	0.17

[a] RSS is the residual sums of squares for the theoretical semivariogram models.

Conclusion

The spatial variability and the interdependence between different soil and plant parameters were explored at transect scale under three different salinity applications by using classical statistics and geostatistical approaches. The results from both the approaches indicated that moderate to large spatial variability existed in this study across the field for soil and plant parameters especially under the $6dSm^{-1}$ salinity treatment. In general, the statistical approach used proved helpful to establish the relationship between the spatial distribution of soil water salinity and the corresponding variability of effects on canopy development and yield indices of bean based on different soil and crop sensors. Field scale variability of soil salinity and crop response have been generally approached by classical randomized blocks schemes allowing for calculating the main statistics of that response as related to the average and variance of soil salinity. By contrast, our study used close monitoring sites along continuous

extended transects rather than randomized blocks. This way, the spatial variability of the relationship soil salinity-crop response were analyzed continuously in the space and the spatial correlation (which cannot be observed in randomized blocks) can be used as an additional and important information for understanding the mechanisms of plant response to salinity.

A MODERN MANAGEMENT MODEL FOR IRRIGATION SYSTEMS

Massimo NATALIZIO*

General Manager of Drainage and Irrigation Consorzio of Sannio Alifano
Piedimonte Matese (CE), Italy
*Corresponding author: massimonatalizio@gmail.com

Abstract

Collective irrigation systems are generally characterized by large areas to be served and large volumes of water to be distributed - water, which may be in short supply in the utilization zone. Improving the efficiency of these systems is possible through the use of automation and remote control, which is necessary particularly where there is a scarcity of water. Automation allows the water manager to have knowledge of the plant operational data in near-real time, facilitates a timely response to demand and ensures supply within the range of predetermined irrigation parameters. For large irrigation networks in open field, the implementation of these delivery systems to end users may require major capital in terms of both set-up and maintenance costs. These funds are not always available to managing institutions and must be justified by careful cost-benefit analysis. A solution to this problem has been implemented in some irrigated plains of the Volturno valley, under the jurisdiction of Consorzio Sannio Alifano. By adopting an appropriate management model, irrigation plant operation using remote control and automation has been achieved with low overall investment. To avoid over-consumption of water and rationalize the management of irrigation networks, an automated decision support system was developed, using state-of-the-art, user-friendly software, implementing GIS models and remote sensing data through satellite imagery, with users having only to book irrigation time. The results of this approach have been positive and will be discussed along with the overall system description.

Keywords*: Management irrigation systems, irrigation advisory services, water saving, remote control, remote sensing.*

Introduction

There are several stakeholders who can take action to improve the efficiency of the irrigation sector. First of all managing institutions of collective irrigation systems, i.e., drainage and irrigation authorities (Consortia), who are tasked with providing accurate estimate of irrigation requirements as well as modern and efficient irrigation system. They are also responsible for the management of the water distribution adapted to farmers' needs. Secondly, there are irrigation users/farmers, who access irrigation systems and utilize them with methods suitable to different environmental conditions of their crops as well as a variety of social conditions. With respect to management institutions, it may be argued that the collective irrigation in a region made by Consortia is typically organized in one of the following ways:

“delivery in turn and time” (ITT) - the delivery of the water to each user is performed on a rotational schedule at assigned time intervals (turns), with fixed flow rate to the farm module and for an established duration (time);

“delivery on-demand”(DOD) - users have the freedom to water the fields in times of their choosing only constrained by limiting a water flow rate to an assigned module (farm module);

“delivery on-booking”(DOB) - water delivery is made to users who are authorized according to requests received (bookings), within an assigned farm module. The date and time are set according to constraints of the irrigation plant which vary during the irrigation season.

Although differing terminology is sometimes used to characterize the above water distribution modes (Reploge and Merriam, 1980), most irrigation Consortia fall into one of these categories. Irrigation collectives systems are typically characterized by considerable surface areas over which to distribute irrigation service (typically on the order of thousands of hectares), and large volumes of water to be distributed, which is not always available in the area of use.

These collective distribution systems are both complex and difficult to control down to the individual delivery points and, thus, can have both high technical complexity and high capital and operating costs. In recent years, due to the reduction of available water resources, investment in the irrigation field have been directed mainly away from networks of open channels for water delivery and towards networks of pressurized pipes, i.e., system modernization rather than irrigation expansion. An irrigation network, while a necessary prerequisite for using more efficient irrigation methods, i.e., sprinkler heads or localized influx such as micro- and drip-irrigation, cannot alone ensure optimal use of water resources. This is particularly true if optimization is understood in terms as obtaining maximum crop production with the lowest consumption of irrigation water compatible with ecosystem constraints (Lamaddalena et al., 2000).

Other factors obviously intervene in the optimization process. For managing bodies emphasis is currently placed on the irrigation infrastructure, using automation and remote control, and on the management of irrigation plants, using of data from automation systems, remote monitoring, etc. The implementation of a system of automation and remote control of an irrigation network puts in the hands of the manager of the system a large amount of data. Unfortunately, until very recently, such data is often of marginal utility to the system operator. In many cases, in order to overcome complexity in their management, irrigation networks have been designed for a DOD approach, allowing users the freedom to irrigate, within a given farm module, at times not otherwise committed. This distribution system, as opposed to the more restrictive ITT system, would appear to represent the best possible solution to water distribution within an irrigation system at least for the end users, who buy the freedom to organize the irrigation practices in the time and manner most suitable to them (Merriam, 1987). The DOD schedule does not limit the frequency, rate and duration of irrigation water applications. This degree of flexibility requires large capabilities of the irrigation system in terms of water storage and pipeline diameter to meet theoretical peak demand, has two main drawbacks from the perspective of the system as a whole. For the managing body, this approach makes it impossible to know both who is irrigating at any given time and where irrigation is being performed, unless there is irrigation system remote control at the last delivery point. In spite of a perceived advantage, the end user in such a system has the risk of not being able to draw from the water network when required either because of a lack of water or reduced water pressure. This risk is, in fact, inherent in the design of any irrigation design based on solely probabilistic methods. The DOB system avoids these problems by providing an “on-demand” schedule controlled in advance by the water manager. It gives the final users assurance of good and safe irrigation and prevents excessive waste of water.

At this point, a clear picture of the needs of both parties in any efficient irrigation system should be evident. The managing body needs to have the knowledge in as close to real time as possible of data with respect to the irrigation plant in order to ensure continuity of supplied to users within predetermined parameters. Such data include flow rate and pressure. By the same token, the individual user must be able to draw the required irrigation water from the delivery outlets in terms of total amount, flow rate and pressure to be able to meet the water requirements of his crop(s) at any given point in time. The following example illustrates how these two needs have been met by the Consorzio Sannio Alifano.

The area of study is shown in Figure 1, encompassing a region to the right of the Volturno River and, specifically, the plains of Vairano Patenora, Riardo, Pietramelara and Pietravairano, in the Province of Caserta. The aim of this paper is highlight those aspects of the study that can be generalized, in order to provide stimulus for both discussion of developing system needs and refinements as well as to illustrate the potential application of this approach to other management bodies.

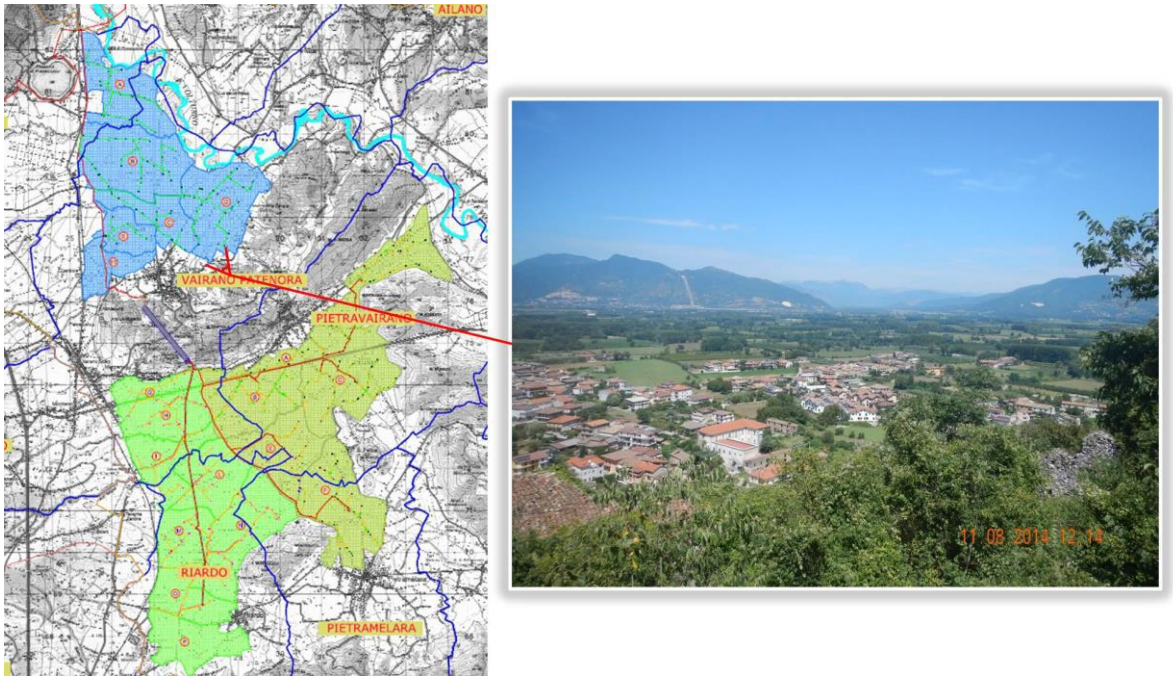

Figure 1. District plains of Vairano Patenora, Riardo, Pietramelara, Pietravairano. The area served by the Consorzio to the right of the Volturno River is shaded in this map.

Materials and methods

The irrigation system encompassing the area illustrated in Fig. 1 has the overall schematic organization illustrated in Figure 2.

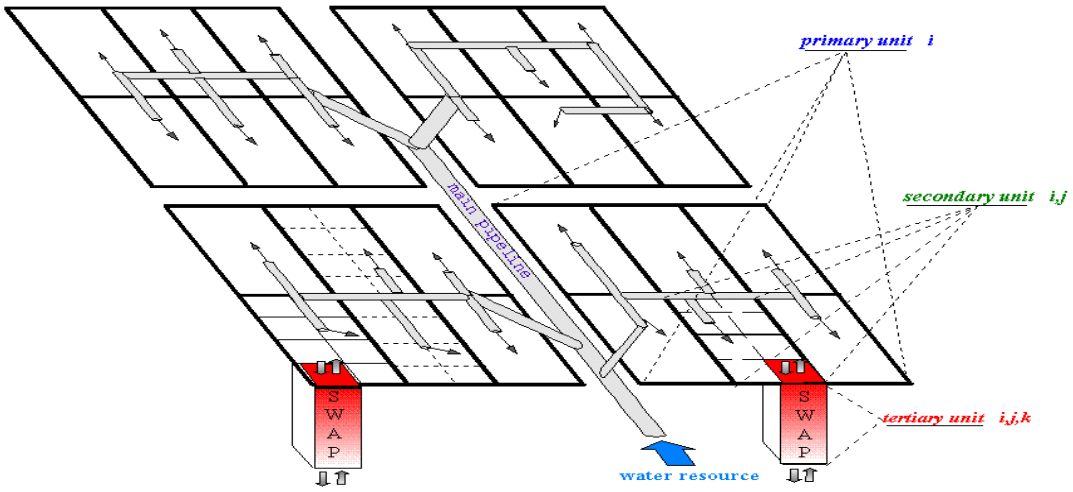

Figure. 2. Schematic organization of irrigation network implemented by the Consorzio Sannio Alifano.

Water flows from the main distribution system to primary units or water districts which are in turn subdivided into any number of secondary units with an average size of 10 hectares, all controlled by the Consorzio. The system is then further subdivided into any number of tertiary units. These could be individual fields under the control of a number of individual users or subdivisions within a single farm encompassing different crop types and/or distribution modules.

The distribution system itself is a network of pressurized piping and the total surface served by this system is 5,690 hectares. Water availability of the entire system, calculated as continuous 24 hours at a unitary flow rate, covering the period at the irrigation tip, is 0.30 l/s/hectare, with a daily irrigation schedule of 16 out of 24 hours. The flow rate at each farm module is limited up to 10 l/s.

The main hydraulic nodes of the network and all the delivery groups installed at the start of each secondary unit are restricted through a remote-controlled system (see Figure 3). The delivery groups are equipped with an electronic card for activation and metering system, called AQUACARD or HYDROPASS (commercial brands), which controls hydrovalve opening and logs irrigation duration, date and volume. The automated delivery group can also be programmed to limit the withdrawals to a fixed amount (i.e. related to the payment of fees or due to overall shortage of water resources).

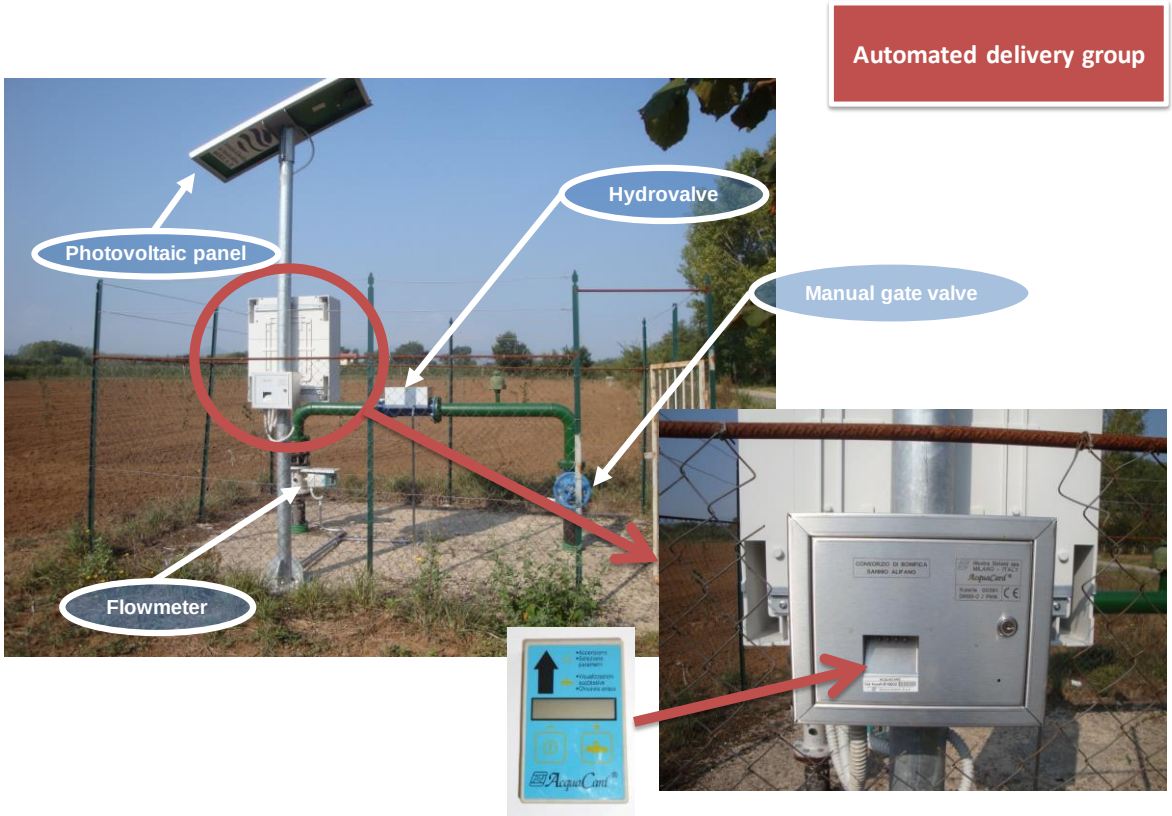

Figure. 3. Remote control of an automated delivery group implemented by the Consorzio Sannio Alifano. Water distribution to users is regulated by means of an “electronic card”.

In the area of study, each secondary unit was equipped with a network of PVC pipes of 125 mm in diameter single and arranged for operation of an outlet (hydrant) to time, enabling the Consorzio to guarantee to each user in every secondary unit a satisfactory degree of freedom in irrigation time and amount. This design choice allowed the Consorzio, through the remote control of the secondary unit, to have real-time knowledge of the user who has opened the group as well as all the data relating to withdrawals from the network. This is due to remote control of the automation equipment by electronic card that is at the start of the secondary unit

(see Figure. 2 and 3). Even in water districts organized differently with the possibility of withdrawals from a large number of hydrants at the same time (i.e., systems divided into larger secondary units), it is possible for the managing body have an adequate knowledge of the functioning of the irrigation system in a manner that ensures satisfactory performance to the end users of the system, without an exorbitant investment in remote control of every automated delivery group implemented at its ultimate limits (i.e. the hydrant at the service of every single parcel, the tertiary units of Fig. 2). This is accomplished by focusing on an appropriate model of irrigation plant management. In this case, the system must be equipped with a remote control system at least until at the start of each secondary unit and with automated delivery group (no remote-controlled) on each hydrant at the service of farm parcels.

Results and Discussion

The management model adopted by the Consorzio Sannio Alifano for the afore mentioned irrigation system is based upon a decision to organize the management of the distribution on the basis of the "reservations" of users. In order to ensure optimum operation of a pressurized distribution network, the managing body must have knowledge of the operation of the irrigation system, a knowledge of user requirements, and knowledge of the flow, pressure and volume of water used at the various distribution points within the system.

To do this, the Consorzio adopted a reservation-based water distribution system with a program for the management of user irrigation reservations. In the case study, the system was equipped with a remote-controlled system at the start of each secondary unit, including the remote control of each automated delivery group. The management approach was based on compiling and updating information on water rights. This simply means that the managing body had an updated record of water rights and land-use cover map. This information, at cadastrian level, was given to Consorzio by the farmers and/or landowners of the parcels to be irrigated. Once having the reference point of the parcel, it was then identified on cadastral maps and, by means a Geographic Information System (GIS), linked to the irrigation network and to the corresponding delivery group. The Consorzio Sannio Alifano began this work based on a 2013 GIS inventory of irrigated plots, which is regularly updated every year. Using this system, the water delivery to each parcel was managed in an easy and rational way.

The most important aspect of the overall water management system was the incorporation of a Geographic Information System (GIS). The GIS made it possible to continuously display real time operation of the irrigation system on the basis of "reservations" accepted and the data collected by the remote control system (see Figure 4). Because they are related to the “reservations” of the users, the GIS data are only an approximation of reality, but integrating them with the data from the remote control system, it is possible to obtain an overall irrigation system picture that is very nearly so. These system overviews are especially useful to the Consorzio, since they are obtained using a remote control system less complex, sophisticated and expensive than otherwise obtainable, implementing automated delivery groups on every individual delivery point, i.e., every hydrant at service of the parcels.

While the implementation of an AQUACARD or HYDROPASS system, connected via mobile phone modem to the remote control centre, is expensive and requires additional manpower, particularly for maintenance, the data acquired from the system adopted by Consorzio was used to verify the degree of system reliability, since managers were able to check the differences between the data derived from "reservations" with actual consumption by end users through automated delivery groups at any time of the irrigation season. This was done in many ways: directly by remote control system or, in case of its temporary outage, by targeted interventions of Consorzio field workers upon water delivery groups, or by reading user irrigation cards in the offices of the Consorzio when irrigation reservations are made.

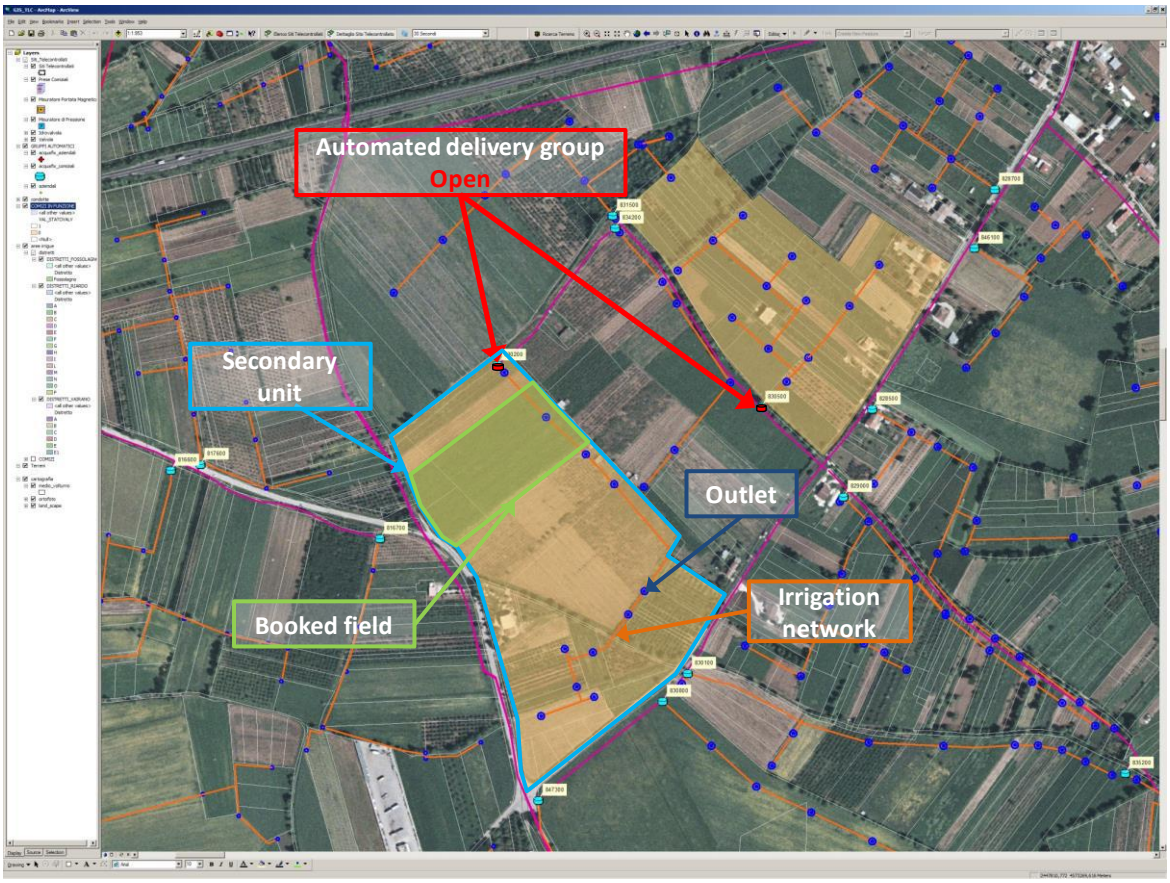

Figure. 4. An overview of the system of water delivery by Consorzio Sannio Alifano.

If the water management body has a "water balance model," it can integrate model predictions into its overall management of the irrigation service. In the case of Consorzio Sannio Alifano, the model used is called IRRISAT, based on the use of satellite imagery (D'Urso et al., 2010; Vuolo et al., 2015). Using such a model, it was possible for the management body to recommend timely irrigation to users or revise water volumes that were more appropriate for the particular crops being grown. This "irrigation advice" permitted maximization of irrigation effectiveness for the user at individual parcel level and optimized water usage within the irrigation district as a whole.

IRRISAT (www.irrisat.it), in particular, was an innovative irrigation support system, such as an "irrigation advisory", based on the use of satellite imagery to monitor the development of crops in the field; it estimates the max amount of irrigation water to be applied in a given time interval and it allows mapping of irrigated areas, such as detecting unauthorized irrigation is also possible. The system integrated satellite sensor data (in the visible and near infrared wavelengths) and *in-situ* agro-meteorological measurements to produce maps of crop water requirements (see Figure. 5).

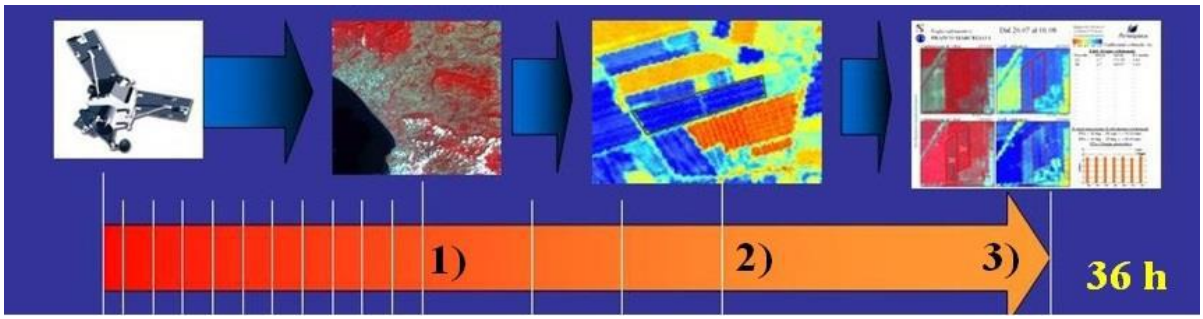

Figure. 5. Schematic of data integration using IRRISAT. Data are available to the users within 36 hours from the satellite pass.

The IRRISAT approach has proven that economic benefits generated by such advisory services are able to fully repay the initial investments, creating advantages for environment and opportunities for all the users of water resources (Vuolo et al., 2015). Accordingly, IRRISAT has been deemed a “best practice” for agricultural applications by EURISY (http://www.eurisy.org/good-practice-campania-encouraging-the-sustainable-use-of-irrigation-water-in-the-region_85) and by the International Selection Committee of the call for “Best Sustainable Practices on Food Security” for EXPO 2015 in Milan (Italy), where it was presented by the writer on July 7th, 2015 (https://www.feedingknowledge.net/home/-/bsdp/5592/en_GB?_1_WAR_feeding_knowledgeportlet_redirect=%2F02-search%3Fp_auth%3D47l29FI2%26p_p_id%3D3_WAR_feeding_knowledgeportlet%26p_p_lifecycle%3D1%26p_p_state%3Dnormal%26p_p_mode%3Dview%26p_p_col_id%3Dcolumn-2%26p_p_col_count%3D2%26p_r_p_564233524_resetCur%3Dtrue%26).

In the specific context of Consorzio of Sannio Alifano, the overall results in terms of cost-benefit analysis, obtained comparing the irrigation season 2012 (pre-IRRISAT) and 2013 (post-IRRISAT), demonstrate water savings of about 18%, while a survey on a sample of monitored farms highlights peaks saving of about 25 to 30% without loss of production.

Since 2013, this system has been repeatedly refined and has been adopted not only in Campania as a whole, but also in irrigated regions of Austria and Australia. In these areas, the technology was rapidly transferred and applied with the same positive results.

In summary, the addition of a "water balance model" to the overall irrigational strategy allowed for additional positive developments in the management system of an irrigation network, by providing the water management body and users feedback to improve the results of water usage as well as saving water.

The overall logic process is illustrated by the flow chart shown in Figure 6.

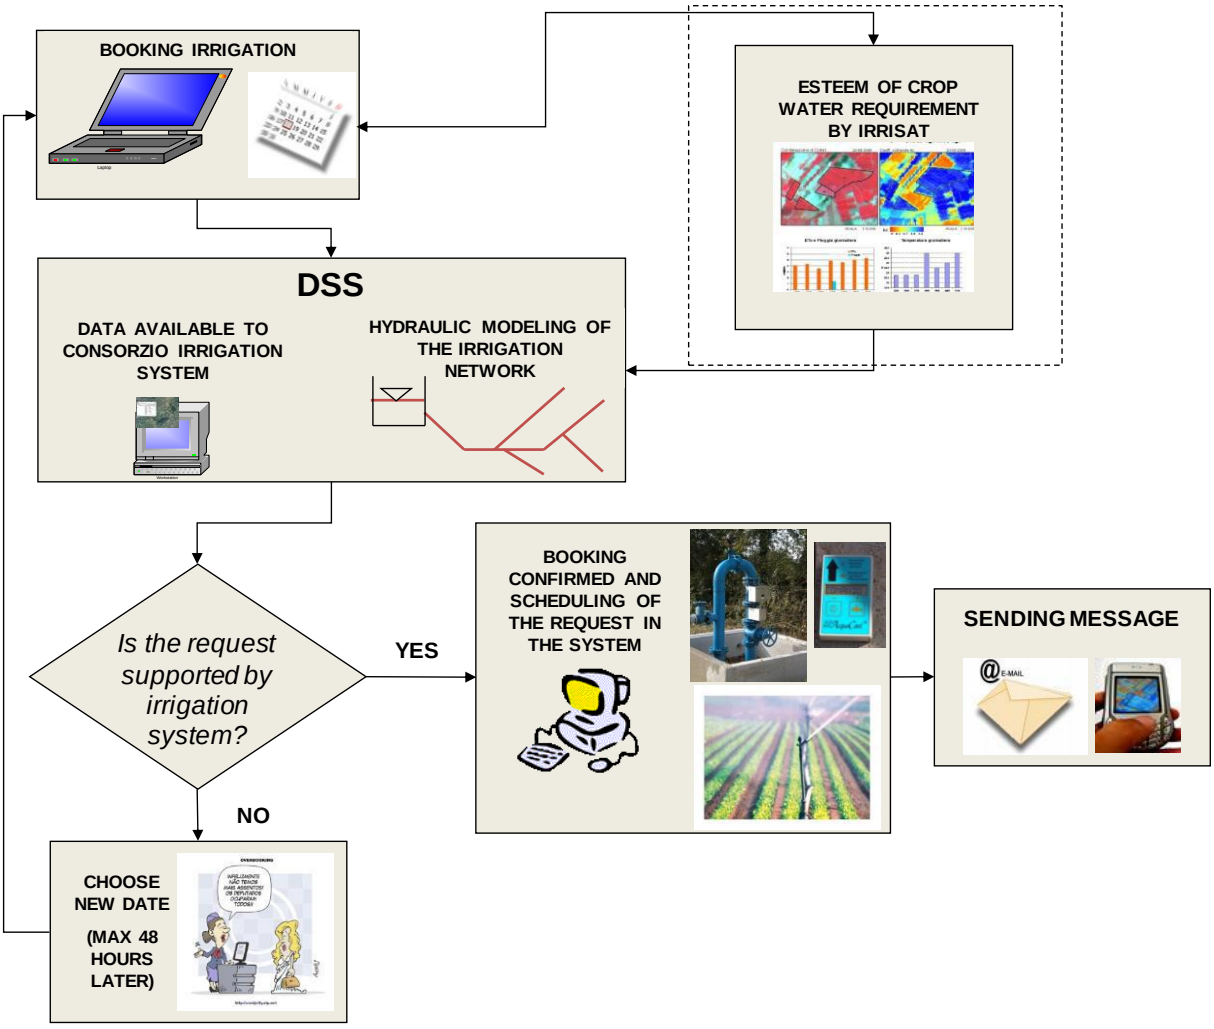

Fig. 6. Flowchart of the "water balance model" showing model input to the overall irrigation system.

Conclusions

Today the availability of computer programs dedicated to the management of network systems and databases, encourages, if not requires, managing bodies of water resources in agriculture to adopt decision support systems (DSS) for the management of irrigation networks. Current DSS are characterized by user-friendly interfaces. Within them, it is possible to implement water balance and crop growth models, geographic information systems and, most importantly, satellite and remote sensing data. Such systems enhance the ability of the managing body to conserve and effectively apply a vital natural resource in the production of food, water. With DDS in place within a water management structure, end users, for their part, only have to express their needs to the management body through a request for watering intervention. In doing so, as a result of a small waiver of absolute freedom of action (i.e., not being able to irrigate at times and volumes of their own choosing but in accordance with the water manager), the users reap the benefits of frequent consultation with experts of the managing body for the solution to their business needs, thereby gaining the ability to irrigate their fields with more certainty in terms of irrigation times and volumes, with the end of maximizing crop yields.

Abstract

Climate change (CC) is the change in climate over time due to natural variability or human activities. Two aspects of the CC must be elucidated: on one hand, the detection of the CC, that is, the proof that the climate has actually changed by identifying statistically significant trends or breaks in the long-term climate data and, on the other hand, there is the problem of CC attribution that includes the identification, at a specified confidence level, of the most likely causes of the CC. Knowledge of trends and variations of current and historical climate variables is relevant to the sustainable management of water resources. One of the important research needs in the CC is to analyze and detect the historical changes in the climate system. We will present the main simple statistical methods for detecting trends in time series of climate data. However, we should, first, check the quality of climate data by verifying the homogeneity of the climate series using statistical tests such as the standard normal homogeneity test or Buishand's range test. Then, we should ensure that climate data satisfy the conditions for application of the methods of trend detection; among them, the independence of observations which is unlikely with climate data. The 'trend-free pre-whitening' statistical approach will be applied to eliminate autocorrelation in data. Finally, only after these two stages of exploratory data analysis, we can test for change detection or existence of trends. There are parametric and nonparametric methods. The former requires that data are normally distributed while the latter do not require any particular form of statistical distribution. The main methods will be presented with their conditions of application and will be illustrated with a concrete example of a series of climate data.
Keywords: *Autocorrelation, climate change, detection, homogeneity, trend*.

Introduction

The Intergovernmental Panel on Climate Change (IPCC) defines climate change (CC) as any change in the state of the climate that can be identified (by statistical tests) by changes in the mean and / or the variability of its properties and that persists for an extended period, typically decades or longer. The CC may be due to natural internal processes or external forcings related to human activity.

Detection of CC is the demonstration that the climate has changed by identifying statistically significant trends or jumps in long-term climate data. In contrast, the attribution of the CC includes the identification, at a given confidence level, of the most likely causes of such change. A key step in research on the CC is to be able to reveal that a change or a trend is present in historical climate records. The CC is detected when the observed overall average trend rises unequivocally above the background natural variability.

In trend analysis, one should, first of all, check the quality of climate data by verifying the homogeneity of the climate series by statistical tests. Then, we should ensure that climate data fulfill the conditions for application of trend detection methods. Among these conditions, there is the independence of observations. Finally, after these two stages of exploratory data analysis, we can test the change detection or the existence of trends by parametric or non-parametric methods.

Checking the homogeneity of climatic series

Breakpoints are discontinuity moments in a time series that can be caused by changes in observation locations, equipment, measurement techniques, environmental changes, etc. Inferences drawn from climate series frequently depend on 'continuity of the measurement process': lack of breakpoints. Chen and Gupta (2000) note that the linear trend estimates are reliable only when the series are consistent over time. Before studying the trends, the homogeneity of the series should be evaluated. Several statistical tests exist. We present two of them: the Buishand amplitude test and the standard normal homogeneity test.

Buishand cumulative deviations test

This test (Buishand, 1982), suggested by the World Meteorological Organization (WMO), is based on cumulative deviations from the mean:

$$S_k = \sum_{i=1}^{k} (Y_i - \overline{Y}) \qquad k = 1, K, n \tag{1}$$

where $\overline{Y}$ is the mean of the values $\mathbf{Y_i}$ and **n** is the number of these values.

For a homogeneous series of recordings, values of Sk fluctuate around 0. If Sk shows a maximum (minimum), a positive (negative) break is present. Rescaled adjusted partial sums Sk* are determined by dividing the Sk values by the standard deviation of the sample:

$$S_k^* = \frac{S_k}{D_y} \qquad k = 1, k, n \tag{2}$$

where $\mathbf{D_y}$ is the standard deviation of the sample.

Based on $\mathbf{S_k}^*$, a statistic ***Q***, sensitive to differences of homogeneity, is defined as:

$$Q = \max_{1 \le k \le n} |S_k^*| \tag{3}$$

If the magnitude of $\boldsymbol{Q}/\sqrt{\boldsymbol{n}}$ exceeds 1.30 then temporal series is heterogeneous (Yu et al, 2006).

Standard normal homogeneity test ***(SNHT)***

SNHT (Alexandersson and Moberg, 1997) is based on the statistic **T(k)** which compares the mean of the **k** 1st observations with that of the **n-k** remaining observations:

$$T(k) = k{z_1}^2 + (n-k){z_1}^2 \quad k = 1, \ldots, n \tag{4}$$

with

$$z_1 = \frac{1}{k} \sum_{i=1}^{k} \frac{x_i - \mu_x}{\sigma_X},$$

$$z_2 = \frac{1}{n-k} \sum_{i=k+1}^{n} \frac{x_i - \mu_x}{\sigma_X} \tag{5}$$

The break occurs when **T(k)** is located near the observation that maximizes the T variable and the null hypothesis of homogeneity is rejected if the test statistic $T_0 = max(T(k))$ exceeds the critical threshold. For a significance level of 5%, this threshold is 9.17 (Khaliq and Ouarda, 2007).

Conditions of application of trend detection methods

The parametric and non-parametric tests for trend require the observations forming the time series are independent and identically distributed (iid). In addition, parametric tests require that observations are distributed according to the normal law. Therefore, before making the trend tests, we should ascertain the normal distribution of data and the independence of observations (no autocorrelation).

Normal distribution

The normality of a series of observations can be verified either graphically or by formal statistical tests. The most commonly used graphs are the histogram and the quantile-quantile graph. Regarding statistical tests, there is a large choice: test of skewness and kurtosis coefficients, the Kolmogorov-Smirnov test, the Anderson-Darling test, etc. The most commonly used tests in climatology are the Shapiro-Wilk test and the median test. Time series will be considered to be coming from a standard normal distribution if at least one of the following criteria is met (Wu et al, 2007): the Shapiro-Wilk statistics ≥ 0.96 or the $|\text{median}| \leq 0.05$. In this case, the parametric tests are recommended. Otherwise, it is required to use non-parametric tests.

Independence of observations

In time series analysis, it is essential to consider the autocorrelation, defined as the correlation of a variable with itself over successive time intervals, before testing for trends. The application of non-parametric tests for the detection of trends can significantly affect the results. Therefore, the time series data must first be tested for the presence of one order autocorrelation coefficient (r1) at the 5% level, using a two-tailed test:

$$r_1 = \frac{\sum_{i=1}^{n-1}\left(X_i - \overline{X}\right)\left(X_{i+1} - \overline{X}\right)}{\sum_{i=1}^{n}\left(X_i - \overline{X}\right)^2} \quad (6)$$

The value of the autocorrelation coefficient (r1) is tested against the null hypothesis at the 95% confidence interval, using a two-tailed test:

$$r_1\,(95\%) = \frac{-1 \pm 1.96\sqrt{(n-2)}}{n-1} \quad (7)$$

If r1 falls between the lower and upper limits of the confidence interval, the data are considered to be serially correlated and methods of pre-whitening, correction variance and trend-free pre-whitening should been used before analyzing for the trend.

Change detection or existence of trends

The objective of the trend test is to determine whether the values of a random variable generally increase or decrease, in statistical terms, over a time period. Parametric or nonparametric tests can be used to decide whether there is a statistically significant trend. The steps of the analysis are: (1) test of the effect of serial correlation (autocorrelation), (2) detection of the trend by applying the Mann-Kendall test, the Spearman test and the linear trend method and (3) estimation of the magnitude of the trend using the Sen estimator. Different methods of statistical tests are used to detect trends in climate time series; these are classified as parametric or non-parametric (Dahmen et al, 1990). Parametric tests are more powerful but require that the data be independent and normally distributed, which is rarely the case for climate data. For non-parametric tests, the data must be independent, but outliers are better tolerated.

Parametric methods

Student t test of the Pearson correlation

The classical Student *t* test assesses the significance of the correlation between the values of meteorological variables and their observation times. The Pearson correlation coefficient is calculated from the covariance and standard deviations of the two variables. The Student *t* test is then used to test p-value of the test statistic.

Linear trend model

Given a temporal series $X_1, X_2, \dots, X_n$, then the linear trend model is given by:

$$X_t = \beta_0 + \beta_1 t + \varepsilon_t, t = 1 \dots n \quad (8)$$

where β_0 and β_1 are the intercept and the slope, respectively and $\{\varepsilon_t\}$ are independent random errors and normally distributed with a zero mean and a constant variance σ^2.

This model is adjusted using the simple linear regression approach. A table of analysis of variance with the p values corresponding to the intercept and slope are provided. The p value of the slope is often used to make a two-tailed test for the significant trend in the time series. This parametric test is based on the t-distribution and requires several assumptions as above. This test is also sensitive to the presence of outliers.

Most studies of climate trends assume a priori that these trends are linear and use, therefore, the least squares linear fit to extract this trend (IPCC, 2013). The analysis of the linear trend can quantify the trend in a simple way. However, estimating the climatic trend using the linear approach is not physically realistic and can lead to uncertainty because the time behavior is complex in a changing climate.

Non-parametric methods

The most common non-parametric tests are the Mann-Kendall (Kendall, 1975) and the test of the Spearman rank correlation (Sneyers, 1990). Mann-Kendall test is the most commonly used. Less common, the Spearman test was used to detect monotonic trends in climate data.

Mann-Kendall test

This test has been widely used to test the randomness versus trend. This is a procedure based on the ranks, robust to the influence of extreme and suitable for asymmetric variables. The null hypothesis, H_0, stipulates that the seasonally adjusted data $\boldsymbol{x_1, \dots, x_n}$ are a sample of $\boldsymbol{n}$ iid random variables. The alternative hypothesis, H_1, of a two-tailed test is that the distributions of $\boldsymbol{x_k}$ and $\boldsymbol{x_j}$ are not identical for all $\boldsymbol{k, j<n}$ with $\boldsymbol{k=j}$. The statistics of the S test, with an average 0 and variance calculated by the equation (11), is calculated using equations (9) and (10) and is asymptotically normal:

$$S = \sum_{k=1}^{n-1} \sum_{j=k+1}^{n} \operatorname{sgn}(x_j - x_k) \quad (9)$$

$$\operatorname{sgn}(x_j - x_k) = \begin{cases} +1 \text{ if } (x_j - x_k) > 0 \\ 0 \text{ if } (x_j - x_k) = 0 \\ -1 \text{ if } (x_j - x_k) < 0 \end{cases} \quad (10)$$

$$Var(S) = \left[\frac{n(n-1)(2n+5) - \sum_t t(t-1)(2t+5)}{18} \right] \quad (11)$$

The notation t is the importance (extent) of any given tie and denotes summation over all ties. If the sample size n>10, the standard normal variable z is calculated using equation (12):

$$Z = \begin{cases} \frac{S-1}{\sqrt{Var(S)}} & \text{if } S>0 \\ 0 & \text{if } S=0 \\ \frac{S+1}{\sqrt{Var(S)}} & \text{if } S<0 \end{cases} \quad (12)$$

In a bilateral test for trend, H_0 is accepted if $|z| \leq z_{1-\alpha/2}$ at the significance level α. A positive value of S is a increasing trend and the negative means a decreasing trend.

Spearman rank test

This test is the nonparametric analogue of the *t* test of Pearson correlation. The statistic of the test is the rank correlation coefficient of Spearman r_s, which is the correlation between the ranks of meteorological variables and observation times. Because of the use of ranks instead of the observed values, the sampling distribution of r_s for a stationary process can be calculated without knowledge of the distribution function.

It is a non-parametric method, based on the ranks. In this test, which assumes that the time series data are independent and identically distributed, the null hypothesis, H0, shows no trend over time; the alternative hypothesis, H1, is that there is a trend and that the data increase or decrease with time i (Yue et al, 2002). The statistics of the R_{sp} test and the standardized statistics Z_{sp} are:

$$R_{sp} = 1 - \frac{6\sum_{i=1}^{n}(D_i - i)^2}{n(n^2-1)} \quad (13)$$

$$Z_{sp} = R_{sp}\sqrt{\frac{n-2}{1-R_{sp}^2}} \quad (14)$$

D_i being the rank of the i^{th} observation, ***i*** the chronological order number, ***n*** the total length of the time series, and Z_{sp} is the value of the Student ***t*** distribution with (***n***–2) degrees of freedom. Positive values of Z_{sp} represent an increasing trend while negative values represent decreasing trend. The critical value of ***t*** at the signification level of 5% from the Student distribution table is defined as ***t***(***n***-2, 1-***α***/2) (Dahmen and Hall, 1990). If $|Z_{sp}| > t(n-2, 1-\alpha/2)$, H_0 is rejected and a significant trend exists in the time series.

Sen's estimator of slope

The importance of the trend is estimated with the help of the Sen's estimator. In this case, a linear trend is present and thus the true slope is estimated by this method. Here, the slope (T_i) for all pairs of data is first calculated as (Sen, 1968):

$$T_i = \frac{x_j - x_k}{j-k} \text{ for i = 1,2,.....,N} \quad (15)$$

where x_k and x_j are represented as data values at times ***j*** and ***k*** (***j***>***k***), respectively. The median of these ***N*** values of T_i is considered as the Sen's estimator of the slope which is given as:

$$Qi = \begin{cases} T_{\frac{N+1}{2}} & N \text{ is odd} \\ \frac{1}{2}\left(T_{\frac{N}{2}} + T_{\frac{N+2}{2}}\right) & N \text{ is even} \end{cases} \quad (16)$$

The Sen's estimator is computed as $Q_i = T^*(N + 1)/2$ if ***N*** is odd and as $Q_i=[T_{N/2}+T_{(N+2)/2}]/2$ if ***N*** is even. Finally, Q_i is estimated by a bilateral test at the confidence interval of **100*(1 - *α*)%** and thus a true slope may be derived from the non-parametric test Q_i with a positive value of Q_i indicating an increasing trend and a negative value meaning a decreasing trend.

Conclusions and recommendations

The research on historical changes in the climate system is a necessary component of research on CC because the historical climate records provide context on natural variation in order to

detect the CC forced by anthropogenic activity. A reliable study of the CC requires, beforehand, climatic series of quality that could be identified by statistical tests of homogeneity. Then, one should ensure the absence of autocorrelation in the climatic series; otherwise, we should manipulate these series to eliminate this serial correlation using, for example, the pre-whitening or variance correction approaches. The next step is to test the normality of the climate series; in the affirmative, trend analysis will be performed by the use of parametric tests such as Pearson correlation and linear regression. If, in contrast, the normality condition is not met, we should use the non-parametric tests such as the Spearman rank correlation, the Mann-Kendall test, or the Sen's estimator of slope.

Abstract

Food losses and waste is generated in important amounts across the food chain, from production to consumption, imposing serious environmental, social and economic costs. More attention is paid in Morocco to food losses while food waste (FW) is generally overlooked. There are few research activities on this problem in the kingdom. This exploratory study aims to evaluate household FW in Morocco. An online survey with 122 Moroccan households was conducted in February-May 2015 to assess the knowledge and relative importance of FW; attitudes towards FW; impacts of behaviors regarding food and food management; quantity and value; as well as barriers and willingness to behavioral change. Sample is gender-balanced (52% female and 48% male) and rather young (80% are less than 44 years old) while most of respondents have high education level. Results show that household's planning and shopping activities are important predictors of FW. On the other hand, attitudes may change according to periods especially in Ramadan (87% declare that FW is higher during this month) and also to the category of food (most wasted product groups are cereals and bakery products, fruits and vegetables). Most of the respondents have a good understanding of food labels. It seems that FW is widespread in Morocco as only 3.3% of respondents declare that they do not waste any food. About two-fifths (39%) declare that their households throw away at least 250 g of still consumable food each week. The economic value of FW generated each month is more than 60 Moroccan Dirham (≈ 6 US$) for 54% of respondents' households. In order to change consumers and household's FW behavior, efforts should be directed towards providing consumers with skills and tools to deal with their food-related activities and to consider environmental and economic impacts of food waste.

Keywords: *Food waste, Online survey, Household behavior, Morocco*

Introduction

Reducing food losses and waste (FLW) is attracting growing public attention at the international, regional and national levels, and is widely acknowledged to contribute to abating interlinked sustainability challenges such as food security, climate change, and water shortage. However, the pattern and scale of food waste throughout the supply chain remains poorly understood, despite growing media coverage and public concerns in recent years (Bagherzadeh et al., 2014). FLW is generated in important amounts across the food chain, from production to consumption, imposing serious environmental, social and economic costs (Gustavsson et al., 2011).

FLW is also an issue in Mediterranean countries. In the final declaration of the 10th meeting of the CIHEAM member states' agriculture ministers, held in Algiers in February 2014, the

relevance of food waste issue in the Mediterranean countries was strongly stressed (CIHEAM, 2014). The lack of data concerning the Southern and Eastern Mediterranean Countries means that research and cooperation on this matter need to be improved (Charalampopoulos et al., 2014).

Regarding Morocco, more attention is paid to food losses while food waste (FW) is generally overlooked. There is a need of research to bridge the knowledge gap on this problem. However, some recent initiatives have been promoted by some public institutions to address this important issue in the kingdom. For instance, on June 11th 2015, the Moroccan Ministry of Agriculture and Fisheries in partnership with the Food and Agriculture Organization of the United Nations (FAO) launched a strategic project in order "*to develop a national strategy and an action plan to reduce FLW in Morocco*". The main activity consists on a study on FLW in the country for a selected key food supply chains. The study aims to develop a vision and strategic directions that will conduct into an action plan to reduce FLW by 50 % by 2024 (Moroccan Ministry of Agriculture and Fisheries, 2015).

This current exploratory survey anticipated the abovementioned study and aims to evaluate household FW in Morocco. The specific objectives concern knowledge and perceived relative importance of FW; attitudes towards food waste; impacts of behaviors regarding food and food management on food wastage; quantity and value of food wasted; and barriers and willingness to behavioral change.

Materials and Methods

The present paper is based on the results of a voluntary survey in Morocco using a questionnaire that was adapted to Moroccan context from previous questionnaires and studies on FW carried out by the Office of Environment and Heritage in 2011 in the State of New South Wales (NSW), Australia (OEH, 2011), and by the University of Bologna (Last Minute Market, 2014).

The tool used to conduct the survey is a self-administered questionnaire. It was made available in English, French and Arabic languages from February till the end of May 2015 through the Survio website (www.survio.com). Participation was entirely volunteer bases and responses were analyzed only in aggregate.

The questionnaire consisted of 26 one option and multiple choice questions structured in 6 sections:

food purchase behavior and household food expenditure estimation; knowledge of food labeling information; attitudes towards food waste; extent of household food waste; economic value of household food waste and willingness and information needs to reduce food waste. In the introductory part of the questionnaire the concept of FLW was introduced to inform the respondents.

Various institutional communication channels were used to disseminate the survey, such as: institution website (National school of Agriculture of Meknes); professional forums (https://fr.groups.yahoo.com/neo/groups/tech_agro/info); social media: (https://www.facebook.com/groups/aniphop) and mailing lists.

Data were analyzed using descriptive statistics (e.g. means, max, min), in order to get a general picture of frequencies of variables, using Microsoft Excel.

Out of 129 questionnaires received, 7 were not considered because there were missing data. Therefore, the total number of the sample is 122 adult Moroccans. The sample is almost gender-balanced (52% female and 48% male), rather young (80% are less than 44 years old) and most of the respondents (more than 69%) have high education level. More than half of the respondents are married with children (55.7 %). As for household composition, half of the respondents lives in households with up to 3 members, while the rest of the sample with 4 to 6 members at home.

Results and Discussion

The survey showed that respondents use to buy food products in different *shopping places* but more from small and minimarkets and rarely on farm. In fact, the market or what is called "souk" (traditional market place in Morocco) takes the first rank with 37%. This could be due to the fact that most consumers look for good quality products with low price. Another point that would be highlighted is that the fact of visiting the souk (mainly the weekly one) is considered as an inherited custom since a large number of Moroccans goes to the traditional market place not only to do shopping but also to meet friends and relatives. At the second rank, come minimarkets with 34%. Actually, one or two minimarkets could be found at each living hood street mainly in big cities of the country. Therefore, the proximity as well as the long working days (i.e. lack of time) for many consumers encourage them to purchase the foodstuff from the closest minimarket. During the last decades, the number of hypermarkets has increased and a competition on presenting different deals begins to get underway, which gives more confidence to consumer to go through. The wide range of available food products at the same location would be also a positive feature that persuades consumers to choose this shopping. Services, which are better on supermarkets than in other shopping places, would be a further reason for resorting at supermarkets. Only 2% of the respondents opt for the farm as a place of food shopping. It is an unusual habit of shopping in Morocco mainly for people from big cities. Furthermore, the supply chain is not well organized, which make direct sale by farmers quite complicated. Only in few places in the kingdom, fresh fruit and veggies start to be sold on the farm.

Regarding *food shopping frequency*, most of the respondents purchase food once a week (31%) or twice per week (25%) but only 15% respondents do their food shopping every day. This frequency could be related to the working and living conditions of every respondent. In addition, this frequency is highly related to the place of food shopping as discussed before.

The survey results highlighted that *the food budget* exceeds the level of 900 Moroccan dirham, MAD (10 MAD ≈ 1US $) per month in more than 65% of the cases. This category corresponds probably to households composed of 4-6 members and more. However, for the purpose of the present research, rather than considering the total food budget, it makes more sense to focus on the percentage of food budget that is lost when food is wasted.

The use of *shopping list* does not appear as a usual technique for most interviewees (30%). Only 25% of the respondents use always a list for purchasing food. The remaining people (45%) resort sometimes to using the list depending on shopping purpose. Consequently, there is a greater awareness that the use of a list can make shopping smarter, and hence contribute, likely, to a reduction of food waste.

Regarding *attraction to offers*, an important number of respondents are always interested (34%) or sometimes (42%) by good deals. The influence of these offers would have sometimes a great impact on the purchased quantity of food. This happens very often in Morocco during some specific periods of the year (Ramadan, religious holidays and other occasions). Therefore, a large part of the purchased foods will eventually have to be stored. This would increase the probability of throwing food thereafter. Much attention is thus to be paid on food labeling predominately the expiry date.

Concerning "*use by*" food label*;* only 85% of respondents understand and have knowledge about this label as they think that food should be consumed or discarded by this date. While 13% consider that the food is still safe to eat after that date if it is not damaged or spoiled. In the case of "*best before*" label, it is surprising that 68% of respondents confuse this label with "*use by*" one as they think that food should be discarded after this date. Only 31% of the survey sample showed good understanding of the meaning of this label. This shows that there is a difficulty in understanding of the two label dates by Moroccan consumers and clear

confusion between the two. Furthermore, it should be pointed out that “best before” label is not widespread in Morocco, and, consequently, not well known by Moroccan consumers.
Luckily, most respondents (88.5%) expressed a high *concern on food waste* and the attitude to avoid it as much as possible. This could be due to the fact that the Moroccan culture, customs and traditions, which are dominated by a religious character, make the act of throwing food something outrageous. About 7% of them are aware of the problems associated with food waste, but they do not think they will change their behavior in the near future. Nevertheless, a very low percentage (4.5%) of them considers FW as a non-relevant problem.
Food waste amount changes from a *period of the year* to another. In fact, according to 87 % of respondents FW increases during the fasting month of Ramadan. This is due to increased difficulty of planning meals during this month. In fact, many households in Morocco use to cook more than what they can eat for fast breaking. Therefore, this highlights the importance of organizing awareness rising campaigns before and during the month of Ramadan in order to reduce FW.
Concerning of the *quantity of food waste*, 50% of the respondents estimated that a very small amount of food is wasted in their household in comparison with 20% of them who consider that they waste much more than it should not. A quarter of them assume that the food waste quantity at the household is reasonable. This result shows that Moroccan consumers are, in general, aware of FW issue. In fact, only 3% of them considered that no food is wasted in their household.
The *uneaten food* is managed in different ways by respondents’ households. Sometimes, the same household uses different uneaten food management strategies. The study showed that, unfortunately, 69% of respondents throw the uneaten food in the trash. However, an important part of respondents (24%) manage uneaten food in good way by giving it as donation. Meanwhile, some respondents use uneaten food to feed animals (24%) or to produce compost (2.5%). While, these two last uneaten food management strategies are clearly better than throwing it in the trash, they do not represent anyway good strategies for FW reduction as also food fed to animals or used to produce compost is to be considered as wasted food.
The frequency of throwing away *leftovers* or *food considered as not good* has been also pointed out in the survey. The results showed that only 12% of the respondents don’t throw leftovers in comparison with more than 46% of them who declared throwing food for less than one time a week. On the other hand, more than 26% of the respondents throw food leftovers 1 to 2 times a week. However, 15 % throw away food leftovers even more than 2 times a week. To sum it up, a high percentage of respondents (88%) throw at least once per week leftovers or food considered not good.
Different *actions towards food* undertaken by the respondents affect the amount and extent of household FW. Among the actions that likely have a negative effect on FW can be mentioned using the leftover and the remaining food as well as eating outdoor. In fact, the survey result showed that 92% of respondents consume at least a meal remaining day before. This practice is certainly good for reducing FW. The survey showed also that 80% of respondents eat out or eat a takeaway at least once a week. This action can reduce also household FW but not necessarily FW in general. In fact, FW can be generated in this case also in food services (i.e. restaurant) that show the importance of involving food services in FW reduction strategies and initiatives. The percentage of respondents of people eating outdoor is quite high taking in consideration the Moroccan context as the Moroccan society still has a traditional and conservative character thus preferring to eat, especially mean meals, at home. This high percentage may not be representative, for the Moroccan context, as the sample considered in this survey is young and has a high education level; so that respondents can be highly influenced by western food habit and consumption pattern.

The result of the survey show that the *main reason behind waste of food* is due to bad food management at home so under the responsibility of final consumer. As the matter of fact, according to 67% of respondents, foods are wasted because they are left in the fridge for a long time. In this case, food is throwing away because it has bad smell or taste, has mold, and does not look good or expired. Poor conservation is a factor determining the increase of FW also for foods that are not stored in the fridge. Bad food management at home, such as errors in meal planning (30%), implies that there are often remains of cooked dishes and that portions are too heavy. Therefore, it is crucial to organize communication campaigns, especially through mass media (Radio, TV), on food management with a particular reference to good practices and rules regarding food storage and preservation at home. Reasons that are due to the food industry and food retail mentioned by respondents are that labels generate confusion and the package does not have always good size.
The *quantity of thrown food* per week depends on different factors inculing houshold composition. About the half of respondents (45%), declared that they never throw food which is still consumable, while (39%) of respondents affirm that their households throw away at least 250g of still consumable food each week. It is worth highlighting that according to the survey results, 55% of respondents waste food even if the quantity wasted is generally small. Hence, urgent measures are needed to address the issue of FW in Morocco as FW is also considered as a waste of resources (land, water, and energy) as well as money.

Table 1: Quantity of thrown food per household and per week

Answer choices	**Ratio (**%)
I do not throw food that is still consumable	45.1
Less than 250g	15.6
Between 250 and 500 gr	21.3
Between 500 gr and 1 kg	8.2
Between 1 kg and 2 kg	5.7
More than 2 kg	4.1

Source: Authors’ elaboration based on the survey results.

The extent of FW varies from a *food group* to another. In general, perishable products are the most wasted food. This result is in line with the outcomes of FAO’s promoted study on global FLW (Gustavsson et al., 2011). In particular, the survey showed that the most wasted food group in the Moroccan context is cereals and the bakery products, followed by fruits, vegetables. Meanwhile, the least wasted food group is roots and tubers, dried vegetables and oilseeds, meat and meat products, and fish and sea food. Milk and milk products are moderately wasted. The high percentage of cereal and bakery products that is wasted is a big environmental and economic problem considering the high amount of these products, especially consumed by Moroccans. This is also a political issue in Morocco, as bread is subsidized in the Cherifian kingdom, so bread waste is considered also as a waste of public budget and, consequently tax payers’ money. It is interesting to notice that, not only *perishability*, but also price is an important factor in determining the extent FW. In fact, meat and meat products, and fish and sea food that are also perishable products, but quite expensive, are among the least wasted foods.

Table 2: Ratio of thrown food per group

Food waste ratio / Food groups	**Less than 2%**	**3 to 5%**	**6 to 10%**	**11 to 20%**	**More than 20%**
Cereals and bakery products (bread, rice, pasta, etc.)	33.6	20.5	13.1	13.9	18.9
Roots and tubers (potatoes, etc.)	63.1	18.0	11.5	2.5	4.9
Dried vegetables and oilseeds (e.g., peas, chickpeas, olives, sunflower)	78.7	12.3	4.9		0.8
Fruits	49.2	27.0	15.6	6.6	1.6
Vegetables	32.8	40.2	16.4	4.9	5.7
Meat and meat products	78.7	11.5	8.2	1.6	0
Fish and seafood	85.2	9.0	4.1	1.6	0
Milk and milk products	59.0	23.8	9.0	5.7	2.5

Source: Authors' elaboration based on the survey results.

Economic value of household food waste depends not only on waste amount (so also on household composition), and the composition of FW, but also on household food habits and consumption patterns. According to the survey, the value of household FW generated each month is more than 60 Moroccan dirham for 54% of respondents' households. The weighted average economic value of the monthly FW generated by each responding Moroccan household is about 100 MAD. This value represents of around 13% of the weighted food budget for the considered sample.

Table 3: Economic value of food waste generated each month by household

Answer choices	**Ratio (**%)
Less than 5 US$	45.9
Between 6 and 20 US$	42.6
Between 21 and 50 US$	10.7
More than 51 US$	0.8

Source: Authors' elaboration based on the survey results.

Better information is the key to reduce household FW. In fact, among the necessary *conditions to waste less food* mentioned by responds *are to be* better informed about the negative impacts of food waste on the environment (44%) and on the economy (38%). Food industry and food retail can play an important role in food waste reduction by improving packaging and making food labeling clear. Government actions to reduce FW can include introducing a new taxing system penalizing food wastage making it inconvenient from the economic point of view. However, implementing such a system is not an easy task in Morocco, giving the inefficient waste management system.

According to the exploratory survey, *information* about different issues are needed, sometimes even simultaneously, by respondents for reducing food waste such as advices on how to properly store food (59%), organizations and initiatives that address the prevention and reduction of food waste (49%), recipes prepared with leftovers (38%). Also

information about how to assess the freshness of products is needed by about a third of respondents (35%).

Conclusion

Food-related behavior and attitude are important factors in determining the amount and extent of food waste. Food habits change according to year's periods, as during the fasting month of Ramadan, with implications in terms of FW. However, the amount of household FW is affected not only by food habit and behavior, but also depends on food groups. In fact, most wasted foods are cereals and bakery products. This fact is alarming taking into consideration that these are the most consumed products in Morocco. It seems that there is still some confusion regarding food labels, which increases the amount of FW. This result represents a big problem as our sample has good education, so it is legitimate to assume that the situation is worse especially considering the relatively high percentage of illiterates in the kingdom. The estimated economic value of FW is rather low but still a source of concern taking into consideration its share in the household food budget. In order to reduce household FW, effort should be directed towards changing consumer behaviors and habits especially household management practices (i.e. fridge management), by providing consumers with knowledge and information to deal with their food-related actions, while fully considering economic and environmental impacts of food waste. The recent initiative of the Moroccan Ministry of Agriculture - in collaboration with FAO - is a step in the right direction, but it is not sufficient. There is a high need for more initiatives (targeting not only FW reduction, but also FW prevention) especially awareness rising campaigns. For that a multi-stakeholder approach and active involvement of all key actors of the food chain, including the private sector as well as civil society, is highly recommended in the future to effectively, efficiently, and sustainably address the issue of FLW in Morocco. This should be put high on the government agenda taking into consideration the environment and economic implication of FLW.

ENVIRONMENTAL IMPACTS OF STANDARD OF LIVING: A CASE STUDY OF MARDAN DISTRICT, KHYBER PAKHTUNKHWA IN PAKISTAN

Anwar HUSSAIN*, Asma SAEED

Pakistan Institute of Development Economics (PIDE), Islamabad, Pakistan
*Corresponding author: anwar@pide.org.pk

Abstract

Household income plays an important role in the improvement of the standard of living. However as the standard of living of the household improves, it also causes environmental degradation. This study investigates the environmental impacts of living standard of the households in the Mardan District. The impact of other factors such as household size, location of the household (urban or rural) and education of the households is also estimated. The study used primary data of 267 households collected through a questionnaire. The sample has been proportionally allocated between two sub-districts namely, Mardan and Takhtabhai. Accordingly the sample size for each Tehsil is 193 and 74 households respectively. Further, the sample size for each Tehsil is allocated to rural and urban areas proportionally. Accordingly, from the whole Mardan districts, 54 households from urban and 213 households from rural areas were selected. The respondents in both rural and urban areas have been selected randomly. The analysis was made through descriptive statistics and regression model. Findings show that household income is significant factor in increasing CO_2 emissions in Mardan District. A positive relationship is also found between household size, education and CO_2 emissions. Findings also revealed that Environmental Kuznets Curve (EKC) is valid in case of rural areas but not in urban areas because the urban consumers use more carbon intensive commodities. Hence an effective policy formulation stressing on public awareness programs, incentives of tax reductions, and better public transport network is conducive to the reduction of CO_2 emissions in the selected District.

Keywords: *Standard of living, Environmental impacts, Environmental Kuznets Curve, Household awareness, Emission factors*

Introduction

The standard of the living is the degree of wealth available to an individual or family with which they can satisfy their wants/consumption of goods and services necessary for well-being. There are many factors that influence the standard of living of an individual or family. The higher the income, the higher is the standard of living because people will be able to buy more goods and services (Perry, 2013). Improvement in the standard of living always remained the priority of the governments but it is also well known fact that improvement in the standard of living or income of the people the usage of vehicles, refrigerators, air conditioners and other fuel items and electrical appliances increases, which ultimately adds to the carbon dioxide emission in the economy. Similarly, household income, urbanization, age of the main income provider and type of the house are the strongly influencing factors of CO_2 emissions (Baiocchi, Minx, and Hubacek (2010); Li and Wang (2010). Similarly, as the food expenditures increases, the solid wastes also tend to increase (Feng, Zou, and Wei (2011).

The GDP per capita increased in Pakistan from US $631 in the year 2004 to US $1024 in the year 2010 (World Bank, 2014) but on the other hand the mean estimated annual cost of environmental and natural resource damage is about 365 billion Rs. per year or 6 percent of GDP. Also, the per capita emissions have been increased from 0.84 metric tons per capita in the year 2004 to 0.93 metric tons per capita in the year 2010 (World Bank, 2014).

Mardan is a typical district of Pakistan where, in the year 2013, about 98% of the household are using electricity for lighting without having much rural urban variation. The usage of gas/oil for lighting in rural and urban areas is 1% and 2% respectively. Similarly, the usage of gas as fuel in urban and rural areas in the year 2013 was 92% and 18% respectively while wood/charcoal usage was 7% and 56% respectively (Government of Pakistan, 2014). In Khyber Pakhtunkhwa province, the per capita consumption of gas in year 2010 was 1422 Cubic Meters but has grown to 2494 cubic meters in the year 2013 (Government of Khyber Pakhtunkhwa, 2014). In the year 2006-07, 65% of the household used gas/oil for cooking in urban areas of District Mardan (Government of Pakistan, 2007) while in the year 2012-13, it increased to 92% (Government of Pakistan, 2014). Similarly in rural areas, 9% of the household used gas/oil for cooking in the year 2006-07 (Government of Pakistan, 2007) , increasing to 18% in the year 2012-13 (Government of Pakistan, 2014). In this District, the total population of registered motor vehicles was 115814 in the year 2012 (Government of Khyber Pakhtunkhwa, 2014) while this was 98576 in the year 2011 (Government of Khyber Pakhtunkhwa, 2012). Apart from these the population of the District also increased significantly over the years. Based on these facts, this study looks how much environmental degradation (CO_2 emissions) takes place followed by estimating the impact of income and non-income factors on carbon dioxide emissions at household level in rural and urban areas of District Mardan.

The literature is rich about the relationship between economic growth and environmental degradation based on secondary data such as (Grossman & Krueger, 1991) who also proposed the idea of environmental Kuznets curve (EKC) the first time. The same was also concluded by Hung and Shaw (2004). Some studies validated the EKC hypothesis for some countries such as Ubaidillah (2011) and (Uddin, 2014). While some didn't validate the hypothesis of EKC such as Mrabet, Achairi, and Ellouze (2013) and Akpan and Chuku (2011). The validity of EKC is not similar for each environmental quality while varies across environmental indicators. Ni, Lu, Lan, Gao, and Pan (2010) found that the indicators of surface water mostly support the EKC, while ambient air and near-shore water's indicators do not support it. Similarly, Shaw, Pang, Lin, and Hung (2010) investigated that EKC hypothesis confirmed by SO_2 and total suspended particulates while it does not confirmed in the case of NO_X. The present study advances to literature through estimating the CO_2 emissions using emission factors followed by estimating its determinants at household level in rural-urban areas of District Mardan.

Materials and Methods

To assess the impact of the standard of living on the environment the present study is based on primary data that have been collected through a questionnaire. The household has been selected randomly for getting information. The questionnaire consists of the information relevant to the household's energy consumption in the form of electricity, natural gas, firewood, liquefied petroleum gas (LPG) cylinder, electrical appliances (refrigerators, freezers, air conditioners, air coolers, fans, washing machine, bulbs, energy savers, electric heater, geyser, iron, vaccume cleaner, television, desktop computer, laptop computer and microwave oven), fuel (petrol and compressed natural gas) used in personal vehicles (car and motorcycle), wastes produced by the household and the household characteristics including household income, family size, location (urban or rural) and education of the main income provider of the household.

The total estimated number of the households during the year 2014 was 330544 (Government of Khyber Pakhtunkhwa, 2014). Keeping the confidence level as 95 percent and confidence interval at ±6 percent, the required sample size calculated was 267 households. The sample has been proportionally allocated between two sub-districts namely, Mardan and Takhtabhai.

Accordingly the sample size for each Tehsil is 193 and 74 households respectively. Further, the sample size for each Tehsil is allocated to rural and urban areas proportionally. Accordingly, the calculated sample size for urban and rural areas of Tehsil Mardan is 45 and 148 households, respectively. The sample for urban and rural areas of Tehsil Takhtabhai is 9 and 65 households respectively. The respondents in both rural and urban areas have been selected randomly.

The study used household income as an indicator for the standard of living as proposed by Government of New Zealand (2007), OECD (2013) and Perry (2013). Apart from income, the other variables included are the household size, location of the household (urban or rural) and the education of the main income provider of the household. The household consumption has been converted into carbon emissions through emission factors proposed by DEFRA (2012), Carbon Neutral Company (2014), Intergovernmental Panel on Climate Change's (IPCC's) Guidelines for National Greenhouse Gas Inventories (Intergovernmental Panel on Climate Change 2006). This procedure has also been used by Zhao and Cui (2013) and Kavi and Viswanathan (2013).

The conversion formula is given as:

$$CO^{hh}{}_{2e} = \Sigma C_i * EF_i$$

Where,

$CO^{hh}{}_{2e}$ = The household carbon dioxide emissions

C_i = The household consumption of the ith energy in the form of electricity, natural gas, firewood, liquefied petroleum gas (LPG) cylinder, electrical appliances (refrigerators, freezers, air conditioners, air coolers, fans, washing machine, bulbs, energy savers, electric heater, geyser, iron, vaccume leaner, television, desktop computer, laptop computer and microwave oven), fuel (petrol and compressed natural gas) used in personal vehicles (car and motorcycle) and wastes produced by the household.

And

EF_i = The CO_2 emission factors of the ith energy

The emission factors for electricity, natural gas, waste, LPG, firewood and fuel (petrol and CNG) used in personal vehicles (car and motorcycle) with reference to Pakistan have been taken from Carbon Neutral Company (2014), DEFRA (2012) and Intergovernmental Panel on Climate Change's (IPCC's) (2006).

Regression analysis has also been carried out to show the impact of household income (standard of living) and other socioeconomic and demographic factors as independent variables on carbon dioxide emissions estimated as dependent variables (Buchs & Schnepf, 2013; Kavi & Viswanathan, 2013). To this end, the following model has been estimated:

$$\ln CO^{hh}{}_{2e} = \beta_0 + \beta_1 Y_h + \beta_2 Y_h{}^2 + \beta_3 HS + \beta_4 HS * Y_h + \beta_5 ED + \beta_6 ED * Y_h + \mu_i$$

Where $CO^{hh}{}_{2e}$ are the household CO_2 emissions in kg per month used as an indicator of the environmental degradation. Y_h is the household income in rupees per month used as an indicator for household standard of living and its expected sign is positive. $Y^2{}_h$ is the squared term of the household income to estimate the existence of the environmental Kuznets curve (EKC) at household level. The expected sign of the squared term of the household income is negative. HS is the household size in number and its expected sign is positive. $HS * Y_h$ is the interaction term of the household size with household income. The expected sign of this is positive. ED is the number of years in education of the main income provider and its expected sign is negative. $ED * Y_h$ is the interaction term of education of the main income provider with household income and the expected sign of this is negative and μ_i is the error

term. Firstly the model is estimated for overall district Mardan and then estimated for rural and urban households of district Mardan separately.

Results and Discussion

In urban areas, the average CO_2 emissions were higher from the usage of air conditioner, refrigerator and freezer because these are mainly used by urban households and also because of the energy-intensive lifestyle of the urban households (Table 1). This means that in the electrical appliances the more polluting items are air conditioner, refrigerator and freezer in urban areas of district Mardan. Similarly the usage of personal transportation also results in higher CO_2 emissions. This is due to the fact that majority of the households have personal transportation facility in their homes.

Table 1. Average household size, income, education and CO_2 emissions in Mardan district

Variable	**Unit**	**Rural**	**Urban**
Monthly household income	Rs.	46285.211	66727.300
Household size	Number	6.671	5.722
Education of the main income provider	Years	11.427	12.056
CO_2 Emissions of HH (kg) per month			
Sui Gas	kg CO_2e	0.734	0.842
Firewood	kg CO_2e	164.645	15.748
LPG	kg CO_2e	13.035	4.892
Personal Transport	kg CO_2e	535.769	68.997
Waste	kg CO_2e	17.431	8.639
Electrical Appliances			
Fans	kg CO_2e	38.689	16.726
Air Conditioner	kg CO_2e	106.951	129.016
Air Cooler	kg CO_2e	19.358	18.180
Energy Saver	kg CO_2e	6.522	7.357
Bulb	kg CO_2e	37.706	25.629
Washing Machine	kg CO_2e	2.506	1.559
Refrigerator	kg CO_2e	96.810	96.582
Freezer	kg CO_2e	64.773	123.082
Television	kg CO_2e	22.554	15.768
Iron	kg CO_2e	8.301	8.759
Vacuum Cleaner	kg CO_2e	37.297	6.993
Geyser	kg CO_2e	54.703	75.528
Electric Heater	kg CO_2e	31.648	55.158
Computer	kg CO_2e	20.975	13.203
Laptop	kg CO_2e	10.949	12.110
Microwave oven	kg CO_2e	44.757	46.000

On the other hand, in rural areas of district Mardan, the lowest CO_2 emissions are from Sui gas. The usage of personal transportation has higher average CO_2 emissions than urban areas of district Mardan. This is due to the fact that rural households are far away from different types of facilities like school, colleges, hospitals, etc. which are situated in urban areas. Therefore majority of the households have personal transportation in their homes. The firewood emissions are also higher in rural than in urban areas because of the low access of Sui gas to rural areas. The average CO_2 emissions of waste in rural area is higher than in urban area because of the large household size.

In the overall Model, the coefficient of income is positive and significant depicting that with the increase in household income, CO_2 emissions increases (Table 2). An inverted U shaped relationship exists between CO_2 emissions and income at household level. This means that as household income increases, the CO_2 emissions also increases, ultimately reaching to a turning point where the household CO_2 emissions then start to decline with a further increase in household income. So, as standard of living improves the environmental degradation increases. Household size is also positive and significant which is in line with the results of Wu, Liu, and Tang (2012) but in contrast to the findings by Li and Wang (2010). The interaction term of income and household size is negative and significant. The education coefficient is positive and significant showing that if the main income provider of a household is educated then the household emits more CO_2 emissions. This finding is in contrast to Baiocchi et al. (2010) but in accordance to Buchs and Schnepf (2013). This positive link between education and household CO_2 emissions is due to the fact that as the households are getting more educated, they move to a high social status and a more carbon intensive consumption pattern. The interaction term of income and education is negative and significant which is also in line with Grunewald, Harteisen, Lay, Minx, and Renner (2012).

Table 2. Regression results of the influencing factors of CO_2 Emissions in Mardan

Variable	**Overall**	**Urban**	**Rural**
	Coefficient	**Coefficient**	**Coefficient**
Income	0.0000177***	0.0000173**	0.0000152**
$Income^2$	-0.00000000002**	0.0000000000019	-0.000000000036***
Household size	0.1304098***	0.120808**	0.1278079***
Income*Household size	-0.00000105**	-0.00000121**	-0.00000081*
Education	0.0261412*	0.0472491**	0.000293
Income*Education	-0.000000401**	-0.000000688*	-0.0000000973
Constant	5.636288***	5.718356***	5.803158***
R^2	0.1371	0.0825	0.1822
F-Statistics	10.22	2.73	7.65
Prob. F-Statistics	0.0000	0.0146	0.0000

Note: *, **, *** 10%, 5% and 1% level of significance respectively. Dependent Variable = CO_2 Emissions (Kg).

In the urban areas, the coefficient of income is positive and significant. The coefficient of income squared term is positive and insignificant implying that the hypothesis of Environmental Kuznets curve (EKC) does not hold true in urban areas of district Mardan. This result is in line with the result of Kavi and Viswanathan (2013). The reason for this is that the urban households follow a carbon intensive lifestyle which restricts the relationship between income and CO_2 emissions to the upward sloping segment of the EKC. The coefficient of household size is also positive and significant. The interaction term of income and household size is also negative and significant in urban areas showing that higher income and larger household size contribute to less CO_2 emissions. Because as the household become wealthier they prefer a clean environment. The coefficient of education in urban areas is positive and significant. Similarly, the coefficient of interaction term of income and education is negative and significant in urban areas.

In rural areas, the coefficient of income is positive and significant further implying that there exists an inverted U shaped relationship between income and CO_2 emissions and so, the EKC exists in rural areas of district Mardan. The coefficient of household size in rural areas is also

positive and significant. The interaction term of income and household size has a negative and significant coefficient. The coefficient of education is positive and insignificant in rural areas. The coefficient of the interaction term of income and education is negative and insignificant. Both education and the interaction term of income and education are insignificant showing that the education level of rural households is not high so the resulting social status is also not high which is associated to a high level of education. As the social status of the rural households is not high so their consumption pattern is also less energy intensive, therefore, contributing to less CO_2 emissions.

Conclusion

Based on findings it is concluded that environmental degradation increases with improvement in the standard of living. Both household size and education positively and significantly affect the CO_2 emissions. The EKC is valid in rural areas but not in urban areas. The influencing factors CO_2 emissions at household level were mainly income, household size and education in district Mardan. To have sustainable standard of living, households should be aware of the environmental impacts of their consumption choices and activities. This can be done through media and public campaigns. Consumers should be given incentive for choosing energy saving goods and services. These incentives can be given in the form of tax reductions for rewarding them to save the energy.

BIODIVERSITY POTENTIAL IN CAMPING DESTINATIONS CORBU AND VADU FROM DANUBE DELTA BIOSPHERE RERSERVE

Ionela DOBRIN, Emilia Brîndușa SĂNDULESCU, Cosmin-Alexandru MIHAI, Mala-Maria STAVRESCU-BEDIVAN*

University of Agronomic Sciences and Veterinary Medicine of Bucharest, Faculty of Agriculture, 59 Mărăşti Blvd., 011464, Bucharest, Romania

Abstract

Corbu and Vadu, two villages from Constanţa County, Romania are recently camping destinations for those tourists seeking natural beauty and the concept of virgin beaches on the Black Sea.

In July 2013 and August 2014, we observed, studied and collected some biological material from these sites situated in the southern part of Danube Delta Biosphere Reserve. Considering the biodiversity potential, we have compiled for the Corbu-Vadu are an inventory of over 23 vegetal families representative for local vascular flora and eight insect orders (Coleoptera, Heteroptera, Homoptera, Hymenoptera, Lepidoptera, Mantodea, Neuroptera, Orthoptera), with special insight on insect-host associations like *Eurydema spectabilis – Crambe maritime*, *Carpocoris pudicus – Eryngium maritimum*, *Rhagonycha fulva – Daucus carota*. From mollusks species, we found the rarer razor clam *Solen marginatus* along the Vadu beach.

As regarding the avifauna, in the summer of 2013, we recorded in the Vadu area 92 species belonging to 13 orders and 35 families of birds. The most abundant in species composition was the order of Charadriiformes.

The impacts of human activities on the protected landscapes and the hygienic conditions of the camping trips in these seaside areas are also discussed.

Keywords: *Danube Delta Biosphere Reserve, biodiversity, anthropogenic impact, beach*

Introduction

The Corbu and Vadu areas, as parts of Black Sea shore, found in the south limit of Danube Delta Biosphere Reserve and in the central Dobroudja region, are home for protected species of fish, amphibians, reptiles and birds but also for insects and vascular flora (Dinu et al., 2009; Făgăraş and Jianu, 2007).

Făgăraş (2008) recorded for Corbu-Vadu seacoast, an area with a surface about 50 hectare, 24 plant associations and 173 number of plant taxa. Unfortunately, in Dobroudja, the natural vegetation has been deeply affected due to the long-termed anthropogenic influence, like tourism and agricultural activities (Nonev, 2008).

In Dobroudja and Danube Delta, there are the highest concentrations of birds in Romania and even in Europe, due to preferred migration corridors and favorable areas for feeding, resting and breeding. The localities from Corbu commune (Corbu, Luminiţa and Vadu) there are just on two from the three main migration routes in Dobroudja, namely Sarmatic route – crossing the Danube Delta and following the seashore, and Sarmatic Maritim, branching directly across the Black Sea to the north. These corridors are used by both spring and autumn migrations (Dinu et al., 2009; Ion et al., 2009). At the same time, the aestival season represents a disturbing factor for the nesting birds in the Romanian coastal area (Bănică, 2008).

It is well known that tourism could have a negative effect on the natural resources in camping destinations from DDBR (http://www.danubeparks.org/). The dunes habitats can be destroyed through the expansion of the touristic activities (Făgăraş et al., 2008).

Regarding the Vadu area, a recent report (TRANSDANUBE, 2014) drew attention to the fact that currently there is an uncontrollably camping activity, that threatens the conservation status for the coastal habitats.

Material and method

Our observations were made in field trips carried out in: 22.07.2013-29.07.2013 (Corbu area – 44°22'44.01"N, 28°42'43.51"E; 44°22'46.64"N, 28°42'43.67"E) and 25.07.2013-30.07.2013, 15.08.2014-17.08.2014, 22.08.2014-27.08.2014 (Vadu area – 44°25'41.70"N, 28°45'53.99"E; 44°25'46.64"N, 28°46'1.41"E; 44°25'47.53"N, 28°46'0.20"E; 44°25'48.73"N, 28°46'4.75"E; 44°25'58.17"N, 28°46'8.98"E; 44°26'38.19"N, 028°44'45.01"E; 44°28'07.14N", 028°45'01.77E").

Biological material, like insects associated with vascular flora, was observed *in situ* and collected from the following categories of habitats: sandy beaches, sand dunes with psammophile vegetation, ruderal places, coastal wetlands and ponds, bushes area along the marine shore line.

Direct observation was the most used method in this type of qualitative research, in order to focus on normal behavior and adaptations of the living organisms in their natural environment (Dobrin et al., 2013). Like any qualitative data analysis, our survey was non-statistical, its methodological approach being guided by the concrete material at hand; sample selection was based on smaller cases, compared to a quantitative research (http://atlasti.com/quantitative-vs-qualitative-research/). Numbers were used to describe a sample and to generate meaning from the data (Sandelowski, 2001). This technique, applied for collecting data about various features and processes, included photographing and videotaping; scientific and vernacular names of the recognized biological specimens were mentioned in a field notebook.

Some steps in sorting and classification of species were conducted in the field, other in laboratory.

The nomenclature for the vascular flora identified in the studied areas is in accordance with the Romanian Flora and Flora Europaea (Ciocârlan, 2000; http://rbg-web2.rbge.org.uk/cgi-bin/nph-readbtree.pl/). Plant specimens were harvested by hand pulling, some being dried and pressed in a herbarium or preserved in alcohol, in order to identify them in the laboratory work.

Insect species, captured with an entomological net, have been identified according to Leraut (2012); some of them were whole preserved in alcohol, prior to study them in UASVM Bucharest laboratories.

For the ornithological study, were used binoculars and spotting field telescopes, working out visual transects to identify birds. The book-guides used are Bruun et al. (1999) and Svensson et al. (2010). In July 2013, the observations were made twice a day, around 7 a.m. and 5 p.m., in various points from Vadu area, such as: the beach, accumulations basins, swampy habitats, village and the area around the neighboring forest.

Also, some bird species included in this research have been reported since the summer of 2007 (Mihai, unpublished data), in the camps organized by the Romanian Ornithological Society (ROS), an organization that aims to study and protect the wild birds. It is already know that the objectives of these camps include monitoring of the bird migration through ornithological observations and ringing activities, and at the same time popularization of ornithology and environmental protection (http://www.sor.ro).

Results and discussion

Our survey presents findings descriptive in nature, involving recording presence of flora and fauna species and the relationship between these components of biological diversity. Similar

approaches were used worldwide by researchers like Bieler and Mikkelsen (2004), Golodets et al. (2013) or Grant and Shepard (1985).

Vascular flora. In the Corbu area, the following plant taxa have been identified in our survey conducted in July 2013: Asteraceae (*Artemisia herba-alba, Centaurea* sp., *Cichorium intybus*, *Cirsium vulgare*, *Xeranthemum annuum*); Apiaceae (*Eryngium maritimum*); Caprifoliaceae (*Scabiosa argentea*); Convulvaceae (*Cuscuta campestris*); Cyperaceae (*Scirpoides holoschoenus*); Elaeagnaceae (*Elaeagnus angustifolia*); Euphorbiaceae (*Euphorbia nicaeensis* ssp. *dobrogensis*); Fabaceae (*Astragalus varius*, *Melilotus albus*); Gramineae (*Calamagrostis epigejos, Leymus racemosus* ssp. *sabulosus, Phragmites* sp.); Labiatae (*Teucrium polium* ssp. *capitatum*); Linaeceae (*Linum austriacum*); Lythraceae (*Lithrum salicaria*); Rosaceae (*Potentilla anserina, Crataegus monogyna*).

In the Vadu area, the following plant families and species have been identified in August 2014: Asteraceae (*Achillea millefolium*, *Artemisia arenaria*, *Centaurea arenaria*., *Onopordum acanthium*, *Scolymus hispanicus*, *Senecio grandidentatus*, *Senecio jacobaea*, *Xanthium italicum*, *Xeranthemum annuum*); Amaranthaceae (*Salicornia herbacea*, *Salsola kali*, *Suaeda maritima*); Apiaceae (*Eryngium maritimum*); Apocynaceae (*Cynanchum acutum*); Brassicaceae (*Crambe maritima*); Caprifoliaceae (*Scabiosa argentea*); Caryophyllaceae (*Dianthus bessarabicus*); Elaeagnaceae (*Elaeagnus angustifolia*, *Hippophae rhamnoides*); Fabaceae (*Astragalus varius*); Gramineae (*Leymus racemosus* ssp. *sabulosus*, *Phragmites* sp.); Juncaceae (*Juncus* sp.); Labiatae (*Ajuga genevensis*, *Teucrium polium* ssp. *capitatum*); Linaceae (*Linum perene*); Lythraceae (*Lithrum salicaria*, *Trapa natans*); Plantaginaceae (*Linaria genistifolia*); Plumbaginaceae (*Limonium ramosissimum*); Polygonaceae (*Polygonum arenarium*); Potamogetonaceae (*Potamogeton crispus*, *Zannichellia palustris*); Rosaceae (*Crataegus monogyna*); Scrophulariaceae (*Verbascum nigrum*); Typhaceae (*Typha* sp.).

As ROS/BirdLife showed (http://www.rspb.org.uk/Images/danubedelta_tcm9-227929.pdf), *Crambe maritima*, *Leymus racemosus* ssp. *sabulosus* and *Eryngium maritimum*, parts of the herbaceous vegetation of the coastal dunes, are globally threatened plant species, being affected by the inadequately controlled economic development and tourism.

Within the coastal wetland of Corbu-Vadu area *Lythro-Calamagrostetum epigeix* represents a main mesophilous plant association, while *Scirpo-Phragmitetum* is among the most important hygrophilous plant communities, as Făgăraş (2008) also mentioned in a previous research.

Insect records. The insect taxons from Corbu, sampled in particular in the reed of the neighboring beach are: Coleoptera (Cantharidae: *Rhagonycha fulva*, Curculionidae: *Apion apricans*, Tenebrionidae: *Blaps mucronata*, Coccinelidae: *Coccinella septempunctata*, Meloidae: *Mylabris floralis*, Melolonthidae: *Polyphylla fullo*); Heteroptera (Pentastomidae: *Ancyrosoma albolineatum*, *Aelia acuminata*, *Dolycoris baccarum*, Scutelleridae: *Eurygaster* spp., Lygaeidae: *Lygaeus equestris*, Nepidae: *Ranatra linearis*, Rhopalidae: *Rhopalus* spp.); Homoptera (Cicadellidae: *Asiraca clavicornis*); Orthoptera (Tettigonidae: *Decticus verrucivorus*, Acrididae: *Dociostaurus maroccanus*); Neuroptera (Chrysopidae: *Chrysopa perla*).

From the dune vegetation of Vadu area, we sampled and identified so far the following insect taxons: Coleoptera (Chrysomelidae: *Cassida nebulosa*); Heteroptera (Pentatomidae: *Dolycoris baccarum*, *Eurydema spectabilis*); Homoptera (Cicadellidae: *Macrosteles sexnotatus*); Hymenoptera (Vespidae: *Vespa velutina*); Lepidoptera (Lymantriidae: *Leucoma salicis*, *Penthophera morio*); Mantodea (Mantidae: *Mantis religiosa*); Orthoptera (Acrididae: *Calliptamus italicus*; Gryllidae: *Gryllus campestris*; Tettigonidae: *Decticus verrucivorus*, *Tettigonia viridissima*).

Mollusk fauna. On both beaches, we noticed species of Gastropoda (*Cyclope neritea*, *Hinia reticulata*, *Rapana venosa*) and Bivalvia (*Anadara* spp., *Cerastoderma edule*, *Chamelea*

gallina, Donax trunculus, Mya arenaria, Mytilus galloprovincialis, Ostrea taurica, Spisula spp., *Tellina tenuis*). The empty shells of european razor clam, *Solen marginatus*, characteristic for slightly muddy fine sands, was found in Vadu beach and has been reported so far only in few sites from the Romanian coastline (NIMIRD Report, 2011).

Avifaunistic diversity in Vadu area. In recent years, this area has been constantly visited, in individual filed trips or as active member (Mihai, unpublished data, 2007-2013) in the ornithological camps organized by ROS. At the end of July 2013, were recorded 92 species of birds belonging to 35 families, as follows: Podicipedidae (*Podiceps cristatus, P. nigricollis, Tachybaptus ruficollis*); Pelecanidae (*Pelecanus crispus, P. onocrotalus,*); Phalacrocoracidae (*Phalacrocorax carbo, P. pygmeus*); Ardeidae (*Ardea cinerea, A. purpurea, Ardeola ralloides, Casmerodius albus, Egretta garzetta, Ixobrychus minutus, Nycticorax nycticorax*); Threskiornithidae (*Plegadis falcinellus, P. leucorodia*); Ciconiidae (*Ciconia ciconia*); Anatidae (*Cygnus olor, Anser anser, Anas plathyrynchos, A. strepera, A. penelope, A. crecca, A. clypeata, Tadorna tadorna, T. feruginea, Aythya ferina, A. nyroca*); Accipitridae (*Buteo buteo, B. rufinus, Circus aeroginosus*); Falconidae (*Falco subbuteo, F. tinnunculus*); Rallidae (*Fulica atra, Gallinula chloropus*); Haematopodidae (*Haematopus ostralegus*); Charadriidae (*Charadrius alexandrinus, C. dubius, C. hiaticula, Vanellus vanellus*); Scolopacidae (*Actitis hypoleucos, Calidris alba, C. ferruginea, C. minuta, C. temminckii, Gallinago gallinag, Limosa limosa, Limicola falcinellus, Numenius arquata, Philomachus pugnax, Tringa stagnatilis, T. totanus*); Recurvirostridae (*Himantopus himantopus, Recurvirostra avosetta*); Glareolidae (*Glareola pratincola*); Laridae (*Larus argentatus, L. melanocephalus, L. ridibundus*); Sternidae (*Chlidonias hybridus, C. leucopterus, C. niger, Sterna albifrons, S. hirundo, S. sandvicensis*); Columbidae (*Streptopelia decaocto*); Cuculidae (*Cuculus canorus*); Strigidae (*Athene noctua*)*;* Meropidae (*Merops apiaster*); Coracidae (*Coracias garrulus*); Picidae (*Jynx torquilla*); Alaudide (*Galerida cristata*); *Hirundinidae* (*Hirundo rustica*); Motacillidae *(Motacilla alba, Motacilla flava);* Laniidae (*Lanius collurio*); Sturnidae (*Sturnus vulgaris*); Corvidae (*Corvus corone cornix, C. monedula, Pica pica*); Sylviidae (*Acrocephalus arundinaceus, A. schoenobaenus, Locustella luscinoides, Phylloscopus collybita, P. sibilatrix, Sylvia curruca*); Muscicapidae (*Muscicapa striata*); Turdidae (*Erithacus rubecula, Oenanthe oenanthe*); Timaliidae (*Panurus biarmicus*); Passeridae (*Passer domesticus, P. montanus*); Emberizidae (*Emberiza schoenilus*).

It should be noted that, over the years, in Vadu area we had the opportuniy to observe, in different seasons, extremely rare species of birds for Romanian fauna. In order to highlight the importance of this area for global avifauna, some birds worth mentioning are terek sandpiper (*Xenus cinereus*), observed in 16.08.2007 and also yellow-browed warbler (*Phylloscopus inornatus*) which could be seen in 29.09.2013.

Besides the Scolopacidae, other abundant in species composition were Anatidae and Ardeidae bird families. Our results can be compared with those of Dorosencu et al. (2004), who observed 177 species of birds in Vadu area, between 18.08.2003 and 01.09.2003. Like in this previous study, we found that the most well represented was the order of Charadriiformes.

Ecological relationships in the study area. In both observed sites, the associations of bushes with *Eleagnus angustifolia* and *Hippophae rhamnoides*, which grow along the sand banks, are important feeding and resting place during the migration of the passerines species (Dorosencu et al., 2004).

The sea buckthorn (*Hippophae rhamnoides*), whose distribution is due to frugivorous birds and vegetative spreading, it is now considered a plant species for dunes formations and stabilization (Strat, 2013).

A typical plant adapted to sand and salt soil, the sea holly (*Eryngium maritimum*), represents an important shelter for insect populations, the main source of food for insectivorous (*Sylvia curruca, Phylloscopus collybita, Phylloscopus sibilatrix, Muscicapa striata, Oenanthe*

oenanthe, Erithacus rubecula) and omnivorous (*Passer domesticus, Sturnus vulgaris, Cuculus canorus)* birds (Ion et al., 2009).
As regarding insect-plant associations, we encountered the trophic relationships between the shield bug (*Eurydema spectabilis*) and the bushes of sea kale (*Crambe maritima*) (Figure 1 a, b) and also between *Carpocoris pudicus* and the sea holly (*Eryngium maritimum*) (Figure 1 c). Both pentatomid species populate the terrestrial littoral biotopes like beach strips with herbaceous vegetation (Skolka, 2008). Also, in the neighboring wetlands of the Corbu beach, the common red soldier beetle (*Rhagonycha fulva*) is a pollinator visiting the inflorescence of the wild carrot (*Daucus carota*) (Figure 1 d).

Figure 1. Insect-plant associations in the study area: a, b: *Eurydema spectabilis* on sea kale (Vadu), c. *Carpocoris pudicus* on sea holly (Vadu), d. *Rhagonycha fulva* on wild carrot (Corbu).

Anthropogenic impact. The human impact is signaled in particular by the garbage thrown by tourists near their tents, cars or trailers parked on the beach. Travelling by cars, motorbikes or boats near the birds' colonies, waste and camping are among the pressures involved in Vadu-Corbu area (TRANSDANUBE, 2014).
As informative and awareness panels installed on Corbu and Vadu beaches recall, camping is permitted only in authorized campsites of the DDBR, properly equipped according to sanitary requirements (www.ddbra.ro/). Also, abandoning waste and plastic packaging, paper, metal or glass is not allowed and is financially penalized. However, every year, the behavior of some tourists proves otherwise (Figure 2). In addition, the disgusting exposed feces, surrounded by used toiled paper, randomly thrown in vegetation, besides the deterioration of the beauty and the balance of natural landscape, could also have negative implications upon the human health.
In terms of helping the affected ecosystems, a good thing seems to be the involvement of volunteers in greening activities. It is a tradition that the Romanian Ornithological Society organizes in the Danube Delta and the sea shore area Vadu-Chituc each year the National

Ornithological Camp, whose members conducting a campaign of collecting the trash on the beach (Figure 3).
Unfortunately, measures to protect the biodiversity of this area are almost nonexistent. Access to the Corbu-Vadu area was not restricted in the last years, leading to abuses made by poachers and people who vandalize plants and any creatures they meet.

Figure 2. Human waste persists in the protected areas of DDBR, despite warnings.

Figure 3. Waste collection campaign in Vadu area, organized by Romanian Ornithological Society.

On the other hand, as there is no management plan in this area, travelers departing leave behind mountains of trash, which mostly affect wildlife fauna or birds that can swallow non-digestible pieces of rubbish, like sharp plastic or glass shards. Moreover, there are Romanian and foreign companies interested in developing residential and leisure complex on the Vadu beach. The Romanian media and the environmental NGOs make desperate efforts to bring to light the abuses from political and administrative environment. First, these constructions violate the administrative laws of the protected areas and perhaps most important is that such buildings in the protected area of DDBR will have negative and irreversible effects upon the important natural heritage worldwide.

Conclusion

Without being exhaustive, the present study still brings a solid contribution to the knowledge of the recent biodiversity in Corbu-Vadu protected zones from the Danube Delta Biosphere Reserve. As other papers and reports pointed out, these sites of the Romanian seacoast offer excellent opportunities both for responsible camping in nature and specialists research (botanists, zoologists, ecologists).
The biological inventory compiled during the summers of 2013 and 2014 included vascular flora, invertebrates (insects, mollusks inhabiting the sandy beaches) and birds.

In terms of the numbers of species, best represented were the following taxons: Asteraceae, Heteroptera and Charadriiformes. Regarding the clams, in Vadu seashore we found empty shells of *Solen marginatus*, a rare presence on Romanian coastline.

Our qualitative survey highlighted also few trophic adaptations of some living organisms in Corbu-Vadu area, like pentatomid bugs associated to their wild plant hosts. Among ecological relationships established in the studied zones, we found that sea buckthorn bushes are important feeding and resting place for the passerines species, while the sea holly represents a good shelter for insect populations, the main source of food for insectivorous and omnivorous birds.

Unfortunately, the anthropogenic impact (feces and toilet paper thrown in vegetation, garbage left by tourists near their tents or cars parked on the beach) is destroying the human health and natural ecosystems. Thus, typical plants of the coastal dunes, *Eryngium maritimum* and *Crambe maritima* seem to be affected by the inadequately controlled economic development and tourism.

Luckily, the members of the National Ornithological Camp organized each year by the Romanian Ornithological Society, lead a campaign of collecting the human waste on the Vadu beach.

Considering the species richness in the area, in near future it should be considered special management measures, in order to protect the environment and limiting the access of the tourists.

THE RECYCLING AND EVALUATION OF LF SLAG FOR SOIL ACIDITY NEUTRALIZATION

Abstract

The aim of the current research was to investigate the properties of some new materials in order to improve the soil acidity and to evaluate to effect of slag from steel refinery on chromic luvisol physico-chemical properties.

Yearly, in Romania are produced from 0.18 up to 0.2 million tonnes of ladle slag that is classified as a dangerous waste due to increased alkalinity. Ladle slag (LF slag) results from steel secondary refinery and cannot be recycled in the process because the iron content is too small. In the same time, ladle slag contains high percent of calcium oxide and other calcium compounds.

Having in view those above mentioned, was developed an experiment at the experimental field from Moara Domneasca using ladle slag as amendment that induce a correction of acidic reaction of soil.

The experiment was designed with five experimental variants with three replicates for each variant: V_1 (control), V_2(1 t/ha), V_3(2 t/ha), V_4(3 t/ha) and V_5(5 t/ha). The biological material used in this experiment was maize in 2013 and wheat in 2014.

The results indicated that slag can be used successfully to correct soil acidity, to improve the main physico-chemical properties of soil and the increase of soil fertility.

Slag from the steel industry brings increases of calcium and micronutrients levels in the soil.

There was an increase in the reaction of chromic luvisol with increasing rate from 5.7 to 6.72 at 20-40 cm depth. The highest yield of maize, 7.97 t ha^{-1}, was obtained in V_4 (5 t/ha) and biomass production was higher in treated variants compared to the control variant. Largest wheat yield increases were achieved as a consequence of the rate of 5 t/ha with nitrogen mineral fertilizers.

Keywords*: recycling, LF slag, soil, acidity, wheat, maize*

Introduction

Utilization of industrial waste materials in order to improve problematic soils is cost efficient and environmental friendly method, as well; it helps in reducing disposal problems caused by the various industrial wastes. The surface of the soil suffers an acidification process especially under no liming conditions, soil pH values less than 5.5 ensuring conditions for strong solubilization of pollutants and their translocation into plants. In Romania more 2 million ha are soils with moderately acid and highly acid reaction (Fig. 1).

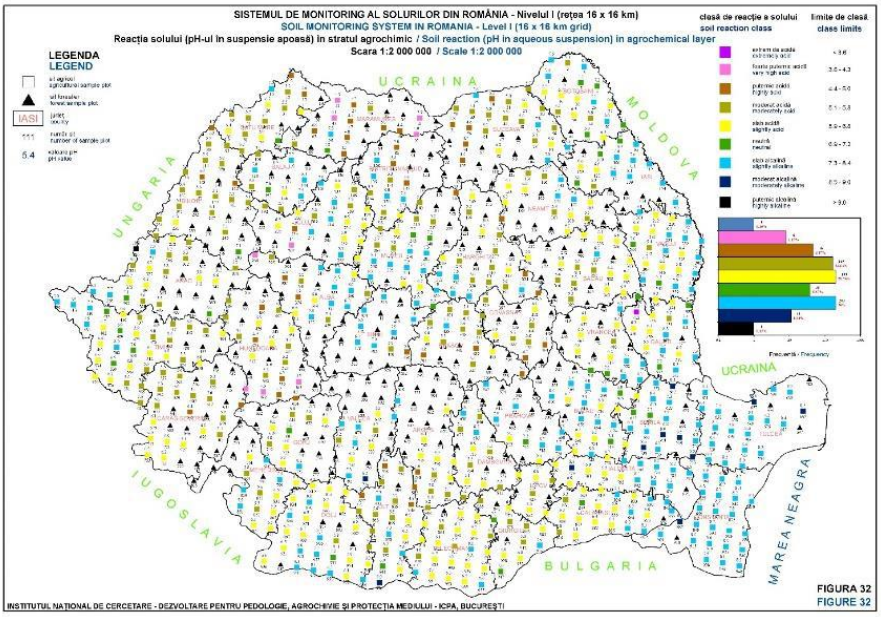

Figure 1. Soil reaction in agrochemical layer from Romania

Yearly, about 45 million tons of LF slag are generated in Europe (www.euroslag.com).
The steel industry produces not only metal, but also by-products which have been successfully used for construction and/or agriculture purposes.
The awareness of environmental considerations and more recently the concept of sustainable development as well as the need for recycling of by-products for economic and environmental reasons has led to rapid development of slag utilization.
The use of fertilizers and liming materials produced from blast furnace and steel slag has a long tradition. For example Thomas phosphate had been used for more than hundred years.
Silicate lime fertilizers (blast furnace lime and converter lime) are approved fertilizers in Germany for more than 60 and 30 years, respectively. They contain elements with useful properties for plant nutrition and soil quality.
The solubility of silicate from slag is often higher than from many other silicate containing soil improvers or rock powders. Blast furnace lime has a mild effect on soil pH. Therefore, it is recommended especially for use on humus, sandy and peat soils. In addition, the high silicate and magnesium content which is readily available to plants promotes yields and plant qualities.
The basicity of the calcium and magnesium compounds in the slag improves soil pH. Both elements also serve as plant nutrients and stabilisers for soil aggregates. Magnesium in slags especially in blast furnace slag has a better solubility than that of magnesium carbonate in limestone and dolomite. Silicate has beneficial effects on plant health, phosphate availability and soil structure. The content of trace elements like manganese, copper, zinc, boron or cobalt satisfies both plant and animal demands (Rex M., 2010).
Mohammadi T. concluded that these materials used on the acid soil increased soil pH and DTPA extractable P more than paper mill sludge (PMS) and increased Mn proportional to the slag application rate, while PMS decreased it.
Aim of this study was testing impact of LF slag application on soil properties and yields of maize and wheat in rotation.

Materials and methods

The field experiment

The stationary field experimental was started in autumn 2012 in the experimental field of the Faculty of Agriculture from Moara Domneasca on chromic luvisol (Fig. 2 and 3). Four rates of LF slag (1, 2, 3 and 5 t^{-1}) and control (without LF slag) were applied. The experimental was performed by randomized block in three replicated (basic plot has 30 m^2). Maize (LG 30.489 hybrid) was grown in the first year (2013) while winter wheat (*Glosa* variety) was grown in the second year of the experiment (2014). The experimental plot was fertilized as follows (kg/ha^{-1}): without mineral fertilized at maize and $100N+0P_2O_5+0K_2O$ (wheat).

Figures 2,3. Experimental field from Moara Domnească, Ilfov County (2013)

Soil characteristics before starting of the experiment

The chromic luvisol is characterized by a clay loam texture, organic matter content of 2.4% and a low acid pH with values of 5.0-5.4 (Mihalache et al., 2013).

Sampling, chemical and statistical analysis

Samples of LF slag were analyzed by Optic Spectometry with plasma inductively coupled ICP-OES, for iron, magnesium, aluminium, silica etc.

In order to show the amendment effect on the main chemical properties of chromic luvisol, soil samples on two depths were taken (0-20 cm and 20-40 cm) from all basic plot. The following soil measurements were performed: the soil reaction (pH) was carried out through potentiometric method, in an aqueous suspension, 1:2.5 (w/v). For determining the reaction of the soil it was used WTW 750 pH-meter; organic carbon was determined using the Walkley-Black-Gogoasa method; humus content was calculated (C_{org}x1.724); phosphorus content was evaluated by spectrophotometric molybdenum blue method, using ammonium acetate-lactate (AL) as extractive solution, at pH 3.7 (Egner-Riehm-Domingo method); total form of nitrogen was determined using Kjeldahl method, meanwhile total phosphorus was assessed spectrophotometrically (as molybdenum blue) and potassium using flame photometry method. Soil samples were collected in the 0-20 cm and 20-40 cm depth for all experimental variants to follow influence on soil reaction and the wheat yield. The obtained data were statistically processed by analyses of variance.

Results and discussions

The material used as amendment has a high content of Ca 43.50% and reaction is strongly alkaline (pH=11.08). In addition, to the high content of calcium, the material has a high content of magnesium and iron, as well. The chemical composition of LF Slag used in experimental field is presented as it follows: Fe 10.55%; Mg 4.10%; Al 2.27%; Si 8.70% and Na 0.034%. The heavy metals found content is less than maximum allowable limits.

Amendment application on the chromic luvisol from Moara Domneasca produced an increase of soil reaction at 0-20 cm depth from 5.51 in control variant up to 6.01 in variant with 5 t/ha of ash applied (table 1). A significant increase of soil reaction was recorded since at the first year of slag application at 20-40 cm depth the pH rised from 5.55 in control variant to 6.35 in variant with 5 t/ha of LF slag applied.

Table 1. The effects of LF slag upon main chemical properties of chromic luvisol (2013)

LF slag t/ha^{-1}	Soil depth 0-20 cm					Soil depth 20-40 cm				
	pH $_{H2O}$	Percent		mg kg^{-1}		pH $_{H2O}$	Percent		mg kg^{-1}	
		C org	N	P	K		C org	N	P	K
0	5.51	1.21	0.147	74	230	5.55	1.23	0.158	87	235
1	5.68	1.35	0.157	106	225	5.77	1.31	0.153	108	270
2	5.80	1.28	0.153	97	298	5.92	1.23	0.155	105	287
3	5.78	1.25	0.151	85	299	5.95	1.21	0.157	87	326
5	6.01	1.32	0.157	78	311	6.35	1.25	0.132	89	317
	LSD values					LSD values				
5%	0.016	0.019	0.0011	1.68	1.64	0.015	0.023	0.003	2.062	1.898
1%	0.024	0.028	0.0016	2.45	2.40	0.023	0.034	0.004	3.001	2.762
0.1%	0.036	0.042	0.0024	3.68	3.60	0.035	0.051	0.006	4.509	4.150

At 20-40 cm depth the phosphorus content increased from 87 mg kg^{-1} to 108 mg kg^{-1}in the case of application of 1 t/ha of amendment. Significant increases of soil phosphorus content were recorded in all experimental variants in comparison with control variant (no limestone amendment application).

Maize yield was positively influenced by the application of different rates of LF slag, in the control variant being 72.15 q/ha; in variant V_5 (5 t/ha) the yield increased to 79.66 q/ha. Yield growth was 4.13 q/ha to V_2 (1 t/ha), 2.83 q/ha to V_3, 2.1 q/ha to V_4 and 1.50 q/ha to V_5 (5 t/ha).

Table 2
Impact of LF slag application on maize (the 2013 crop year) and wheat (2013/2014 crop year)

LF slag t/ha^{-1}	Maize (2013) yield t/ha^{-1}	Wheat (LF slag +0 N and LF slag +100 kg N ha^{-1})					
		Winter wheat yield t/ha^{-1}		Ears number per square meter		Soil pH (H_2O)	
		0 N	100 N	0 N	100 N	0 N	100 N

0.1%	0.68	0.70	0.67	7.36	16.89	0.14	0.29

In 2014, the amendment application improved the chemical properties of chromic luvisol by increasing soil reaction with slag application rate (Table 2).

Figures 4. The variation of soil reaction on the depth 0-20 cm (2014)

High yields were obtained due to the residual effect of amendment and application of 100 kg of nitrogen. The highest yield was obtained by applying a LF slag rate of 5 t/ha. Our opinion is that applying LF slag rates of 3 t/ha are recorded yield increases that are significant under soil and climatic conditions of Moara Domneasca (Fig. 4).

Direct application of various rates of slag caused, depending on the rate applied, better wheat crop development, a greater number of ears and a significant increase of wheat yield in 2014 from 4.6 t ha $^{-1}$ at control variant to 6.3 t ha $^{-1}$ in the variant with 5 t/ha LF slag. The number of wheat ears was between 482-600 ears/m^2.

Research conducted with various plants showed an increase of production, due to better use of plant nutrients by changing the soil reaction.

The highest yield in climatic conditions of the year 2014, were recorded by applying slag and fertilization with 100 kg nitrogen, respectively by applying the LF slag rate of 2 t/ha the yield was 7.3 t ha $^{-1}$ and 7.9 t ha $^{-1}$ for LF slag rate of 5 t/ha. To obtain high yields are recommended amendment and mineral fertilizers application.

Conclusions

These wastes from secondary refinery of the steel can be used with good results in agriculture and with positive influences on the maize and wheat crops.

LF slag resulted from the refinery of the steel may be used as amendment for correction of the acidic soil reaction.

Slag from the steel industry brings increases of calcium and micronutrients levels in the soil.

There was an increase in the reaction of chromic luvisol with increasing rate from 5.7 to 6.72 at 20-40 cm depth.

The harvest increase per tonne of LF slag was 0.4 t ha^{-1} at a rate of 1 t/ha and 0.15 t ha^{-1} at a rate of 5 t/ha.

The highest yield of maize, 7.97 t ha^{-1}, was obtained in V_4 (5 t/ha) and biomass production was higher in treated variants compared to the control variant.

Yield increases registered on chromic luvisol under conditions of 2014, on the wheat crop, was significant due to better recovery of nutrients. Largest yield increases were achieved as a consequence of the rate of 5 t/ha with nitrogen mineral fertilizers.

The presented research have revealed that there is a residual effect of slag reflected by soil reaction and increased yields at rates above 2 t/ha.

The research that was carried out allowed us to recommend applying slag to 3-4 years this depending on the chemical composition of the slag and heavy metals content, in order to avoid environmental issues.

Acknowledgments

The researches carried out for the elaboration of the present paper were financed by Romanian Program “Partnerships for Priority Domains”, project PN-II-PT-PCCA-2011-3.2-0807 “Amelioration Acid Soils using Waste from Metallurgical Industry” (AMELSOL), Contract no. 122/2012.

GRANULOMETRY FEATURES IN MOUNTAIN SOILS

Iraida SAMOFALOVA

Perm State Agricultural Academy, Perm, Russia
*Corresponding author: samofalovairaida@mail.ru

Abstract

Grain size distribution is an important physical characteristic of the soil and one of the characteristics of its dispersion. We studied the grain size distribution of mountain soils in subalpine zone in the Middle Urals. Results show grain size distribution of the soil varies from medium loamy to clay, depending on the location of the formation of soils and dominant vegetation type. In the soils under subalpine meadows marked accumulation of large and medium content of sand in the profile, which indicates that the prevalence of physical weathering and sand particles can bring to the surrounding areas as a result of denudation. Soils have a stable same structure particle size distribution with predominance of the average content of coarse dust in the structure. Statistical distribution analysis is determined for the content of sand, silt and clay fraction. The average content of clay particles in the soil under the crooked and subalpine meadows is slightly more than 15%, and in the soils of park woodlands – 30% with a maximum variation in space. Thus, the distribution of size fractions in the soil profile and their relationship to each other are diagnostic indicators of elementary soil-forming processes in the burozems, litozems, organo-accumulative soils of the subalpine zone, which are expressed in the title of the classification of soils.

Keywords*: mountain soils, subalpine meadows, elementary soil particles, clay, grain size distribution*

Introduction

Grain size distribution is a basic soil property as so as it defines all the major soil processes. Grain size distribution (GSD) expressed in terms of content of the grain size fractions is an important physical characteristic of the soil and one of the characteristics of its dispensability. The soil GSD also provides insight into the genesis, evolution and use of soils (Tatarintsev, 1998. Tatarintsev et al., 2008. 2012). Soil physical properties depend not so much on the content of physical clay (FC) but on the ratio of the grain size fractions that determine the characteristics of structure and function at higher levels of organization of the soil. The ratio of size fraction in grain size distribution, particularly sand, coarse dust, and the average amount of fine dust and sludge, N.A. Kaczynski (1958) refered to as a soil type, V.P. Panvilov (1973) and V.L. Tatarincev (1998) as structure, I.V. Mikheeva (2001, 2005, 2012) as formula, and E.V. Shein (Theories and techniques of soil physics, 2007) as a texture of grain size distribution. By the distribution of particle content by size, we can characterize the studied object detailed enough and compare different soil sites.

The purpose of the research is to determine the particle size characteristics of mountain soils in the subalpine belt in the Middle Urals.

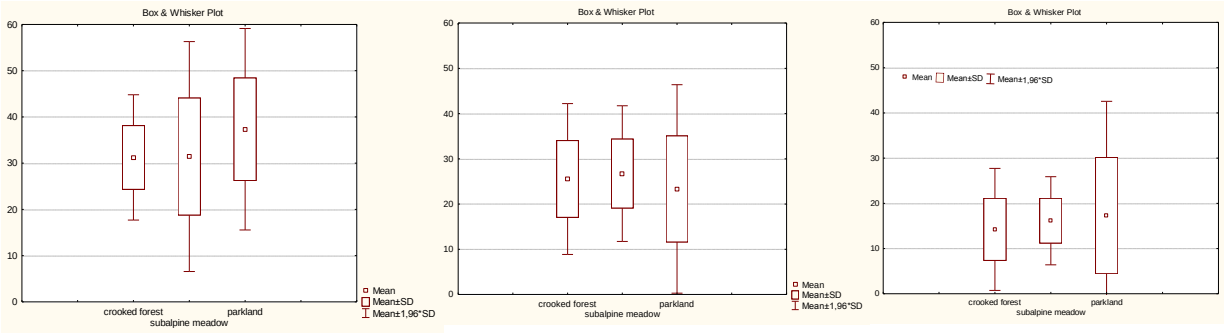
Materials and methods

We carried out the investigations in 2012-2014 on the territory of "Basegi" State National Reserve. Soil cross sections were made on the mountain of North Basegi (height 951.9 m asl) in the subalpine belt (crooked forest, subalpine meadows, parkland at an altitude of 920-557 m asl on the western macroslope of the Northern Urals. A total of 36 cross sections were made in a subgoltsy belt (8 cross sections in the crooked forest sub-belt, 18 in subalpine

meadows, 10 in parkland). Russian profile-substantive soil classification of year 2004 was used to describe and identify the names of the soils. We measured soil grain size distribution with pipette method, version of N.A. Kaczynski (with pyrophosphate method of soil preparation to the analysis). Statistical analysis of study data was performed in the "Data Analysis" software in Microsoft Excel and the STATISTICA 5.0 software.
The investigated mountain soils belong to the stem of postlitogenic soil forming. Based on morphogenetic characteristics of soils, the following formations were identified: lithosoils (layer thickness less than 30 cm), structural and metamorphic (picked horizon BM), organic-accumulative (median horizon is not pronounced as an independent genetic formation).

Results and discussion

Soil grain size distribution in the subalpine belt is lightweight medium loamy and light loamy in humus horizons and becomes heavier, heavy loamy and clay in roach. The ratio of elementary soil particles (ESP) in soil content is a result of manifestation and interaction of soil-forming processes and physical weathering.
ESP distribution through the soil profile is given by sub-belts (Fig. 1). The minimum of the average index by the content of the sand fraction is typical of soils in subalpine meadows, but the variation of the index is maximum (Fig. 1a). The minimum variation of the sand fraction is noted in soils in crooked forest. The minimum value of the average content of coarse-silty fraction is typical of soils in crooked forest and the maximum of park woodland soils (Fig. 1b). Less index variation is noted for soil in subalpine meadows and greater for parkland soil. The minimum value of the average index for the clay fraction is typical of soils in subalpine sub-belt (Fig. 1c). The maximum variation of the index observed in the soils of parklands and the minimum in the soils of sparse forest.



a) b) c)

Fig. 1. Statistical diagrams (Box Plots) of distribution range of grain size fractions content: a) sand fraction, 100-50 mkm; b) coarse-silty fraction, 50-10 mkm; c) clay fraction, <10 mkm (crooked forest n=9, subalpine meadow n=16, parkland n=8)

Thus, the content and the ratio of ESP factions is different within the subalpine belt. Sand and clay fractions content is more stable in crooked forest soils. Subalpine meadows soils have a smaller variation of the clay fraction. In parklands, soils are characterized by diversity of all factions content.
ESP accumulation and removal throughout the soil profile varies in the Middle Urals. At higher elevations (920 m) in crooked forest there is a sharp reduction of the clay fraction content, while the the silt fraction content in the profile does not change and the sand and coarse-silty fraction increase down the profile (Fig. 2).

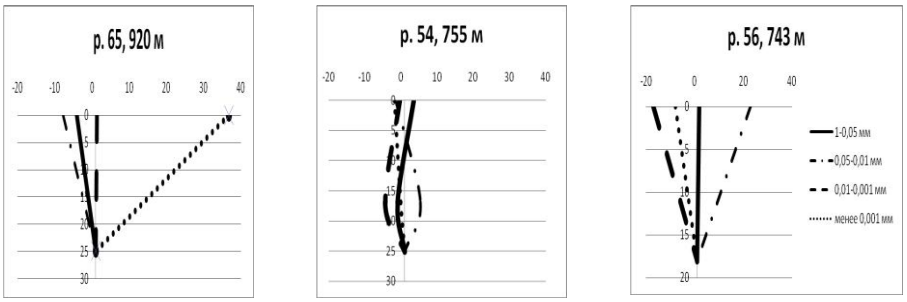


Fig. 2. Size fractions in grain size distribution of crooked forest soils

At an altitude of 750-800 m in the middle of the soil profile accumulation of coarse-silty fraction is marked. In litho-gley soils (c. 56) there is depletion of silt and clay fractions and a sharp increase of their content in roach. Thus, different elementary soil particles ratio in the grain size distribution is formed in crooked forest soils depending on the conditions of soil forming.

In subalpine meadows soils (Fig. 3) grain size fractions distribution in organic-accumulative soils (c. 69, 68, 63, 66) proceeds as follows: accumulation of silt and depletion of sand fraction in the upper horizons, followed by a decrease and an increase in roach, correspondingly. Organic-accumulative soil at an altitude of 700 m (c. 5) has the lowest content of coarse-silty and clay fractions.

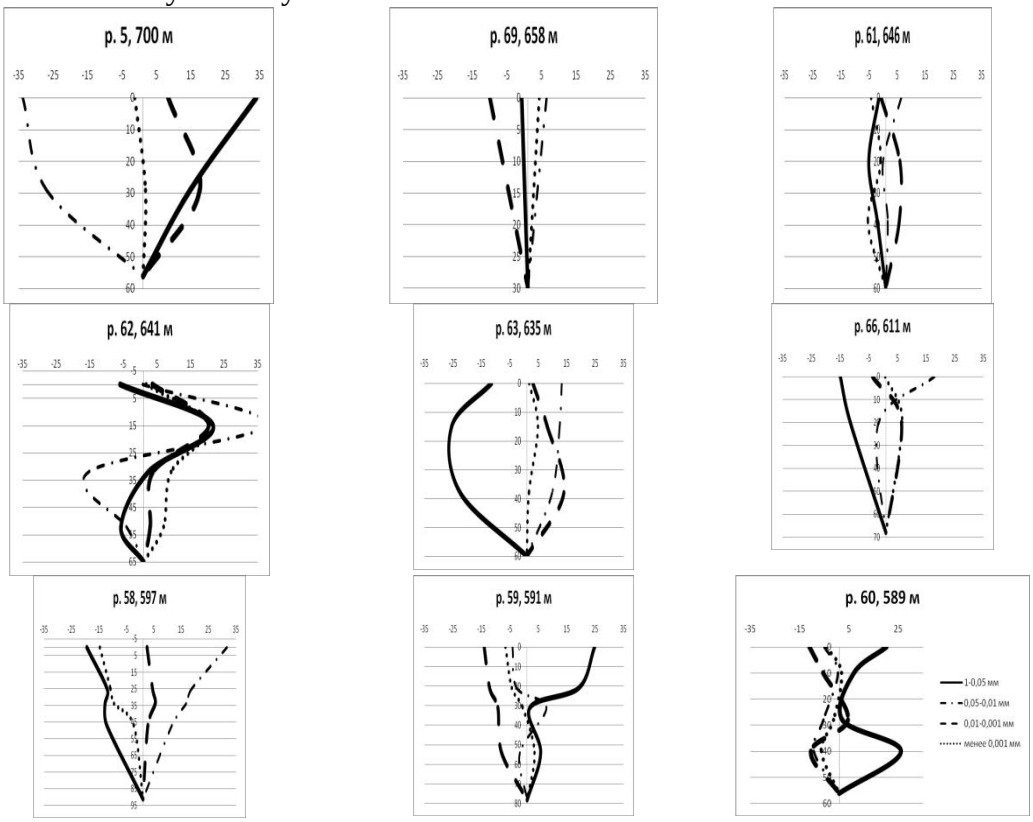

Fig. 3 Grain size fraction distribution in subalpine meadows soils

Fossil organic-accumulative soil at an altitude of 589 m (c. 60) has complex fractions distribution. In the humus horizon there is an accumulation of sand fraction, followed by a decrease in it, but in the fossil horizon [AY] there is an increase in sand content. The content of silt and clay fraction increases with depth, and in the horizon [AY] a reduction in the

content of these fractions occurs with a subsequent increase in roach. Thus, this ESP distribution leads to the conclusion that the soil is polygenetic.
In grey metamorphic soils, elementary soil particles content have a different ratio. So, in c. 61 there is a reduction in clay and sand fraction and an increase in coarse-silty and silty fraction, and in c. 62 all fraction increase and then decrease in roach.
In brown soils (c. 58, 59), more diversified ratio of the particles is observed and an increase of the clay fraction in roach occurs.
In organic-accumulative soils (c. 55, 73, 72) of parklands (Fig. 4) sand fraction content decreases and accumulation of coarse-silt fraction occurs. At an altitude of 570 m (c. 1) the soil is depleted with sand fraction, and clay fraction increases with depth, but then reduces again in roach. Clay-elluvial brown soil (c. 57) has a low content of clay fraction. Grey humus lithosoil is depleted with silt and clay fractions through the profile and, on the contrary, enriched with sand and coarse-silt particles.

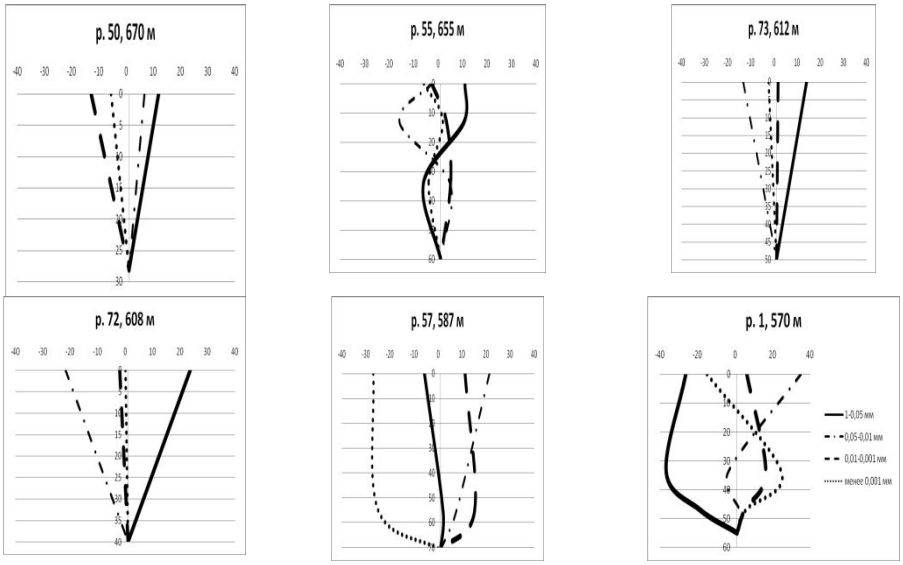

Fig. 4. Size fractions in grain size distribution in parkland soils

We have conducted a correlation analysis to determine the relationship between the content of GSD fractions and soil properties. Thus, in crooked forest soils contents of all fractions is primarily dependent on the altitude. In addition, the sand fraction content has a close inverse relationship with the profile thickness (r = 0.85). The content of the clay fraction has a very close relationship with the profile thickness and medium relationship with the soil rubbility, and the average inverse relationship with the altitude (r = -0.47).
In subalpine meadows sub-belt the content of coarse-silty fraction has an inverse strong relationship with the altitude (r = -0.73). The content of the clay fraction in soils of subalpine meadows is most strongly related to the profile thickness (r = 0.73) and average with soils rubbility (r = 0.45).
In soils of parklands, a close inverse relationship with the profile thickness observed for the silt and coarse-silt fraction, and the average relationship for clay and sand fraction. The content of silt fraction has close inverse relationship (r = -0.92) with area altitude, and sand fraction has an average inverse relationship with it.

Conclusion

Grain size distribution is an important soil diagnostic feature, because it helps to determine the degree of profile elluviality and illuviality. Soil profile differentiation by grain size

distribution is a result of regular changes in the activity profile of chemical and physical weathering, and relations between them. Location of soil at an altitude affects the grain size distribution due to different manifestations of denudation and steepness of the slope which affects the processes occurring in the soil and respectively the distribution of elementary soil particles.

The following features can be distinguished based on soil grain size in subalpine belt: grain size distribution is loamy; high content of coarse-silty fraction associated with the presence of physical processes of rocks and minerals weathering; distribution of coarse silt through the profile is very poorly differentiated; soil profile is mostly differentiated by the content of sand and silt fractions; ratio of elementary soil particles depends on the area altitude and vegetation at this altitude, as well as on the soil profile thickness.

Abstract

Chitosan is a promising component for modification of the prescription food due to functional-technological and bio-correction properties. Traditional resource base of chitosan - nibs from the shells of crab - has a high cost and limited resources. The evaluation of process efficiency in the use of alternative raw materials - shells of freshwater crayfish, shrimp, industrial waste recycling oyster mushroom for dietary chitosan. Technological parameters in assessing the effectiveness of various types of raw materials were the number of stages in the production of chitosan, the total duration of the process of chitosan and the output of the finished product. Chitosan from various sources received by traditional technology, comprising the sequential steps of deproteinization and demineralization of chitin-containing raw material obtained by deacetylation of chitin. The results show that for dietary chitosan to use the most technologically advanced crab by-products raw shrimp in comparison with other sources available in the regions remote from the pool of the king crab catch. The rational dosage of chitosan in compoundings of the meat chopped semi-finished products focused on a segment of the market of consumers with average level of the income is proved. It is shown that chitosan from an armor of a shrimp provides increase of functional and technological properties of mincemeat in the range of concentration of 1-4%. On the basis of an organoleptic assessment of products its dosage – 2% to the mass of meat raw materials is defined. Quality of the developed meat chopped semi-finished products with addition chitosan conformed to requirements of normative documents.

Keywords: *Chitin, chitosan, polymers, degree of deacetylation, functional properties*.

Introduction

Actual problem at the present stage of the development of engineering and technology is the safety of biological systems. This problem is directly linked to the health of the person in modern conditions, which are characterized by unfavorable environmental conditions over large areas, pollution from human waste, especially waste of polymeric materials.

The most important task facing the food industry - the preservation and maintenance of human health through nutrition. Another important task is to ensure the safety and sustainability of products and industries, which is to develop effective and efficient ways for processing of secondary resources sector of agriculture. Perspective raw material for the decision of tasks is a natural biopolymer – chitosan [Alieva, 2001; Antipova et al., 2004; Varlamov, 2002]. This polymer has many unique properties: high biological activity and compatibility with the tissues of humans, animals and plants, does not pollute the environment, because it is destroyed by enzymes of microorganisms, can be widely applied in environmental protection [Nikitenko et al, 2013; Slivkin et al, 2013].

Objective: to evaluate the technological efficiency in the use of alternative raw materials - shells of freshwater crayfish, shrimps, industrial waste recycling of oyster mushroom for production food chitosan and for its appropriate dosage with the composition of meat stuffing.

Materials and methods

We used crab shell containing raw material (SCRM) obtained in the industrial processing of freshwater crayfish, Arctic shrimp, as well as chitin-containing industrial wastes of mushrooms of the genus Pleurotus, meat minced systems based on beef and pork from only one variety of trimming, which was used as the basis for the development of modified recipes of meatballs and schnitzels and burgers and schnitzels culinary readiness with the use of chitosan in the range of concentrations from 1 to 4 % by weight of raw meat. The definition of functional and technological properties of multicomponent meat stuffing systems with chitosan, organoleptic and physico-chemical indicators of the quality of meat products culinary readiness conducted according to the recommendations [Antipova et al., 2004].

Mass fraction of moisture in raw materials and finished products was determined by drying the samples at 100-105 °C for 5 h [Antipova et al., 2004].

Mass fraction of protein in raw materials and products was determined by Kjeldahl method.

Mass fraction of fat in the raw materials was determined by the extraction method for defatted residue in accordance with the recommendations [Antipova et al., 2004].

Mass fraction of mineral substances was determined after combustion of organic matter in a muffle furnace at the temperature of 500-700 °C for 5-6 h to constant mass in accordance with the recommendations [Antipova et al., 2004].

For the isolation of chitin dry crushed raw material was mixed with water in the ratio 1:10, after which the mixture portion has made a concentrated hydrochloric acid at room temperature. At the stage of demineralization the pH change was controlled, at the increasing of pH to 7 the following portion of the acid was added. The demineralization process was considered complete at the pH 3-3,5, not changing for 30 min. It was established experimentally that the total amount of acid introduced at the stage of demineralization, corresponds to a solution of hydrochloric acid with a mass fraction of 4-4,5 %. The period of time during which the portioned acid was added amounted to 60-65 min. Then demineralized SCRM was washed with tap water to pH 6,5-7,0.

For removal of protein fractions (deproteinization) from demineralized SCRM we used the solution of sodium hydroxide with mass share of 5 % at 100 °C for 1,5 hours. Processed with alkali the chitin-containing raw material was cooled to ambient temperature and washed with distilled water to pH 7.0 at a water ratio of 1:6. The obtained chitin was washed and air-dried for 24 hours.

Then there was made the deacetylation of chitin. To dried chitin was added a sodium hydroxide solution with a mass fraction of 50 % and heated in a water bath for 2 h. The solid residue was separated from the liquid fraction by centrifugation and washed with distilled water to pH 7,0. The obtained chitosan was washed with an aqueous solution of ethanol with a volume fraction of 20 % and acetone until colorless, repeatedly washed with distilled water to neutral reaction and dried in air.

The quality of the obtained chitosan was adjusted on a complex of indicators. The content of minerals was established by dry ashing.

The degree of deacetylation was determined by potentiometric titration on universal ionometer EV-74 using a glass electrode.

The molecular weight of chitosan was determined by a standard viscometric method. The measurements were carried out at 250 °C in a capillary viscometer Ubbelohde, the diameter of which is equal to 0.54 mm. Calculation of molecular weight was carried out according to equation of Mark-Kuhn-Houwink [Gartman et al, 2013].

Residual protein in chitosan was determined by the colorimetric method with biuret reagent.

Functional and technological properties of model force meat with chitosan from crab by-products of raw shrimp were determined in accordance with the recommendations of [Antipova et al., 2004].

Results and discussion

The process of allocation of chitin and chitosan was preceded by a general analysis of the chemical composition of raw materials (table 1). The next stage of the study was the determination of the mass fraction of chitin in raw materials of animal and vegetable origin (table 2). Chitin refers to insoluble polymers, therefore, to its separation from the fruiting bodies of mushrooms, crabs and shrimp need a consistent and complete removal of protein and mineral parts of the material – deproteinization (DP) and demineralization (DM).

Table 1 - Total chemical composition of a crayfish shell, and mushrooms of oyster kind.

Object of investigation	Mass share, %				
	Moisture	Protein	Fat	Carbohydrate	Ash
Crayfish (SCRM)	64,54	11,43	0,45	-	13,97
Shrimp SCRM	73,43	8,37	2,12	-	8,98
Oyster mushrooms	89,22	1,67	0,52	6,78	0,81

Table 2 - Content of chitin in SCRM of crayfish and oyster mushrooms

Object of investigation	Mass share of chitin, %
Crayfish (shell)	9,61
Shrimp SCRM	7,18
Oyster mushrooms	0,52

The release of chitosan from various raw material sources was carried out in accordance with the traditional technological scheme which includes crushing stages of the initial raw material, deproteinization, demineralization and deacetylation of obtained chitin [Gartman et al, 2013]. Characterization of physicochemical properties of chitosans obtained by a general process scheme from various sources, illustrates the data presented in table 3. Physico-chemical properties of the obtained products of the deacetylation of chitin identified as meeting the requirements for food chitosan (JC-067-00472124). As it follows from the data presented in table 3, the chitosan from shrimp shell has physicochemical properties similar to the properties of chitosan of other crustaceans, forming in acetic acid solution with a mass fraction of 2% more viscous solutions, and also under the same conditions of obtaining isdistinguished by a higher degree of deacetylation.

Table 3 - Comparative characteristics of physico-chemical qualities of chifosan from different sources

Indices	Permissible meanings for food chitosan (TC 9289-067-00472124)	Sources of chitosan		
		SCRM of Shrimp	SCRM of crayfish fresh	Biomass of oyster mushrooms
Characteristic viscosity (in the 2 % solution of acetic acid), dl/g	Is not normed	11,56	10,7	10,15
Molecular mass, to	Is not normed	56,0	52,0	43,0
Degree of deacetitisation, %	Not less than 75	78	76	75
Ash,%	Not more 0,7	0,4-0,45	0,4-0,5	0,1
pH of 1 % solution in 2 % of CH_3COOH	Not more 7,5	5,9	6,0	6,5
Protein residue, %	Not more than 0,1	0,05-0,1	0,01-0,05	0,04
Mass share of moisture, %	Not more than 0,1	9-10	8-10	8-9
Appearance	Scales size 1-3 mm	Scales size 1-2 mm	Scales size 1-2 mm	The size of particles 0,1-0,2 mm
Bulk mass	Is not normed	0,25-0,4	0,15-0,4	0,6-0,7

These functional properties of chitosan from SCRM shrimp allow to consider it as perspective functional-corrective component of food products. The introduction of chitosan into the water, which does not interact chemically with it, provides a rapid swelling of the polymer, and every bit of chitosan swells separately from the others and the resulting mass (Sol) is homogeneous (free of lumps).It was established that chitosan from shrimp shell has a fast swelling properties: water absorption was 10,9 cm^3/g for 4-5 minutes. The fact that chitosan of shrimp SCRM is a hydrocolloid, determines its potential functionality processing for food purposes of livestock products in branches of meat, fish and dairy industries.

Technological efficiency in the use of SCRM of crawfish, shrimp, industrial waste recycling of mushrooms of the genus Pleurotus for food chitosan was assessed by the following indicators: the number of stages in the production of chitosan, the total duration of the process of obtaining chitosan and the product yield (table 4).

Table 4 - Evaluation of technological efficiency of different kinds of raw materials for obtaining of chitosan

Technological parameters	Kind of raw materials		
	Shrimp	Crayfish	Mushroom
Quantity of stages chitosan production	3	4	5
Total time of chitosan production, h	5	6,5	7
Output of chitosan, % to mass share of the raw material	5,03	4,91	0,45

The results indicate that for the production of food chitosan is technologically better to use SCRM shrimp in comparison with other sources. This is actual for regions that are geographically distant from traditional and new basins of the king crab catch.

Testing of chitosan was performed in the concentration range from 1 to 4% for multicomponent forcemeat systems for meatballs and schnitzels with a ratio the price – quality oriented on consumers with average income. It was investigated the effect of chitosan on functional and technological properties of meat model systems – water-binding capacity (WCC), water-holding capacity (WHC), fat-holding ability (FHA), emulsifying ability (EA) and emulsion stability (ES). In model meat systems we used the stuffing from one-grade beef and pork chopping on the mincer with a hole diameter of the lattice 2-3 mm at the following ratio: 2:1 for meatballs, 5:4 for schnitzel.

It was established that chitosan improves functional and technological properties (FIP) of meat systems. Values of the FIP model stuffing for meatballs and schnitzels had no significant differences. The nature of the effect differed for individual indicators. So, the WCC has increased by 20% on average for the tested systems at the concentration of chitosan 2 %, further increase did not give significant effect. Increase WBC was 14,5 %; stabilization of this indicator occurred at 3 % of chitosan. FHC increased by 21,7 and 22,7 %; EA – 26,05 % 23,11 % for model force meat of for meatballs and schnitzels, respectively, when the mass fraction of chitosan 4 %. Similar curves were obtained for emulsifying ability, it increased by 26,1 and 23,1 %.

In the next phase of research were defined organoleptic characteristics of molded film from model force meat of meat products after cooking. The addition of chitosan in the amount of 1 % does not affects the organoleptic characteristics, 3 % leads to a slight deterioration of taste, and the dose increased to 4 % leads to considerable deterioration.

Conclusions

The established identity of the physico-chemical properties of chitosan, obtained under similar conditions from SCRM of shrimp and freshwater crayfish, testify to their similar chemical nature and molecular structure. Chitosan obtained from mushrooms of the Pleurotus genus, is distinguished by the following characteristics: intrinsic viscosity (in 2 % acetic acid), molecular weight, degree of deacetylation, primarily due to the formation of the chitin, the chitin-glucan complex (CGC).

Technological indicators characterize the chitosan from shrimp SCRM as polymorphic system with a dominant fraction of particles of 1-2 mm, a moisture content of not more than 10 %,

with poor flow ability and a very small bulk mass.
The viscosity of chitosan solution in acetic acid solution with a mass fraction of 2 % and the ability to swell in aqueous environments are considered as a perspective functional food component, including for the prevention of alimentary-dependent diseases.
Thus, SCRM shrimp can be processed in conditions compatible with conditions of food, including fish processing enterprises with obtaining food chitosan in the form of additional marketable products. Using of chitosan in the amount of 2 % by weight of raw meat does not deteriorate the organoleptic characteristics of the products. It can be used to obtain a wide spectrum of meat and food products, with high quality and mass yield. The content of chitosan in an amount of 2 g per 100 g of the product is 40 % of the adequate level of consumption of chitosan per day, and allows to meet the daily requirement of dietary fiber fiber on 10 % [Rosstat, 2015]. Such products can be recommended for people with obesity, with a lack of function of the digestive system, diseases of the pancreas; for elderly people.

Abstract

Mountain Soil in subalpine zone of the Middle Urals formed in specific environmental conditions associated with the mobility of rock debris on the slopes, a failure in intensive filtering the wash water regime, a significant number of herbaceous litter. A specific feature of these soils is the high acidity: pH salt extracts slightly vary within 3.7-4.2, indices hydrolytic acidity 10-22 mEq / 100 g. Buffer properties of soils were determined by continuous potentiometric titration of salt suspensions prepared in ratio of 1: 2,5. According to the results of potentiometric titration determined by calculation methods the number of protons absorbed. Graphical methods helped to calculate buffer area and the degree of reduced buffer capacity. The pH dropped to an average of 2,50-3,16; ΔpH figure was 0,9-1,45. The amount of absorbed protons averaged 70-90 mg / kg of soil, which corresponds to 75-95% of the amount added. In general, the buffer properties of the soils in relation to acid are low. This is confirmed by the reduced buffer capacity indicator constituting 7-27% of the reference area with absolute buffering capacity. This figure corresponds to very low and low buffer capacity of soils to acid attack.

Keywords: *mountain soils, buffer, protons, absorption, acidity*

Introduction

Acid-base buffering capacity is one of the measures of soil adsorption capability. Studying of acid-base buffering capacity of soils is of great theoretical and practical significance in connection with the progressive acidification of soils in some regions of the world due to both natural and anthropogenic factors. Studying of buffering capacity is recommended in order to gather data on modern soil formation and soil genesis (Zayzheva, 1987; Savchenko, 1989; Ponizovskiy, Pampura, 1993; Pevnuy, Sokolova, 1997; Nadtochiy, 1998;, ,Shamrikova et al., 2002; Shamrikova et al., 2003; Ufimtseva, Pokatilova, 2005; Ushakov, 2005; Tolstokaeva, Zharikova, 2009; Shamrikova et al., 2011; Shamrikova, Sokolova, 2013; Soil and soil cover…, 2013; Lyzhenko et al., 2014).

Most of natural soils in humid regions of the taiga-forest zone is characterized by acid pH and low bases saturation (Podzol Soil…, 1980; Podzol Soil…, 1981; Forest Soil…, 1997). This is a wide range of soils: podzolic, sod-podzolic, sod-gley, brown forest, swamp-podzolic, glebous swamp. In addition to the natural acidic background of forest soils, there is a source of anthropogenic acidification: acid rain. Most of researchers believe it is one of today's most important regional problems (Acidification today and tomorrow, 1982; Wisniewcki, Keitz, 1983; Tamm, David, 1989; Acidification research…, 1991; Derome, 1991). The problem of acid rain is related to the phenomenon of transboundary transport of acid-forming pollutants from industrial regions of Central Europe, as well as air pollution from its own sources of emissions (Makarov et al., 1994). Acidic solutions have both direct and indirect impact that is reflected in imbalances in elements intake by plants due to different intensity of their desorption into soil solution under the influence of acid rain (Sokolova et al., 2012).

The main mechanisms of buffering reactions are studied mainly using potentiometric titration (continuous potentiometric titration – CPT). The chemical reactions that cause buffering are

very diverse and include the interaction of H + and OH- ions with solid components of the soil body and the components of soil solution (Filep, Radley, 1989). Each soil type is characterized by its own set of mechanisms of such interactions. The effectiveness of acid-base buffering capacity is determined by the capability of soil systems to extinguish high amplitude activity of protons in reactions in soil according to the scheme: acid → base+proton (Nadtochiy, 1998).

Investigation of acidity and cation exchange properties being the most informative indicators of forest soils condition is an important part of their monitoring (Grishina et al., 1991; Makarov et al., 1994; Kopzhuk et al., 2001). This paper is particularly relevant for the soils of protected areas because of the specific characteristics and objectives of their functioning (Kopzhuk, Livantsova, 2003). Protected areas preserve habitat forming functions and biodiversity of ecosystems (Dobrovolskiy et al., 2003). In addition, the safety of PAs themselves depends on the state of the environment and its protection both in neighbouring and fairly remote areas. PAs can compensate for adverse anthropogenic impact since nature is capable of autoregeneration.

There are two major national parks in Perm region with protected natural forests of the Middle and Northern Urals. Studies on the soil cover of the Urals began later than in other mountain areas and were neither permanent or systematic and isolated (Samofalova et al., 2014). The most unique mountain landscapes in the Urals are believed to be those of the sub-alpine (subgoltcy) belt, where the mountain soils are formed under special environmental conditions associated with mobility of debris on the slopes, a collapsing filtering at intensive percolative regime, and a significant number of herbaceous litter (Samofalova et al., 2013, 2014). The high acidity is a specific feature of the soils, and therefore they are unstable for potential acid effects caused by industrial centers of Perm region. From this point of view, it is important to study the acidic properties of these soils and their buffering capability in relation to acid effects.

Materials and methods

The subject of the research are subgoltcy belt soils on Basegi mountain range located between 58^{o} 50' and 60^{o} N, to the west of watershed of the Urals, a part of the "Basegi" State Natural Reserve. This territory is located in an area of ridge-residual low-hill terrain in Middle Urals. The meridionally elongated range consists of three mountains: North Basegi (951.9 m), Middle Basegi (994.7 m) and South Basegi (851 m). Cold and wet climate with continental features. According to zonal distribution of vegetation, the area is located in the middle taiga subzone of boreal forest zone and the following belts can be isolated here: mountain forest, subgoltcy (subalpine) and mountain-tundra (goltcy). Subalpine belt is mild and includes three subbelts: parkland, subalpine meadows, and crooked forest.

The reserve is located far from industrial centres. There are Kizel-Gubakhinsky and Lysvensky-Chusovskoy industrial centres within 42-73 km to the west of the crest with a developed mining, chemical and metallurgical industries which are the sources of pollution and since the prevailing wind direction is west and south-west the air transport of pollutants in the protected area is possible.

Soil cross sections were made in subgoltcy belt on the North Basegi and Basegata mountains. Russian soil classification of year 2004 was used. Analytical studies were performed at the Department of Pedology of the Perm State Agricultural Academy. Buffering properties of the soils were determined by CPT of salt suspensions prepared at a ratio of 1:2.5. The titration was performed with 0.1 n solution of HCl; the total amount of acid of 10 ml corresponds to a load of 100 mmol/kg soil. Time of reaction of the acid with the suspension was 2 minutes. Based on CPT results, the number of absorbed protons was calculated; buffer areas and the extent of the reduced buffering capacity were calculated graphically. Based on the graphical

analysis, the buffer area was determined, as well as the reduced rate of buffering capacity, which is determined relative to the absolute buffering capacity set as 100%. The graph of buffering capacity of the sample looks like a horizontal line with pH = 7. The scales given in (Glazovskaya, 1990; Bogdanova, 1994; Nadtochiy, 1998) were used to estimate soils buffering capacity.

Results and discussion

Soils have a truncated profile mildly differentiated on horizons with a high content of gravel. The investigated soils belong to the stem of postlitogenic soil forming. Based on morphogenetic characteristics of soils, the following formations were identified: lithosoil (layer thickness less than 30 cm), organic-accumulative (median horizon is not pronounced as an independent genetic formation), structural and metamorphic (picked horizon BM) (see Table 1).

Table 1. The natural conditions of soil formation

Cross section number, alt, m; E, G, soil name	Horizons	PT, cm	Vegetation, relief
North Basegi mountain			
C. 54, 755, south, 20, Gray humus lithosoil	AY_1-AY_2-AY_3	17	Birch crooked forest; moderately drained levelled area
C. 49, 617, southern, 3-5; Organic-accumulative	AY-Aym-CLM	40	Miscellaneous grass and gramineous meadow; slightly drained levelled area
Basegata			
C. 62, 641, western, 5, Grey metamorphic	AY-AEL-BM_1-BM_2-CLM	65	Silk and miscellaneous grass meadow; drained gentle
C. 58, 597, western, 5, Elluvial brown soil	AY_1-AY_2-AYel-BM-CLM	91	John's-wort and miscellaneous grass meadow; drained gently sloping area
C. 60, 589, western, 5, Fossil, organic-accumulative	AY-AYm-AY(CLM)-[AY]-[CLM]	56	Silk and miscellaneous grass meadow; slightly drained gently sloping area

Note: E – slope exposition; G – slope gradient; PT – profile thickness.

Actual acidity in soils is characterized by pH of 4.8-5.6. The higher pH value in cross section 54 is probably related to the nature of plant litter in birch croocked forest where base saturation is higher. pH values of salt extracts vary from 3.5 to 4.2 within the profile. Hydrolytic acidity values are 10-22 mEq/100 g. Soil absorbing complex is significantly not saturated with bases, in some cross sections the degree of unsaturation reaches 80-90%. Biological accumulation of bases does not compensate for their removal with the groundwater flow, although some reduction in the degree of unsaturation has been noted in the humus horizons.

The CPT method allows to register mostly fast proceeding buffering reactions, which include ion exchange, protonation and deprotonation of pH-dependent exchange positions and dissociation of organic and mineral compounds in the solid body. Based on CPT results, the number of absorbed protons was calculated with the following formula:

$H^+absrpd. = H^+src. + H^+add. - H^+fin.$,

where $H^+src.$ is the source number of H^+ protons in suspension; $H^+add.$ is the added number of protons; $H^+fin.$ is the final number of protons in suspension after reaction with the solid body of the soil.

The pH of soil suspension decreased to an average of 2.50-3.16 after adding of the maximum amount of acid (Fig. 1). In the acid exposure on the first (top) humus horizons, pH shifted 1.1-1.3 units relative to the initial values. In the lower humus horizons, ΔpH was 0.90-1.45. The highest pH value noted in grey humus lithosoil (c. 54) with less apparent acidic properties. According to scale (Glazovskaya, 1990) such ΔpH value means that buffering capability of

mountain soils is above average. Lowering the pH results in the soil properties deterioration, as aluminum and iron ions at concentrations toxic to biota emerge in the soil solutions.
In humus horizons, ΔpH largely depends on the level of hydrolytic acidity (r = -0.85), content of clay (r = -0.89) and silt (r = -0.83) fractions, and also on removal of the silt fraction (r = -0.92) and accumulation of the sand fraction (r = 0.65), as well as conservative part of organic matter content (r = -0.71).
The amount of protons absorbed at the end of titration averaged 70-90 mmol/kg of soil, which corresponds to 75-95% of the amount added. The absorption capacity decreases as the proton concentration in the solution grows. In suspensions from humus horizons it decreases from 97 to 70%. Increasing the intensity of the absorption observed at pH below 3.9-3.6; 3.0; 2.5. The absorption of protons in these pH ranges is a result of reactions of displacement of exchange bases, dissociation of organic and mineral complexes followed by protonation of organic ligands, mineral dissolution.

Figure 1. Change in the adsorption capability and pH at the acid titration of soil suspensions of humic soil horizons in subalpine belt

In general, these areas are characterized by high capacity, as indicated by ΔpH (see Table 2). The buffering area is low which indicate that the soil "buffers" mildly. The buffer capacity was 7-27% of the area of the sample with absolute buffering capacity, which corresponds to a

very low and low buffer capacity of soils to acid effects. It should be noted that buffering capacity of mountain soil to acid effects decreases along with altitude decrement (r = 0.76).

Table 2. The buffering area and the degree of reduced buffering capacity of mountain soils

Cut №	Horizon, depth, см	pH CPT	The buffering area, sm^2	The degree of reduced buffering capacity	ΔpH
54	AY_1 2-9	4,3	9,0	27,0 (low)	1,4
49	AY_1 5-14	3,7	6,0	20,0 (very low)	1,2
62	AY	3,6	7,0	22,0 (low)	1,2
58	AY_1 2-25	3,9	6,0	19,2 (very low)	1,5
	AY_2	3,8	4,3	15,8 (very low)	1,2
60	AY	3,3	1,1	6,8 (very-very low)	1,9

Reduced buffering capacity is largely dependent on the content of alluvium (r = 0.73), medium and fine dust (r = 0.53), and also on the accumulation of dust (r = 0.82) and removal of the sand fraction (r = -0.56). Buffering properties of soils in subalpine belt have an average dependence on the silicon content (r = 0.46) and inverse dependence on the iron content (r = -0.68). Thus, buffering properties are associated with mineralogical composition of the soil as indicated by the relationship between reduced buffering capacity and the entropy of the bulk composition (r = -0.70). At the most non-uniform distribution of the system components, entropy tends to zero thereby increasing the buffer soil resistivity. The reduced buffering capacity has a direct relationship with the content of organic matter (r = 0.76) and its conservative part (r = 0.64), and a reverse relationship with a degree of humification (r = -0.67).

In the studied humus horizons, buffering intensity peaks are well defined in the pH range of 2.7-2.45. At the same time the pH values are consistent with humus content. Obviously, the buffering reactions in this range are associated with organic and mineral derivatives of humic acids.

Decrease of the solution pH causes a decrease in negative charge of organic compounds due to attenuation of ionization of COOH groups and reducing the protonation of clay minerals in soils. Scientists believe that at recharge of colloidal particles of $Fe(OH)_3$ and $Al(OH)_3$ and organic colloids of amphoteric nature their positive charge also increases (Motuzova, 1994). As a result, base exchange capacity, strength of bond between metal and soil and selectivity coefficient decrease, which in turn results in elevated proportion of metals in soil adsorption complex, so elements adsorption decreases in general.

20 to 80 mmol/kg acid we spent on suspension titration in pH fange 2.7-2.45. Among the analyzed soils structurally metamorphic soils had the maximum buffering capacity to the acid: elluvial brown soils (c. 58), grey methamorphic (c. 62). Organic-accumulative soil and grey humus lithosoil show less resistance to acid.

Conclusion

Increasing the acid load of mountain soils in the subalpine belt reduces their adsorption capability. Thus the soils of mountain landscapes are sensitive to acid effects. In the buffering structure, pH values of 3.9-3.0 and 2.5 are thresholds. In pH interval from the start point of titration to 3.0 in all horizons the main buffering reaction is displacement of exchangable cations by a proton. In the horizons containing organic material the dissociation reaction of organic and mineral complexes is added to them followed by protonation of organic ligands. At lowering pH below 2.5 units dissolution of iron sesquioxide occurs. Reactions associated with dissolution of mixed-layer clay minerals are possible in mineral horizons (AEL).

Soils in subalpine belt have low and very low buffering capacity and as a consequence low environmental and geochemical resistance to acid effects. Reduced buffering capacity is the

most objective indicator to evaluate the buffering properties that allows to compare soils formed under different environmental conditions. At the same time the use of the relative pH shift to assess buffering capacity is justified for soils with similar acidity values. Evaluation of buffering capacity and absorption capability of soils can be used as an objective criteria for qualitative assessment of the soil state for soil and environmental monitoring.
